Fig. 2. Typical pulse height distribution of the alpha particles from the reactions $Al^{27}(p, \alpha)Mg^{24}$ resulting in the ground and first excited states of Mg^{24} at a laboratory angle of 60° for 11.53 Mev protons.

($Q=+0.227$ Mev[9]) in the first excited state of Mg^{24}. The energy resolution (full width at half maximum) was about 2.8% and the complete separation of the two peaks was obtained. Background due to oxygen and carbon contamination and reactions other than (p, α) reactions, for instance (p, p') reaction, is expected to have no influence upon the spectra, considering the Q values ($Q=-5.208$ Mev[10]) for $O^{16}(p, \alpha)N^{13}$ and $Q=-7.563$ Mev[10]) for $C^{12}(p, \alpha)B^{9}$) and the energy losses in the counter volume.

§ 3. Results and Discussion

Examples of the angular distributions are shown in Fig. 3. Error bars represent the uncertainties due to counting statistics. All the angular distributions measured here are collected and the three-dimensional views of them as a function of the incident proton energy and the C.M. angle are shown in Figs. 4 and 5. The curves in these figures were drawn smoothly among experimental points as those in Fig. 3. Measured angle and magnitude of experimental errors are similar to those in Fig. 3. As can be seen from Fig. 4 and 5, for both reactions the variation of the shape of the angular distributions with the bombarding energy is rather smooth in the higher energy region, but becomes rapid gradually with decreasing energy.

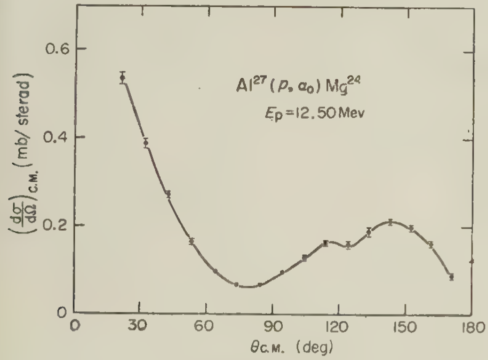

Fig. 3a.

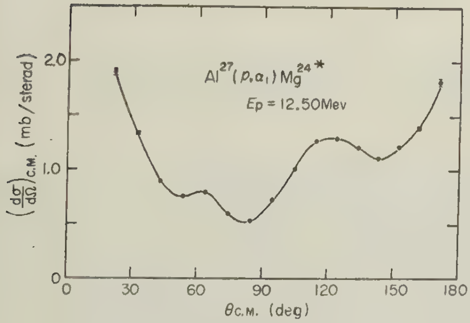

Fig. 3b.

Fig. 3. Angular distributions of the alpha particles from the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$ at 12.5 Mev incident proton energy. The solid curves were drawn smoothly among experimental points. The errors are smaller than the points, unless shown otherwise.

Fig. 6 shows the excitation curves at laboratory angles of 50°, 90° and 130° for the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)\cdot Mg^{24*}$ as well as those for the total cross sections integrated from the angular distributions. For both reactions there appear some resonance-like peaks and valleys in the excitation curves at laboratory angles of 50°, 90° and 130°, but their positions are not coincident with one another and in the higher energy region these peaks disappear in the excitation curves for the total cross sections. Therefore these facts are considered to come from the variation of the shape of the angular distributions with the bombarding energy and not from the presence of the intermediate resonance levels proposed by Igarasi *et al.*[5]) Thus it should be noted that without the measurement of the total cross sections it is dangerous to ascribe the resonance-like peaks in the excitation curves for the differential cross sections to the presence of the intermediate resonance levels.

It is interesting to compare these results with the triton pickup or exchange theories. According to the simple theories of these surface direct interactions,[3]) the angular distribution for the reaction $Al^{27}(p, \alpha)Mg^{24}$ is found to be essentially expressed as follows:

$$\frac{d\sigma}{d\Omega} \propto [j_l(Qr_0)]^2 ,$$

where j_l is the spherical Bessel function of order l, and Q is the momentum transfer as obtained by following equation:

$$Q=\left| \boldsymbol{k}_p - \frac{M_i}{M_f} \boldsymbol{k}_\alpha \right| ,$$

where $\boldsymbol{k}_p$ and $\boldsymbol{k}_\alpha$ are the center of mass momenta in units of $\hbar$ of the incident protons and emergent alpha particles, respectively, and M_i and M_f are the masses of Al^{27} and Mg^{24}, respectively, and r_0 is the interaction radius. No angular distributions in the pre-

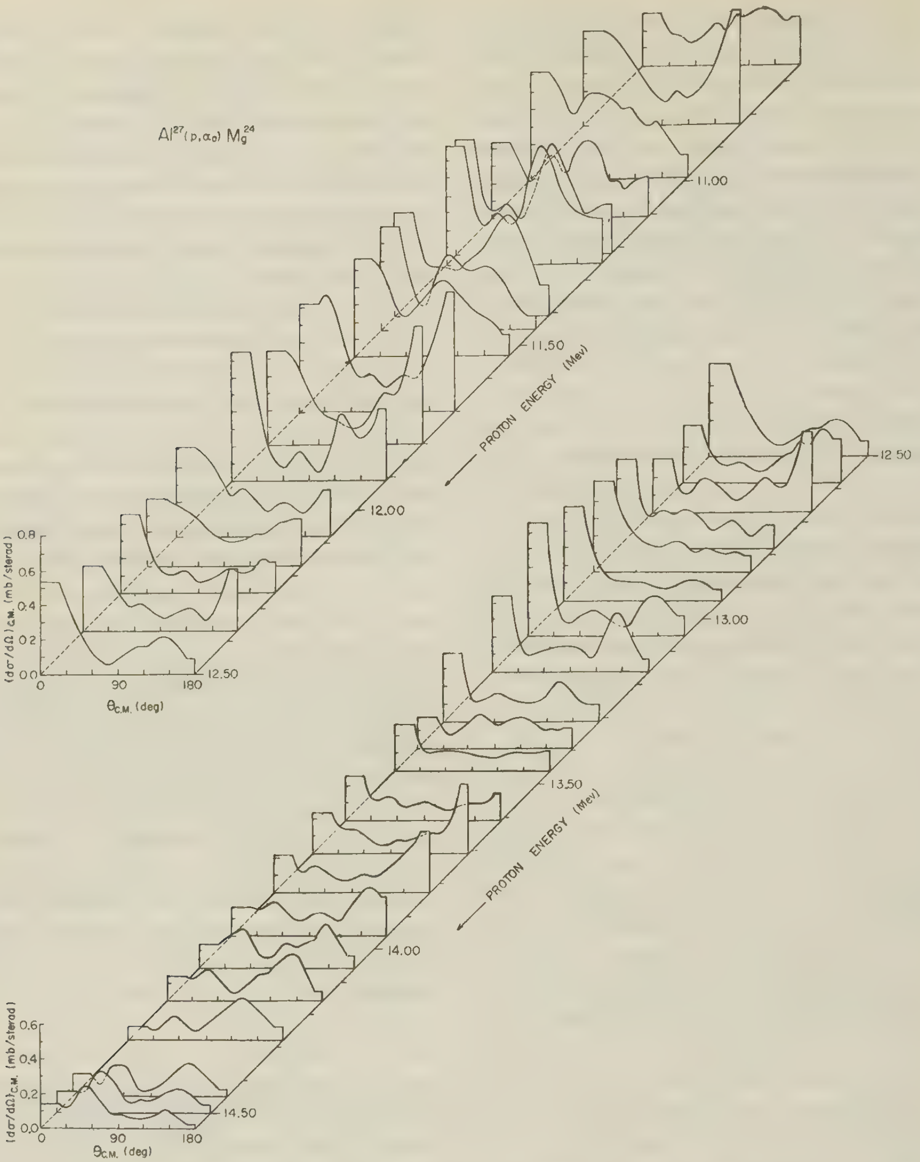

Fig. 4. Three dimensional view of the angular distributions for the reaction $\mathrm{Al^{27}}(p, \alpha_0)\mathrm{Mg^{24}}$ as a function of the incident proton energy and the C.M. angle.

sent experiment are expected to be well fitted by the direct interaction theories but partial fitting may be expected at least in the higher energy region.

To interpret the present data, the peak positions in the angular distributions were plotted in Fig. 7 as a function of the incident proton energy and the C.M. angle. It can be seen that there are several mountain ranges, that is, groups of the peak positions in this figure. The presence of these mountain ranges suggests that the direct interaction process plays an important role in these reactions. The movement of the peak positions to the forward angle with increasing energy agrees in general with the prediction of the direct interaction theories. The triangles in Fig. 7 indicate the peak positions calculated from the direct interaction theory with radii of the denoted values in this figure and with the values of $l=2$ and $l=0$ for the reactions $\mathrm{Al^{27}}(p, \alpha_0)\mathrm{Mg^{24}}$ and $\mathrm{Al^{27}}(p, \alpha_1)\mathrm{Mg^{24*}}$, respectively, at 11, 12, 13 and 14 Mev. These values of the radius were chosen to give the best fit to the mountain ranges. It can be seen that the general behaviours of the

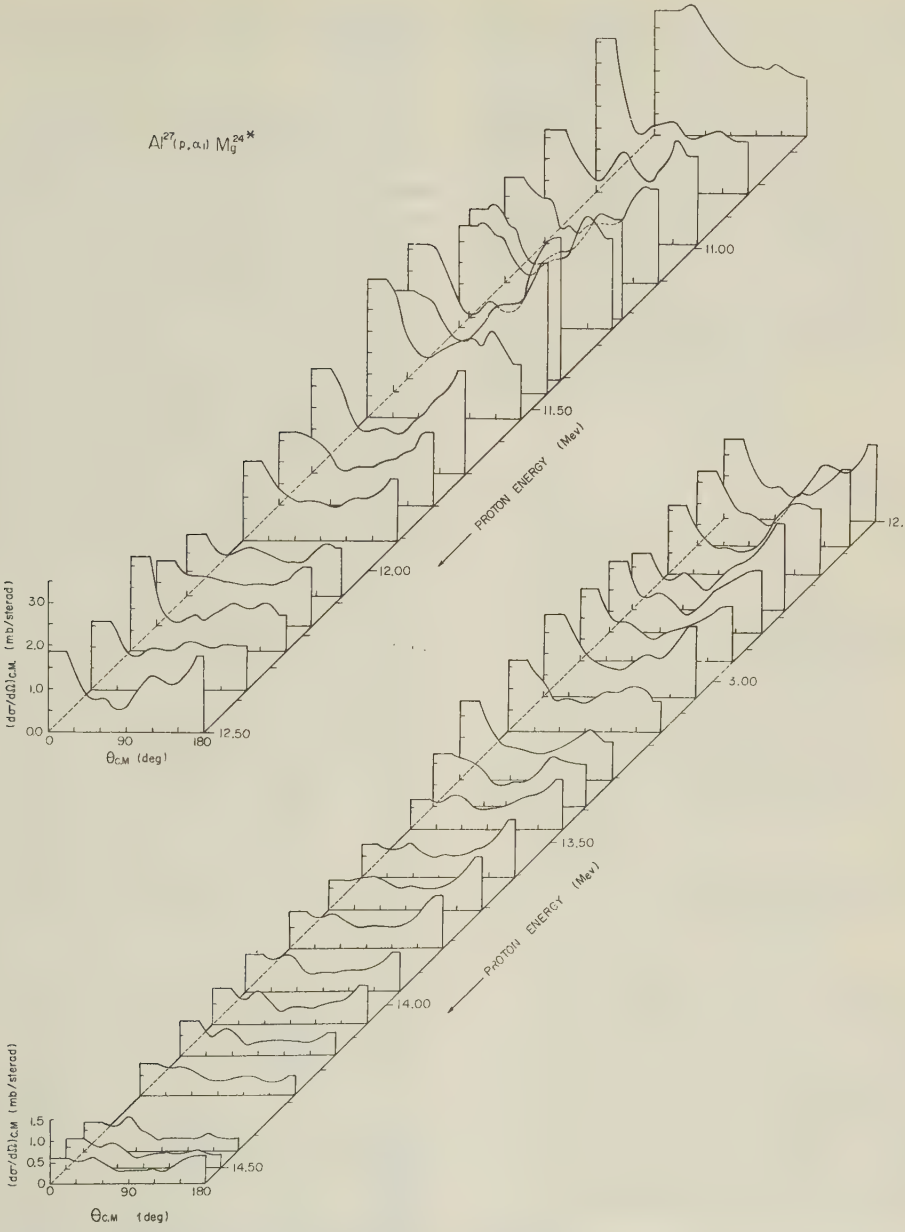

Fig. 5. Three dimensional view of the angular distributions for the reaction $Al^{27}(p, \alpha_1)Mg^{24*}$ as a function of the incident proton energy and the C.M. angle.

mountain ranges are reproduced by the triton pickup theory, although these values of the radius are considerably larger as compared with those used commonly and vary with the incident proton energy. Therefore the direct interaction process seems to play an important role in these reactions in the entire energy region observed here.

The observed sharp energy dependence cannot be explained by the simple theories of direct interaction which predict very slowly changing differential cross sections. Modification of the direct interaction theories,[11] including the distorted wave treatments, would probably also not produce such a sharp energy dependence. Owen and Madansky[12] have obtained good qualitative agreement with the angular distributions for the reactions $B^{11}(d, n)C^{12}$ and $C^{13}(He^3, \alpha)C^{12}$ which show large energy dependence, extending the ordinary deuteron stripping theory to include the effect of heavy particle stripping. This heavy particle stripping process gives the angular distribution having backward peaks for emitted alpha particles. The backward peakings which appear in the angular distributions at several incident energies in the present results show possibly the evidence of considerable contribution of the heavy particle stripping process.

On the other hand, assuming that the reaction $Al^{27}(p, \alpha)Mg^{24}$ occurs through the compound nucleus formation, the sharp energy dependence cannot be expected from the statistical theory,[13] which is based on the assumptions that there are many levels of all types at the excitation energy of the compound nucleus (continuum assumption), and the corresponding wave functions have a random phase so that when phase averages are performed all interference terms will vanish (statistical assumption). In this case, therefore, the continuum or statistical assumption cannot be satisfied. The compound nucleus, Si^{28}, would have up to 22.2 and 25.6 Mev of excitation at 11.0 and 14.5 Mev of bombarding energy respectively. Since there are 29 levels[14] in Si^{28} between 13.75 and 14.69 Mev, assuming the level density $\omega(E) \propto \exp(E^{1/2})$,[15] $\omega(22.2)$ and $\omega(25.6)$ are calculated to be about 80 and 115 levels/Mev respectively, although there is some uncertainty connected with the

calculation oft he level density by this equation.

In the lower energy region, since level spacing in the compound nucleus is such that several levels should be excited at each energy, the variations of the excitation curves for the total cross sections and of the shape of the angular distributions with energy may be due to the fluctuations in the number or properties of the compound nucleus levels and to the interference between the compound nucleus and direct interaction processes. The smoothing-outs of the excitation curves for the total cross sections and of the variation of the shape of the angular distributions with increasing energy could be the effects of decreasing level spacing in the compound nucleus and of increasing contribution from the direct interaction process which is seen from the shape of the angular distributions.

Recently we have studied the angular distributions for the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ [16] resulting in the ground and first excited states at 7.7∼14.1 and 7.6∼12.9 Mev respectively. It has been found that the direct interaction processes are predominant at the proton energies above about 11 Mev. This behaviour seems to be similar to that of the present result.

Since misdetermination of the solid angle in the previous work was found, absolute values of the cross sections in the previous (p, α) experiments on Al, Cr[2] and F[7] should be multiplied by a factor of 1.39. Corrected values of the cross sections for the previous $Al(p, \alpha)$ data[2] are in agreement with the present values.

In conclusion, the variations of the excitation curves for the total cross sections and of the shape of the angular distributions with energy in the lower energy region may be due to the fluctuations in the number or properties of the compound nucleus levels and to the interference between the compound nucleus and direct interaction processes. The smoothing-outs of the excitation curves for the total cross sections and of the variation of the shape of the angular distributions in the higher energy region seem to be due to the effects of decreasing level spacing in the compound nucleus and of increasing contribution from the direct interference between the interaction process. However, in the entire energy region, the compound nucleus and direct interaction processes, and some contribution from the heavy particle stripping process cannot be neglected.

The authors wish to thank Professor K. Kimura and Professor T. Sidei for their interests and encouragements throughout this work. Their thanks are also due to the cyclotron crew of the Institue for Nuclear Study, University of Tokyo, for their kind hospitality and patient cooperation.

Angular Distributions of the Reactions $Co^{59}(p, \alpha)Fe^{56}$ at 7.7~14.1 Mev and $Mn^{55}(p, \alpha)Cr^{52}$ at 7.6~12.9 Mev*

By Hiroshi OGATA and Hidehiko ITOH

Department of Physics, Faculty of Science, Kyoto University

(Received June 13, 1960)

The angular distributions of the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ resulting in the ground and first excited states of the residual nuclei have been measured at 7.7, 8.7, 9.8, 10.85, 11.9, 13.1 and 14.1 Mev and at 7.65, 8.85, 9.65, 10.7, 11.8 and 12.9 Mev of the incident proton energy, respectively, making use of proportional counters.

Similar behaviour was obtained for these four reactions. For the reaction $Co^{59}(p, \alpha)Fe^{56}$ the forward peak in the angular distribution is prominent at 14.1 and 13.1 Mev and disappears gradually with decreasing proton energy, and the angular distribution is approximately 90° symmetrical below about 11 Mev. For the reaction $Mn^{55}(p, \alpha)Cr^{52}$ the angular distribution is considerably forward peaked at 12.9 and 11.8 Mev and it approximately 90° symmetrical below about 10 Mev. It was found that the total cross section integrated from the angular distributions for both reactions decrease smoothly with increasing proton energy.

It is considered that the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ resulting in the ground and first excited states of the residual nuclei occur through the similar reaction process, that is, in the lower energy region the compound nucleus process plays a predominant role, although some contribution from the direct interaction process cannot be neglected, and the contribution from the direct interaction process becomes gradually significant with increasing proton energy and is predominant above about 11 Mev.

§ 1. Introduction

The studies of the (p, α) reactions for various elements play an important role in the investigation of the nuclear reaction mechanism. A number of studies of the (p, α) reactions have been reported, but most of them have been carried out for light elements. For light elements, such as C^{12} 1) or F^{19},2),3) the reactions resulting in lower states of the residual nuclei appear to favour description by the simple direct interaction theories. Recently we have studied the angular distributions for the reactions $Al^{27}(p, \alpha)Mg^{24}$ 4) resulting in the ground and first excited states of Mg^{24} at 37 energies between 10.5 and 14.5 Mev. The sharp energy dependence of the angular distributions shows that these reactions occur through the complicated processes.

For medium and heavy elements, Brady5) has measured the angular distribution for the reaction $Rh^{103}(p, \alpha)Ru^{100}$ resulting in the ground state. The strong forward peaking of the angular distribution suggests that the alpha particles are produced by direct interactions. Investigations of the (p, α) reactions in targets of wide range of atomic number have been performed by Fulmer and Cohen6) at 23 Mev and by Fulmer and Goodman7) at the proton energies between 9.5 and 23 Mev. It has been reported that the alpha particles from the heaviest elements and the high energy parts of the spectra from lighter targets are strongly forward peaked and are produced by direct interactions, and an alpha particle model may be important for the nuclei for which the compound nuclei are integral number of alpha particles.

---

* This experiment was performed using a 160 cm variable energy cyclotron at the Institute for Nuclear Study, University of Tokyo.

Numerical data obtained in this experiment will be published in Memoirs of the College of Science, University of Kyoto.

In a previous paper,[8] we have reported the angular distributions of two alpha particle groups from the reaction $Cr^{52}(p, \alpha)V^{49}$, one of which corresponds to the alpha particles resulting in the first three levels and the other corresponds to the levels up to about 1 Mev excitation except the first three levels. It has been found that the reactions $Cr^{52}(p, \alpha)V^{49}$ occur mostly through the compound nucleus formation at lower incident energies below 11 Mev and then the contribution from the direct interactions becomes significant gradually with increasing energy.

For medium weight nuclei studies of the (p, α) reactions to a single level of the residual nucleus have not been reported, but they give probably more reliable information concerning the reaction mechanism. Therefore the present work was undertaken to investigate the angular distributions of the reactions $Co^{59}(p, \alpha)Fe^{56}$ resulting in the ground and first excited states of Fe^{56} at 7.7~14.1 Mev and of the reactions $Mn^{55}(p, \alpha)Cr^{52}$ resulting in the ground and first excited states of Cr^{52} at 7.6~12.9 Mev, as a part of our extensive investigations on the (p, α) reaction.

§2. Experimental Procedure

The experiment was performed with the proton beam from a 160 cm variable energy cyclotron at the Institute for Nuclear Study, University of Tokyo. The general experimental method has been described in the preceding paper.[4]

For the reaction $Co^{59}(p, \alpha)Fe^{56}$, the target was a self-supporting cobalt foil of 0.62 mg/cm² in thickness which was obtained by an electroplating method. For the reaction $Mn^{55}(p, \alpha)Cr^{52}$, manganese metal evaporated onto a mylar film (0.8 mg/cm² thick) was used and the thickness of the manganese target was 0.55 mg/cm².

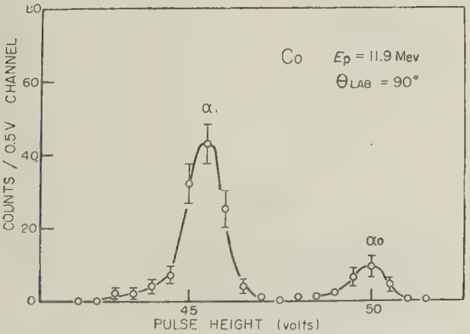

Fig. 1. Typical pulse height distribution of the alpha particles from the reactions $Co^{59}(p, \alpha)Fe^{56}$ resulting in the ground and first excited states of Fe^{56} at a laboratory angle of 90° for 11.9 Mev protons.

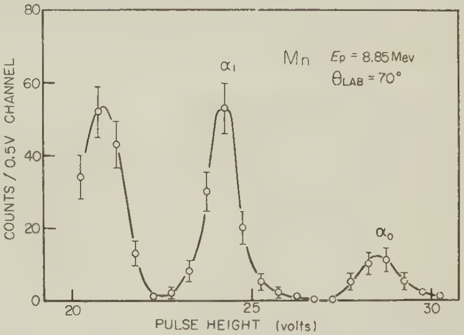

Fig. 2. Typical pulse height distribution of the alpha particles from the reactions $Mn^{55}(p, \alpha)Cr^{52}$ resulting in the ground and first excited states of Cr^{52} at a laboratory angle of 70° for 8.85 Mev protons.

Figs. 1 and 2 show typical pulse height distributions of the alpha particles from the reaction $Co^{59}(p, \alpha)Fe^{56}$ at a laboratory angle of 90° for 11.9 Mev protons and from the reaction $Mn^{55}(p, \alpha)Cr^{52}$ at a laboratory angle of 70° for 8.85 Mev protons, respectively. Two peaks in Fig. 1 correspond to the reactions $Co^{59}(p, \alpha_0)Fe^{56}$ resulting in the ground state of Fe^{56} ($Q_0 = +3.23$ Mev[9]) and the reaction $Co^{59}(p, \alpha_1)Fe^{56*}$ resulting in the first excited state of Fe^{56} ($Q_1 = +2.39$ Mev[9],[10]). The energy resolution (full width at half maximum) was about 2.5% and complete separation of these two peaks was obtained. While, in Fig. 2, there appear three peaks of which first two correspond to the reactions $Mn^{55}(p, \alpha_0)Cr^{52}$ resulting in the ground state of Cr^{52} ($Q_0 = +2.58$ Mev[9]) and the reaction $Mn^{55}(p, \alpha_1)Cr^{52*}$ resulting in the first excited state of Cr^{52} ($Q_1 = +1.13$ Mev[9],[10]). The energy resolution was about 3.5% and complete separation of these two peaks was obtained. In both reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ for larger angles and at higher proton energies, the separation was slightly worse and the spectrum analysis was necessary. However, the ambiguity accompanied by this analysis was rather small.

Since the results of spectroscopic analysis for Co and Mn metals used as targets scarcely showed the existence of impurities, for both reactions the background due to impurities is expected to have no influence upon the experimental results. Furthermore, for the reaction $Mn^{55}(p, \alpha)Cr^{52}$ the background due to carbon and oxygen contained in the mylar film does not affect the experimental results owing to the large negative Q-values of the reactions $C^{12}(p, \alpha)B^{9}$ and $O^{16}(p, \alpha)N^{13}$.

§ 3. Results and Discussion

Figs. 3 and 4 show the angular distributions for the reactions $Co^{59}(p, \alpha_0)Fe^{56}$ and $Co^{59}(p, \alpha_1)Fe^{56*}$, respectively, at 7.7, 8.7, 9.8, 10.85, 11.9, 13.1 and 14.1 Mev of the incident proton energy. It can be seen from Fig. 3 that the forward peak in the angular distribution for the reaction $Co^{59}(p, \alpha_0)Fe^{56}$ is prominent at 14.1 and 13.1 Mev and disappears gradually with decreasing proton energy, and the angular distribution is approximately 90° symmetrical below about 11 Mev. For the reaction $Co^{59}(p, \alpha_1)Fe^{56*}$ quite similar behaviour can be seen from Fig. 4.

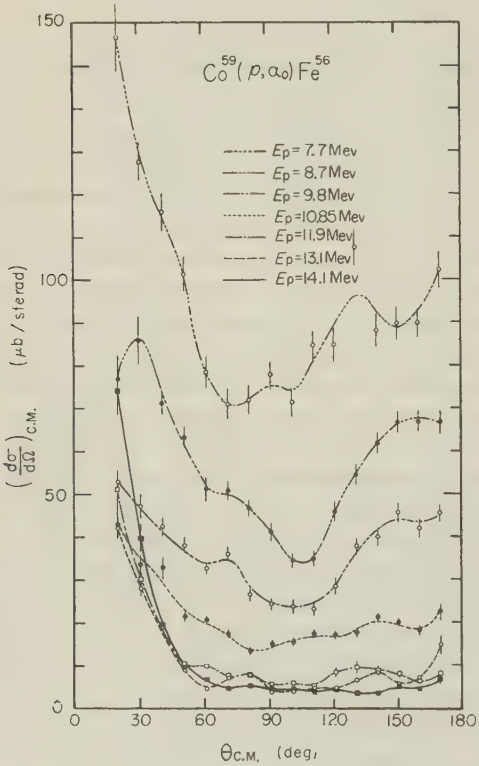

Fig. 3. Angular distributions of the alpha particles from the reaction $Co^{59}(p, \alpha_0)Fe^{56}$ at 7.7, 8.7, 9.8, 10.85, 11.9, 13.1 and 14.1 Mev. The error bars represent the uncertainties due to counting statistics.

The reactions $Co^{59}(p, \alpha_0)Fe^{56}$ and $Co^{59}(p, \alpha_1)Fe^{56*}$ at 14.1 and 13.1 Mev seem to occur predominantly through the direct interaction processes. It is interesting to compare these angular distributions with the simple theory of the surface direct interaction by triton pickup or knockon process. According to this theory,[11] the angular distribution for the (p, α) reaction is expressed as follows:

$$\frac{d\sigma}{d\Omega} \propto [j_l(Qr_0)]^2 , \qquad (1)$$

where j_l is the spherical Bessel function of order l and Q is the momentum transfer as obtained by following equation;

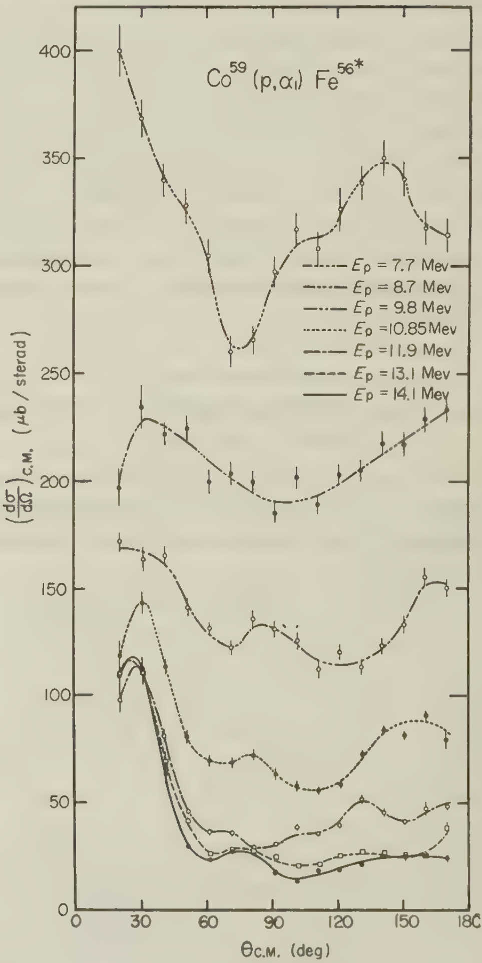

Fig. 4. Angular distributions of the alpha particles from the reaction $Co^{59}(p, \alpha_1)Fe^{56*}$ at 7.7, 8.7, 9.8, 10.85, 11.9, 13.1 and 14.1 Mev. The error bars represent the uncertainties due to counting statistics.

$$Q=\left| k_p - \frac{M_i}{M_f} k_\alpha \right| ,$$

where k_p and k_α are the center of mass momenta in units of $\hbar$ of the incident protons and the emergent alpha particles, respectively, M_i and M_f are the masses of the target and the residual nuclei, respectively, and r_0 is the interaction radius. The dashed curves in Figs. 5 and 6 have been calculated from Eq. (1) with the values of $l=3$ and $r_0=4.8\times10^{-13}$ cm for the reaction $Co^{59}(p, \alpha_0)Fe^{56}$ and with $l=1$ and $r_0=5.4\times10^{-13}$ cm for the reaction $Co^{59}(p, \alpha_1)Fe^{56*}$, respectively, at 14.1 Mev. These theoretical curves are considered to fit qualitatively the experimental data, although the magnitudes of interaction radii differ slightly from one another, and seem to be rather smaller as compared with those used commonly. The approximately 90° symmetrical angular distributions at 9.8, 8.7 and 7.7 Mev are consistent with the prediction of the statistical theory of the compound nucleus. The total cross sections integrated from the angular distributions, for the reactions $Co^{59}(p, \alpha_0)Fe^{56}$ and $Co^{59}(p, \alpha_1)Fe^{56*}$ are shown in Fig. 9, and it can be seen that they decrease monotonously with increasing proton energy.

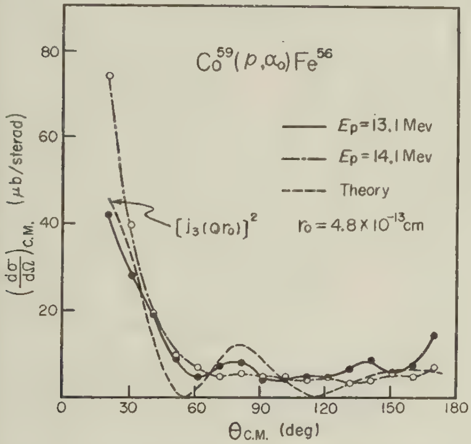

Fig. 5. Angular distributions of the alpha particles from the reaction $Co^{59}(p, \alpha_0)Fe^{56}$ at 13.1 and 14.1 Mev. The dashed curve shows the theoretical angular distribution at 14.1 Mev.

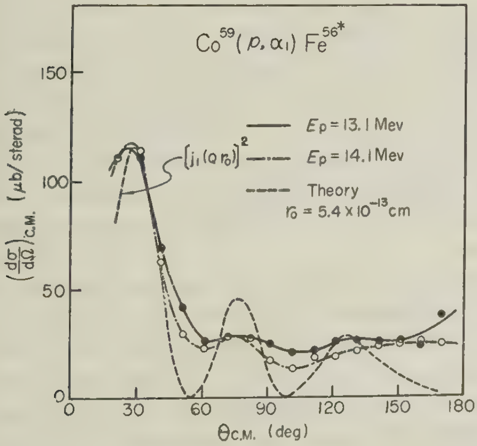

Fig. 6. Angular distributions of the alpha particles from the reaction $Co^{59}(p, \alpha_1)Fe^{56*}$ at 13.1 and 14.1 Mev. The dashed curve shows the theoretical angular distribution at 14.1 Mev.

Figs. 7 and 8 show the angular distributions of the alpha particles from the reactions $Mn^{55}(p, \alpha_0)Cr^{52}$ and $Mn^{55}(p, \alpha_1)Cr^{52*}$, respectively, at 7.65, 8.85, 9.65, 10.7, 11.8 and

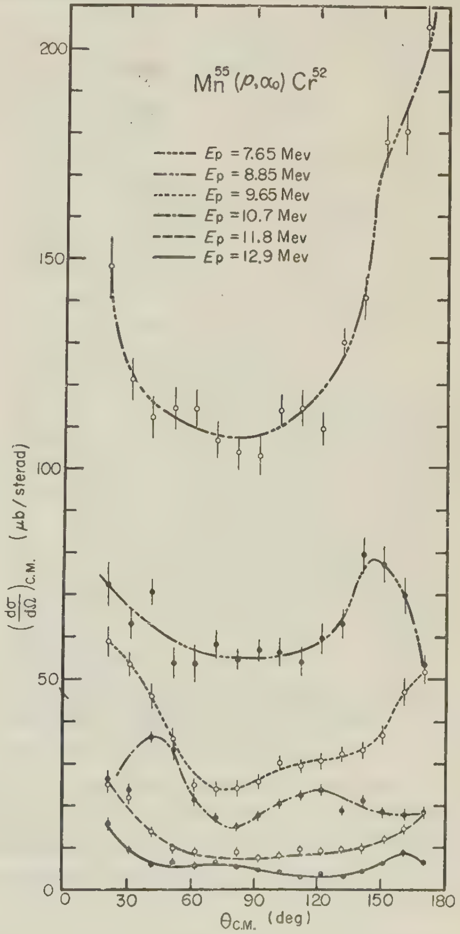

Fig. 7. Angular distributions of the alpha particles from the reaction $Mn^{55}(p, \alpha_0)Cr^{52}$ at 7.65, 8.85, 9.65, 10.7, 11.8 and 12.9 Mev. The error bars represent the uncertainties due to counting statistics.

12.9 Mev. It can be seen from Figs. 7 and 8 that the angular distributions for both reactions are considerably forward peaked at 12.9 and 11.8 Mev, and are approximately 90° symmetrical below about 10 Mev. These behaviours are very similar to those in the case of Co^{59}, although the forward peakings in the higher energy region are not so conspicuous and in general the angular distributions are more smooth. It can also be said that the direct interaction processes play a main role in these reactions above about 11 Mev and the compound nucleus process becomes predominant with decreasing proton energy. The total cross sections for the reactions $Mn^{55}(p, \alpha_0)Cr^{52}$ and $Mn^{55}(p, \alpha_1)Cr^{52*}$ are shown in Fig. 9 with those for the reaction $Co^{59}(p, \alpha)Fe^{56}$. They also decrease monotonously with increasing proton energy.

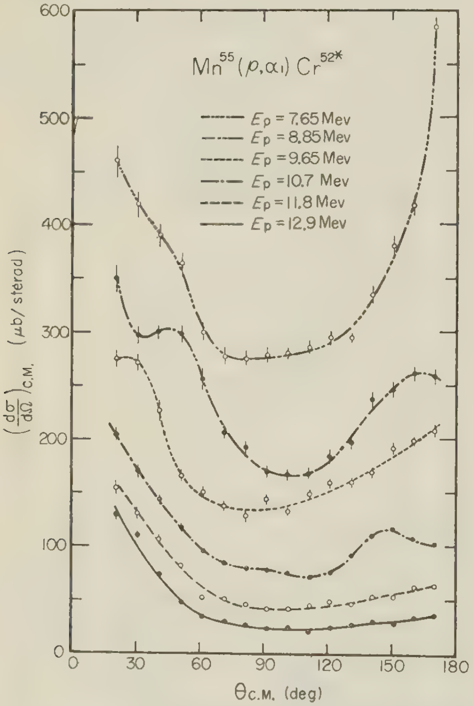

Fig. 8. Angular distributions of the alpha particles from the reaction $Mn^{55}(p, \alpha_1)Cr^{52*}$ at 7.65, 8.85, 9.65, 10.7, 11.8 and 12.9 Mev. The error bars represent the uncertainties due to counting statistics.

For the reaction $Mn^{55}(p, \alpha)Cr^{52}$, the behaviours of the angular distributions, the absolute values of the total cross sections and the energy dependence of the total cross sections are quite similar to those for the reaction $Co^{59}(p, \alpha)Fe^{56}$. In both reactions the mass numbers of the target elements and the reaction Q values are similar to each other, and the targets are the odd-even nuclei. Therefore, it can be expected that the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ occur through the similar reaction process.

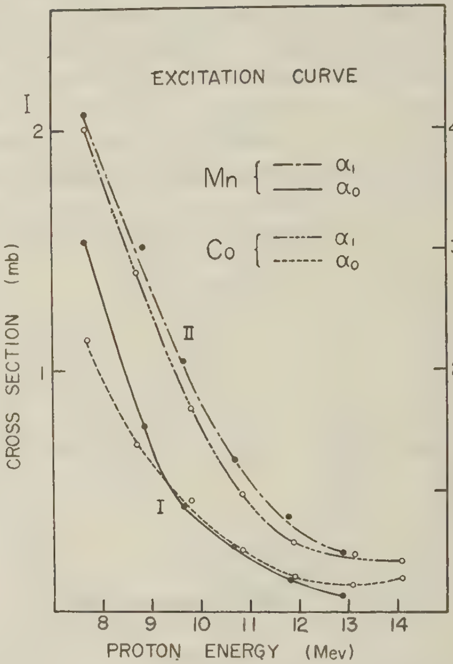

Fig. 9. Total cross sections integrated from the angular distributions for the reactions $Co^{59}(p, \alpha_0)Fe^{56}$, $Co^{59}(p, \alpha_1)Fe^{56*}$, $Mn^{55}(p, \alpha_0)Cr^{52}$ and $Mn^{55}(p, \alpha_1)Cr^{52*}$ as a function of the proton energy.

The difference between the cross sections for the reaction $Cr^{52}(p, \alpha)V^{49}$ [8] and the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ may be due to following facts for the reaction $Cr^{52}(p, \alpha)V^{49}$ that Cr^{52} is an even-even nucleus, the reaction Q value is -2.59 Mev[10] and some levels of the residual nucleus are concerned.

Recently experimental investigations of the (p, p') reactions for medium weight nuclei at 8~14 Mev have been carried out by Kikuchi *et al.*[12] and Hu *et al.*[13] It has been found that the angular distributions of inelastically scattered protons are prominently forward peaked, and these (p, p') reactions occur mostly through the direct interaction processes down to 8 Mev. The difference between the angular distributions for the (p, α) and (p, p')

reactions is considered to be due to larger contributions from the direct interaction processes relative to the compound nucleus process in the (p, p') reactions than in the (p, α) reactions. It must also be noted that the absolute cross sections for the (p, p') reactions are by two orders of magnitude larger than those for the (p, α) reactions. These facts may suggest that the reduced widths for the (p, α) reactions are quite smaller as compared with those for the (p, p') reactions.

It is expected that the monotonic decrease of the total cross sections with increasing energy up to about 11 Mev could be explained with the statistical theory of the compound nucleus, but the slower decrease or flattening in the higher energy region could not. Since it was shown from the angular distributions that the reaction $Co^{59}(p, \alpha)Fe^{56}$ proceeds predominantly through the compound nucleus process at 8 Mev, a rough calculation of the total cross sections from the evaporation theory[14] was performed and the result was normalized to the experimental one at 8 Mev. The calculated cross sections are nearly in agreement with experimental ones up to about 11 Mev, but become smaller in the higher energy region and are about one fifth at 14 Mev. This fact also means that the direct process is predominant in the higher energy region. This fact is consistent with that obtained from the angular distribution.

In conclusion, it is considered that the reactions $Co^{59}(p, \alpha)Fe^{56}$ and $Mn^{55}(p, \alpha)Cr^{52}$ resulting in the ground and first excited states of the residual nuclei occur through the similar reaction process, that is, in the lower energy region the compound nucleus process plays a predominant role, although some contribution from the direct interaction process cannot be neglected, and the contribution from the direct interaction process becomes gradually significant with increasing proton energy and is predominant above about 11 Mev.

The authors wish to express their thanks to Professor K. Kimura and Professor T. Sidei for their interests and encouragements throughout this work. They are also indebted to the cyclotron crew of the Institute for Nuclear Study, University of Tokyo, for their kind hospitality and patient cooperation.

A Study of Pulse Height Distribution of Boron—Trifluoride Proportional Counters

By Mikiya YAMANE

Hitachi Central Research Laboratory, Kokubunji-machi, Tokyo

(Received May 28, 1960)

The pulse height distribution of boron trifluoride counter under overall irradiation by slow neutron has been treated allowing for the wall effect of the counter. Energy spectra, $R(\varepsilon')$, is given under assumption of a Gaussian resolution function by,

$$R(\varepsilon')\approx\frac{s}{2RE_0}\int_0^{E_0}\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\varepsilon'-\varepsilon)^2}{2\alpha^2}\right\}d\varepsilon+\left(1-\frac{S}{2R}\right)\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\varepsilon'-E_0)^2}{2\sigma^2}\right\},$$

where s and E_0 are the whole range and initial energy of alpha-particle respectively, and R is the radius of the counter. Agreement between theoretical and experimental distribution has been discussed for appropriate filling pressures.

§ 1. Introduction

Neutron counters filled with boron trifluoride gas have been used extensively and studied by many investigators since the first experiment of Korff and Danforth[1]. The principle of the operation of the counter is based on the reactions

$$B^{10}+n\rightarrow Li^7+\alpha+2.78\ \mathrm{MeV}$$

or

$$B^{10}+n\rightarrow Li^{*7}+\alpha+2.3\ \mathrm{MeV}$$

and thus it is expected that the shape of pulse height distribution for an ideal counter should show two sharp peaks. However several experiments revealed the appreciable broadening of the peaks because of (a) fluctuation of the number of initial ion pairs and (b) fluctuation of the gas multiplication. The fluctuation of the number of initial ion pairs is primarily due to the counter wall effect which produces a long tail on the low energy side of the peak[2]. The fluctuation of the gas multiplication is mainly due to electron capture which is ascribed to unsatisfactory purification of the filling gas[3].

The purpose of this paper is to investigate the wall effect and to afford a quantitative basis to the spectral properties of the counter.

§ 2. Calculation

While the full energy of the slow neutron-induced disintegration, when spent in the counter gas, gives rise to a full energy pulse, the case in which the disintegration fragments suffer the wall effect gives lower energy pulses depending on path length of the particles through the counter gas. We shall first consider the distribution of the path length of the particles for a counter, of which the end effect is much smaller than the wall effect.

Assumptions employed for calculation are as follows:

(1) The slow neutron-induced disintegration takes place uniformly throughout the counter. This assumption will be justified for counters of reasonable dimension and of reasonable filling pressure, since the mean free path of neutron is much longer than the diameter of the counter.

(2) The track of the disintegration fragments occurs in random direction. This is most probable for fully thermalized neutrons.

(3) The Li^7 fragment has a much smaller range than alpha particle. Thus the wall effect will be mainly due to alpha particles.

A fraction of alpha-particles whose track intercepts the counter wall be expressed by,

$$n_1=\int_0^s f(l)dl\ , \qquad (1)$$

where $f(l)$ is the distribution function of the path length of alpha-particles and s is the whole range of alpha-particle in the gas. The length of the path of alpha-particle originating at a distance r from the axis, moving in direction θ, ϕ and hitting the wall is given by, (Fig. 1)

$$l^2\sin^2\phi\cos^2\theta+2rl\cos\theta+r^2+l^2\cos^2\phi-R^2=0\ , \qquad (2)$$

where θ is an angle between OX and the rack.

ϕ is an angle between OY and the projection of the track on the plane YOZ.

R is the radius of the counter.

Now, from the assumptions (1) and (2), n_1 is also expressed by the following equation:

$$n_1=\frac{1}{\pi R^2}\int_{R-s}^{R} 2\pi r dr\cdot\frac{4}{4\pi}\int_0^{\pi/2} d\phi\int_0^{\theta_0}\sin\theta d\theta\ , \tag{3}$$

vhere

$$\theta_0=\cos^{-1}\frac{-r+\sqrt{r^2\cos^2\phi+R^2\sin^2\phi-s^2\sin^2\phi\cos^2\phi}}{s\sin^2\phi}\ , \tag{4}$$

Using eq. (2) and transforming the variable from θ to l, eq. (3) becomes then

$$\begin{aligned} n_1&=\frac{2}{\pi R^2}\int_{R-s}^{R} rdr\int_0^{\pi/2} d\phi\int_{R-r}^{s}\frac{1}{l^2\sin^2\phi}\left\{\frac{r^2\cos^2\phi+R^2\sin^2\phi}{\sqrt{r^2\cos^2\phi+R^2\sin^2\phi-l^2\sin^2\phi\cos^2\phi}}-r\right\}dl \\ &=\frac{2}{\pi R^2}\int_0^{s}\frac{dl}{l^2}\int_0^{\pi/2}\frac{d\phi}{\sin^2\phi}\int_{R-l}^{R}\left\{\frac{r^2\cos^2\phi+R^2\sin^2\phi}{\sqrt{r^2\cos^2\phi+R^2\sin^2\phi-l^2\sin^2\phi\cos^2\phi}}-r\right\}dr \\ &=\frac{2}{\pi R^2}\int_0^{s}\frac{dl}{l^2}\int_0^{\pi/2}\left\{\frac{4R^2}{3\sin^2 2\phi}\left(\sqrt{R^2-\frac{l^2}{4}\sin^2 2\phi}-R\right)\right. \\ &\qquad\left.+\frac{3}{2}l^2\sqrt{R^2-\frac{l^2}{4}\sin^2 2\phi}-\frac{l^2}{3}+\frac{2}{3}l^2\cos^2\phi\right\}d\phi\ . \end{aligned} \tag{5}$$

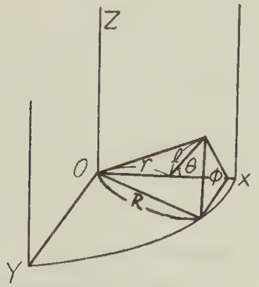

Fig. 1. Path length of alpha-particle in the counter.

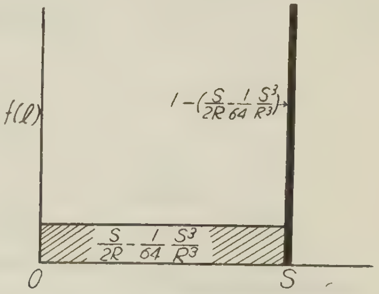

Fig. 2. Distribution of path length of alpha-particles in the counter.

When the range of alpha-particle is smaller than the diameter of the counter, this integral is evaluated by expanding into power series and integrating each term:

$$n_1=\int_0^{s}\left(\frac{1}{2R}-\frac{3}{64}\frac{l^2}{R^3}-\frac{15}{6144}\frac{l^4}{R^5}\cdots\right)dl\ . \tag{6}$$

By equating the integrands of eqs. (1) and (6) we obtain the distribution of the path length through the counter:

$$f(l)=\frac{1}{2R}-\frac{3}{64}\frac{l^2}{R^3}-\frac{15}{6144}\frac{l^4}{R^5}\cdots\ . \tag{7}$$

Since the first term is large compared with other terms, this distribution is nearly constant from 0 to s. Now, a fraction of alpha-particles which strike the wall of the counter is given by,

$$n_1=\frac{s}{2R}-\frac{1}{64}\frac{s^3}{R^3}-\frac{3}{6144}\frac{s^5}{R^5}\cdots\ . \tag{8}$$

This expression indicates that the degree of the wall effect is approximately the ratio of the range of alpha-particles to the diameter of the counter, the result of which is consistent with our anticipation. Thus the remainder, $n_2=1-\left(\frac{s}{2R}-\frac{1}{64}\frac{s^3}{R^3}\cdots\right)$, will be accounted for the line spectrum of the slow neutron-induced reaction. Calculated distribution of the path length is shown in Fig. 2.

In the calculation of energy spectra, an account must be taken of the total ionization along the track of alpha-particles. Assuming that the total ionization is proportional to the path length of alpha-particles in the gas, energy loss spectrum will be obtained from eq. (8),

$$I(\mathcal{E})=\frac{s}{2R}\frac{1}{E_0}-k(\mathcal{E})\,, \tag{9}$$

where E_0 is the initial energy of alpha-particle and $k(\mathcal{E})$ corresponds to all terms except the first in eq. (7), and is much small compared with $s/2R\cdot 1/E_0$.

Finally we return to resolution effect accompanying the multiplication process of the counter. By analogy with the resolution function of the photomultiplier system proposed in the paper by Miller and Snow[4], we assume a Gaussion resolution for the counter:

$$\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\mathcal{E}'-\mathcal{E})^2}{2\sigma^2}\right\},$$

where σ is empirically determined from the width of the peak. Thus the expression for the energy spectra of α-particles is

$$\begin{aligned}R(\mathcal{E}')&=\int_0^{E_0}\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\mathcal{E}'-\mathcal{E})^2}{2\sigma^2}\right\}I(\mathcal{E})d\mathcal{E}+n_2\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\mathcal{E}'-E_0)^2}{2\sigma^2}\right\}\\&\approx\frac{s}{2RE_0}\int_0^{E_0}\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\mathcal{E}'-\mathcal{E})^2}{2\sigma^2}\right\}d\mathcal{E}+\left(1-\frac{s}{2R}\right)\frac{1}{\sqrt{2\pi}\sigma}\exp\left\{-\frac{(\mathcal{E}'-E_0)^2}{2\sigma^2}\right\}.\end{aligned} \tag{10}$$

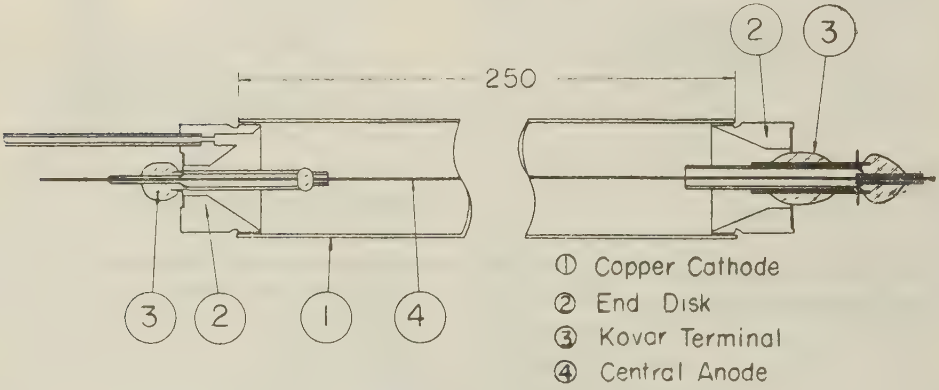

Fig. 3. Construction of the counter.

The first term is an error integral and readily evaluated, for instance, from the table of Jahnke and Emde.

§ 3. Experimental

Fig. 3 shows the construction of our experimental counter. Counter cathode ① is copper cylinder 12.5 mm in radius and 250 mm in length, which at both ends is soldered with copper end discs ② together with open skirt Kovar glass terminals ③. The radius of tungsten central wire ④ is 0.05 mm and the active length is 205 mm.

The counter was evacuated using a mercury diffusion pump and outgassing is performed at 300°C, and then filled with boron trifluoride gas.

Boron trifluoride gas for counter filling was generated by thermal decomposition of enriched boron trifluoride-calcium fluoride complex. The subsequent purification of the gas was performed in similar way as described by F. Hudswell et al.[5] The purity of the gas was examined by mass spectrometer and traces of impurities (mainly BFOH) was detected.

Measurement was made under overall irradiation by slow neutron using a 20 mc Ra–Be source and paraffin moderator. Pulses obtained were fed via a cable of about 1 meter (≈70 pF) to A–1 type amplifier having rise and fall time constants of 0.3 μ sec and 3 μ sec respectively. They were then fed to Baird Atonic type one channel pulse height analyzer.

§ 4. Results and discussion

Pulse height distributions for a counter containing 50 cm Hg BF_3 are shown in dashed lines in Figs. 4–6. Operating voltages are 1900 V, 2400 V and 3100 V, and the gas multiplication at those voltages are 9, 70 and 1000 respectively. It is seen that at lower operating voltage the two peaks arising from transitions to excited state and ground state of Li^7 are completely resolved as shown in Fig. 4, whereas at higher operating voltage 2.8 MeV peak is masked by 2.3 MeV peak.

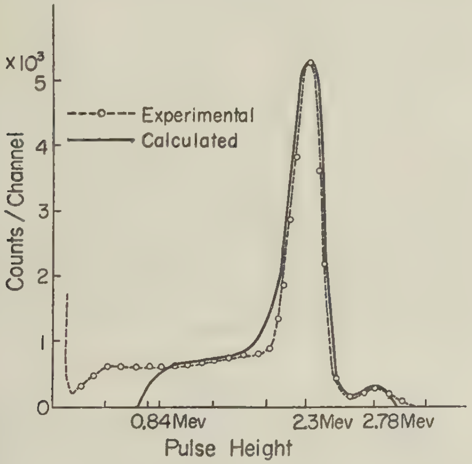

Fig. 4. Pulse height distribution of the counter. H.T=1900 V. Gas multiplication=9. Pressure =50 cmHg of BF_3.

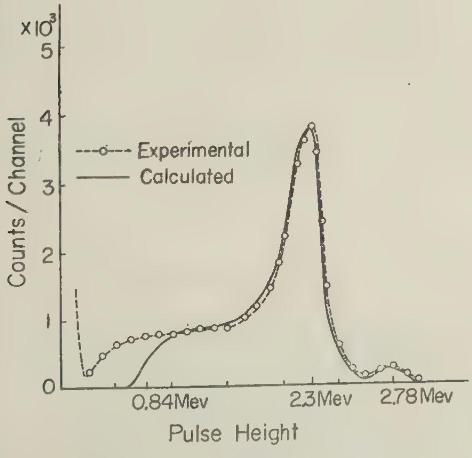

Fig. 5. Pulse height distribution of the counter. H.T=2400 V. Gas multiplication=70. Pressure =50 cmHg of BF_3.

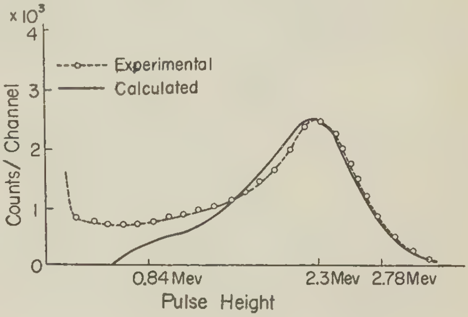

Fig. 6. Pulse height distribution of the counter. H.T=3100 V. Gas multiplication=1000. Pressure=50 cmHg of BF_3.

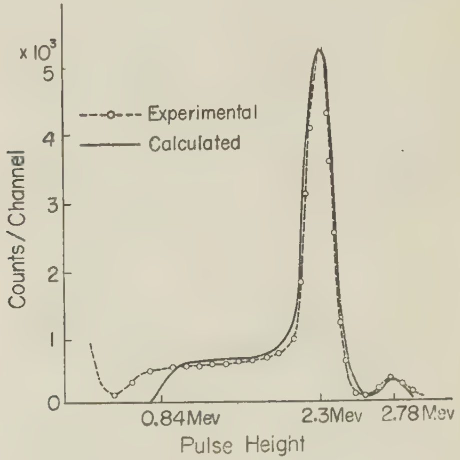

Fig. 7. Pulse height distribution of the counter. H.T=2200 V. Gas multiplication=9. Pressure =60 cmHg of BF_3.

The widths of 2.3 MeV peak at $1/e$ maximum are 0.34 MeV, 0.49 MeV and 0.92 MeV and thus the values constant σ of Gaussian resolution function are 0.12 MeV, 0.174 MeV and 0.326 MeV respectively.

The increase in width of the peak with operating voltage will be due to the fluctuation of gas multiplication.

The marked tail on the low energy side of the peak is apparently due to the wall effect of the counter. Since the whole range of alpha-particle with energy 2.3 MeV×7/11, in 50 cm Hg BF_3 is about 12 mm, calculated wall effect ($s/2R$) in our 25 mm diameter counter is about 48%. Substituting the values of σ and $s/2R$ in eq. (10), the energy spectra of alpha-particles are readily obtained. With addition of energy of Li^7 fragments, 2.3 MeV× 4/11, the general shapes of the calculated spectra are shown in full lines in Figs. 4–6.

The slight discrepancy between the theoretical and experimental curves, in which the tail of the experimental curves extends much further to low energy region, will be attributed to the wall effect of Li^7 fragments of which no account is taken in theoretical treatment because of much shorter length of the track.

Measurements for counters of different filling pressure was also made in order to make clear the effect of the range of the particles. The results are shown in Figs. 7 and 8 for counters containing 60 cm Hg and 70 cm Hg BF_3. The gas multiplication is about 9 and operating voltages are 2200 V and 2500 V respectively. It is seen that the wall effect of of Li^7 fragments observed at the lower end of the distribution, and of alpha-particles measured as intensity at the tail of the distribution reduces with increased filling pressure. The ratio of the area of low energy tail to total area of the spectra and the values of theoretically calculated wall effect are summarized in Table I.

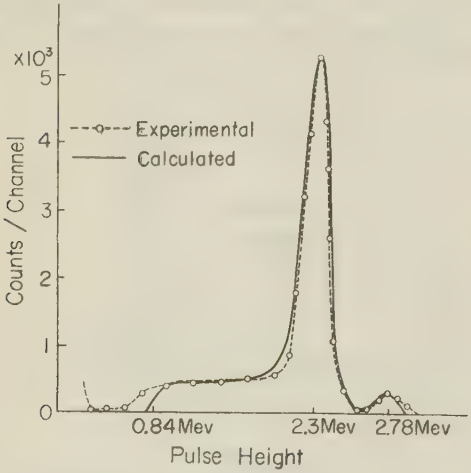

Fig. 8. Pulse height distribution of the counter. H.T=2500 V. Gas multiplication=9. Pressure =70 cmHg of BF_3.

Table I. Wall effect of the counters.

Filling pressure	H.T.	Calculated ($s/2R$)	Experimental
50 cm Hg	1900 V	48%	57%
60 cm Hg	2200 V	40%	45%
70 cm Hg	2500 V	34%	40%

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 10, OCTOBER, 1960

Mixing Ratio of the 440-keV Gamma Radiation in ^{23}Na

By Akira MIZOBUCHI, Toshio KATOH and Jian-zhi RUAN

Department of Physics, Faculty of Science, Osaka University, Osaka

(Received May 30, 1960)

The angular distribution and the direction-polarization of the 440-keV gamma rays in ^{23}Na$(p, p'\gamma)^{23}$Na reaction have been measured at the 1.29-MeV resonance. For these measurements the following results were observed; for the angular distribution, $W(\theta)=1-(0.091\pm0.004)P_2$ $(\cos\theta)$ and for the polarization parameter, $p=+0.69\pm0.02$. From the observed results, the mixing ratio of the 440-keV gamma radiation was obtained as $(\mathrm{E2/M1})^{1/2}=+0.045\pm0.015$. This value agrees with the prediction from the collective model.

§ 1. Introduction

The properties of low lying states of the nuclide ^{23}Na have been investigated by many workers$^{1-5)}$. The ground and the first excited states are known to have spins 3/2 and 5/2, respectively, and both even parities. In addition, the spins and the excitation energies for low lying states agree with the predictions from the collective model$^{3)}$. It is of interest, therefore, to investigate the pattern of the gamma radiation from the excited state. The angular distribution and the direction-polarization correlation of the 440-keV gamma radiation from the first excited state in ^{23}Na$(p, p'\gamma)^{23}$Na reaction were measured at the 1.29-MeV resonance. The angular distribution of the 440-keV gamma radiation was fitted to the form $W(\theta)=1+A_2P_2(\cos\theta)$. Moreover the direction-polarization correlation was mesured by a polarimeter using the Compton effect, and this kind of the measurement was pointed out by Metzger and Deutch$^{6)}$, and Fagg and Hanna$^{7)}$. The polarization was measured for the gamma rays emitted to the direction $\theta=90°$. The mixing ratio, $\delta=(\mathrm{E2/M1})^{1/2}$, of the 440-keV gamma radiation has been obtained from the coefficient of the angular distribution, A_2, and the polarization parameter, p.

§ 2. Experimental procedure

The Osaka University static generator provided protons for this experiment. The energy of the protons was analyzed by a magnet controlled by the proton resonance. A sodium target was prepared by evaporation of NaCl on a 0.1 mm copper backing. Its thickness was estimated at a few keV at the 1.29-MeV from the excitation function. A resonance in the ^{23}Na$(p, p'\gamma)^{23}$Na reaction is found at $E_p=$ 1.29-MeV and this resonance state have spin 1 and odd parity$^{4)}$. The bombarding energy of protons was set at this resonance peak.

The gamma ray detector used was a 1.5″$\phi\times$1.5″ NaI(Tl) scintillation spectrometer. For the observation of the angular distribution of the 440-keV gamma rays, a single channel pulse height analyzer was employed, which was set to count the full-peak portion of the 440-keV gamma rays in the pulse height spectrum shown in Fig. 1.

In the case of the measurement of angular distribution, the gamma detector having a slit of 25 mmϕ was mounted at 25 cm from the target, and on a angle-changer centered on the target.

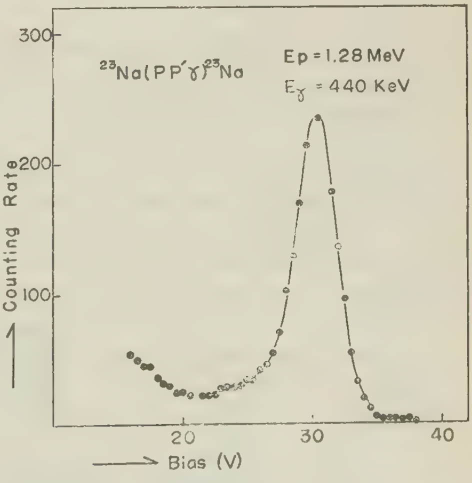

Fig. 1. Pulse height spectrum of gamma rays in ^{23}Na$(p, p'\gamma)^{23}$Na reaction at the 1.29-MeV resonance. These data were obtained using 2.5″$\phi\times$2.5″ NaI(Tl) scintillation spectrometer.

The experimental geometry for the direction-polapization measurement is shown in Fig. 2 The polarimeter using the Compton effect was a $2''\phi\times2''$ plastic scintillator. The gamma rays scattered by the polarimeter had been detected by a NaI(Tl) scintillation spectrometer, and the coincidence spectrum of the gamma rays which coincided with the Compton recoil electron in the polarimeter were determined. The typical coincidence spectrum is shown in Fig. 3. A schematic diagram of the electronics is shown in Fig. 4. The fast coincidence circuit[8] had the resolving time, $2\tau=30\times10^{-9}$ sec.

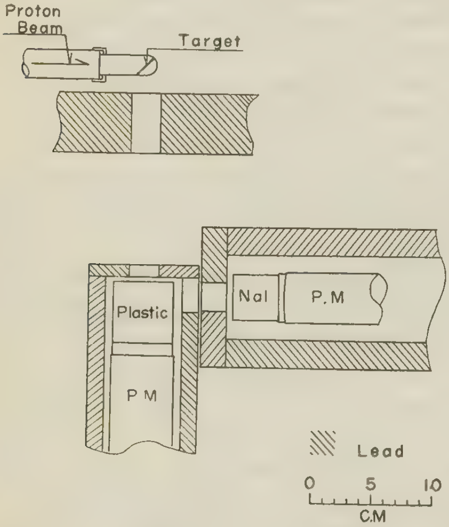

Fig. 2. Plan view of the geometrical arrangement in direction-polarization measurement. The plastic scintillator was used as a polarimeter and the gamma rays scattered by the polarimeter were detected by NaI scintillation spectrometer, which was set at the positions parallel to and vertical to the plane of the paper, by means of rotation of the detector.

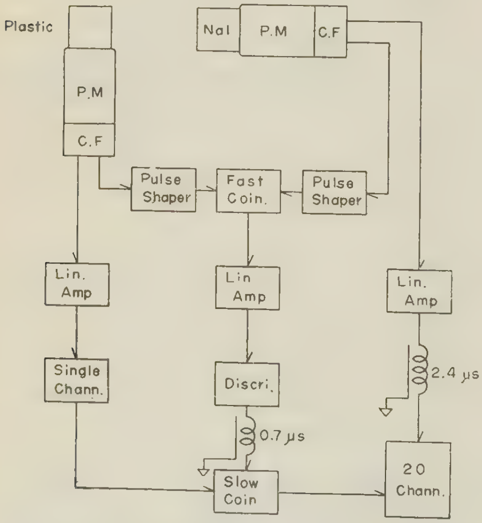

Fig. 3. Schematic diagram of the circuits used in this experiment.

The polarimeter is arranged so that $\theta=90°$, where θ is the angle between the direction of the incident beam and the emitted gamma rays. $N_{//}/N_{\perp}$ is defined as the ratio of the coincidence rate for the position when the detector of the Compton scattered photons is in the plane defined by the incident proton beam and the emitted gamma rays to the coincidence rate for the perpendicular position.

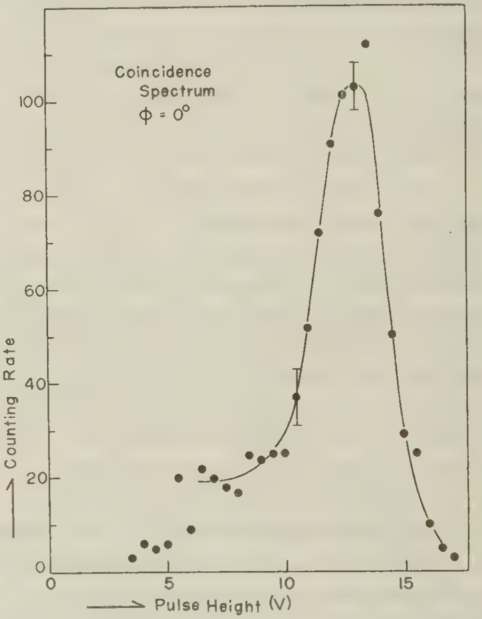

Fig. 4. Pulse height spectrum of the scattered gamma rays in coincidence with Compton recoil electron in the polarimeter.

The ratio $N_{//}/N_{\perp}$ and polarization parameter p are related through the following expression:

$$N_{//}/N_{\perp}=(p+R)/(1+pR),$$

where R is the sensitivity of the polarimeter. For the case of the ideal geometry, R is simply the ratio of two differential cross sections for Compton scattering, $d\sigma_{\phi=90}/d\sigma_{\phi=0}$, where ϕ is the angle between the direction of polarization of gamma rays and the plane defined by the incident and scattered gamma rays. The polarimeter used in this experiment had a value $R\risingdotseq5.9\pm1.0$, which was calculated by the Klein-Nishina formula considering the effect of the solid angle.

§ 3. Results and Discussion

The angular distribution of the 440-keV gamma rays in the $^{23}\mathrm{Na}(p, p'\gamma)^{23}\mathrm{Na}$ reaction was measured at the 1.29-MeV resonance. It is shown in Fig. 5. The experimental data were fitted to the form $W(\theta)=1+B_2\cos^2\theta$ using the method of least-squares. In Fig. 5 the solid line indicates the least-square fit. The result obtained exhibits $B_2=-0.142\pm0.005$. And this value were rewritten by the coefficient, A_2, of the distribution in the Legendre polynominal, *i.e.* $W(\theta)=1+A_2P_2(\cos\theta)$. Then, $A_2=-0.091\pm0.004$ was obtained.

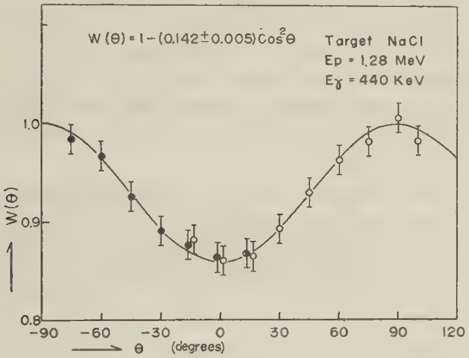

Fig. 5. The angular distribution of the 440-keV radiation. The solid curve is least-square fit of the distribution to the form $W(\theta)=1+B_2\cos^2\theta$.

Next, at the same resonance $N_{//}/N_{\perp}=1.30\pm0.04$ was determined for the polarization measurement. The polarization parameter, p, was obtained as $p=0.69\pm0.02$ from the above result.

The coefficient of the distribution and the polarization parameter of the gamma radiation for $^{23}\mathrm{Na}(p, p'\gamma)^{23}\mathrm{Na}$ reaction depend on the mixing ratio of the multipole order for gamma rays, and on the angular momentum and the channel spin for incident protons. These values, A_2 and p, have been expressed in a convenient form by Biedenharn and Rose[9] and Sharp *et al*[10].

The assignments of the ground and the first excited states of ^{23}Na and the resonance state of $^{23}\mathrm{Na}(p, p'\gamma)^{23}\mathrm{Na}$ reaction at the 1.29-MeV are known to have $3/2^+$, $5/2^+$ and 1^-, respectively[1-5]. Using these spin assignments, δ and t which agree with the experimental values A_2 and p were obtained as shown in Fig. 6, where δ and t are $(E2/M1)^{1/2}$ and the ratio of the intensities of incident protons entered a resonance state with $l=3$ to with $l=1$, respectively. By way of the experimental results, the mixing ratio of the 440-keV gamma radiation was obtained as $\delta=+0.045\pm0.015$.

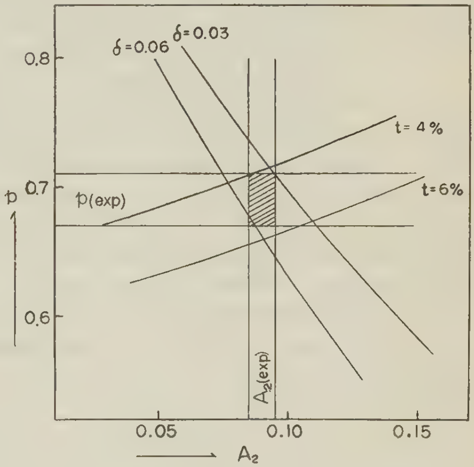

Fig. 6. The values of A_2 and p calculated as function of δ and t. The parameters δ and t are $(E2/M1)^{1/2}$ for the 440-keV gamma rays and (intensity of f-wave) (intensity of p-wave), for incident protons respectively.

It is assumed that the angular momentum of inelastically scattered protons has $l=1$, and the channel spin of incident protons has $S=2$. This assumption is reasonable from following consideration: (1) Since the inelastically scattered protons have low energy, the angular momentum $l=3$ would be excluded. (2) If the channel spin of incident protons mixed $S=1$ with $S=2$, t would be more large without changes of δ.

According to the independent particle model,

Table I. The values of $(E2/M1)^{1/2}$.

Paul and Montague[13]	0.02	Theoretical value
Rasmussen et al.[15]	+0.057	Experiment of mean life for resonance scattering
Present experiment	+0.045±0.015	

the ground and the first excited states of ^{23}Na are states of abnormal coupling of three like particles$^{11)}$, such as $(d_{5/2})^3\,3/2$ and $(d_{5/2})^3\,5/2$, respectively. The selection rule given by Moszkowski$^{12)}$ forbids M1 transition between these states. Paul and Montague$^{13)}$ studied the low lying states of ^{23}Na for rotation particle coupling$^{14)}$. The level energy and the spins agreed with the experimental data were obtained. Their calculated value of the mixing ratio of the 440-keV gamma radiation is given as $\delta=0.02$. As shown in Table I, this value agrees with the present result and the experimental result of Rasmussen, Metzger and Swann$^{15)}$. It is, therefore, supported that the nuclide ^{23}Na has the collective charactor.

(d, α) Reactions on Some Light Nuclei

By Chuin HU

Faculty of Science, Osaka University

(Received May 30, 1960)

Angular distributions of the emergent alpha particles from the reactions $O^{16}(d, \alpha_0)N^{14}$(g'nd.), $N^{14}(d, \alpha_0)C^{12}$(g'nd.), $N^{14}(d, \alpha_1)C^{12*}$(4.44 Mev state), $F^{19}(d, \alpha_0)O^{17}$(g'nd.), $F^{19}(d, \alpha_1)O^{17*}$(0.872 Mev state) and $P^{31}(d, \alpha_0)Si^{29}$(g'nd) were investigated at several bombarding energies in the region from 10.3 Mev to 11.4 Mev. The distributions which cover the angular range between approximately 25° and 160° in the center-of-mass system, exhibit generally oscillatory and forward peaking behavior.

The intensity of the transition to the 2.31 Mev ($T=1$) state of N^{14} was measured in the range from 10.5 to 11.4 Mev in the step of 100 keV interval by aluminum absorber. The alpha particles from the targets were detected by a thin CsI(Tl) crystal scintillation spectrometer.

The experimental results were compared with the theoretical curves calculated by simplified direct-interaction model of Butler and the model which includes heavy particle stripping process. The attempts to fit some data were also made by using an approximate expression derived by Newns for double stripping process.

§1. Introduction

A number of investigators pointed out that a large majority of particle-nuclear reactions at bombarding energies from 10 to 50 MeV, which leave the final nucleus at low-lying excited levels, are induced by the direct-interaction process, and that the observed angular distributions show generally stripping-like patterns.

By the development of the theory of deuteron stripping by Butler[1] and others[2], the analysis of the angular distributions in these reactions, which leave the residual nucleus in some definite quantum state, have provided many useful informations on the properties of these states in nuclei. The (d, p) or (d, n) reaction receives a predominant contribution from a direct interaction. There are, however, few reasons why only this particular type of reactions should show clearly a direct interaction feature compared to other reactions. According to Butler[3], when the direct process plays a remarkable role, the predicted shapes of the angular distributions of (d, p), (p, α), (p, p'), (α, α'), etc. have no sharp distinction to each other and are expected to have a similar form. The theoretical differential cross sections for the direct process exhibit generally oscillatory behavior with a rapid decrease in intensity at angles larger than that of the primary peak.

On the other hand, many other theoretical treatments were given by several authors[4] assuming individual character involved in each special reaction on the standpoint of direct interaction.

In contrast with the reactions of (d, p), (p, p'), etc., little effort was done in the experimental studies for the angular distribution of (d, α) reaction, and also little is yet known about the possible reaction mechanism for this reaction on light nuclei with the medium bombarding energy. Therefore, in addition to the investigations which had been reported previously[6),7),12),13)], the present data on the angular distribution of (d, α) reaction on light nuclei with about 11 MeV incident energy, may be expected to have the possibility to give useful informations concerning the reaction mechanism, and will offer some facts to check the validity of the theory which has been derived by Newns[5] in a similar way as deuteron stripping reaction.

Another important process of nuclear reaction which competes with the direct process stated above is the compound nuclear process, by which many nuclear reactions at low bombarding energies are explained reasonably. Of course, it is expected that the contributions from the compound nucleus formation can not be neglected for our case. The energy dependence would be observed in the shape of angular distribution, if both the continuum and statistical assumption about compound nucleus are violated in the compound nucleus process. The angular distribution would be symmetric about 90° in two limiting cases in which the reaction proceeds through single compound nucleus level or through a large numbers of the compound nucleus levels involved in the energy width of incident beam[14]. In order to observe the contribution of the compound process, this work was investigated at several bombarding deuteron energies in the region from 10.3 to 11.4 MeV.

In the $O^{16}(d, \alpha_1)N^{14*}$ (2.31 MeV state) reaction, minor breakdown of the isotopic spin selection rule governing transition to the first excited state of the N^{14} nucleus had been observed by Dalton, Hinds and Parry[6] at the bombarding energies of 6.8, 7.1, 7.2 and 8.7 MeV, and by Browne[7] from 5 MeV up to 7.5 MeV. The failure of the selection rule in this reaction was explained by Browne[7] on the basis of Coulomb force admixing the isotopic spin impurities into the intermediate state configurations. Therefore, the appearance of the forbidden group suggests the existence of $T=1$ level in the compound nucleus F^{18}, and the compound process plays considerable roles in the nuclear reactions. Isotopic spin conservation fails at low bombarding energies, but such breakdown cannot be expected at the bombarding energies where the reaction proceed through direct interaction[24]. It is, therefore, interesting to extend the range of bombarding energy in order to determine whether the forbidden group appears or not.

§ 2. Experimental procedures

The experiments were performed with 11.4 MeV deuterons from the Osaka University 44-inch cyclotron. The layout of the cyclotron and associated equipments had been shown elsewhere[8]. The beam was collected in a Faraday cup which was always held at ground potential, and was measured by a vibrating reed electrometer. The measurements of the angular distribution were made at angles ranging from 20° to 130° or 160° in the laboratory system with steps of 10° interval. The counter angle could be set to ±0.1° by means of a varnier scale and the angular resolution was ±1.0°.

The emergent alpha particles were detected by a thin uniform CsI(Tl) crystal on a R. C. A. 6342 photomultiplier. To resolve the product alpha particles from the longer ranged charged particles, such as protons and deuterons, which

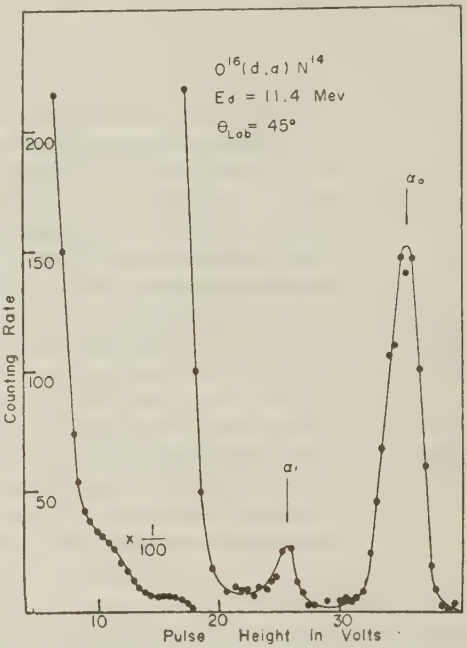

Fig. 1. Pulse-height spectrum of alpha-particles emitted at $\theta_{lab.}=45°$ from a mylar target bombarded with 11.4 MeV deuterons. An aluminum absorber (3 mg/cm²) was inserted in front of a counter.

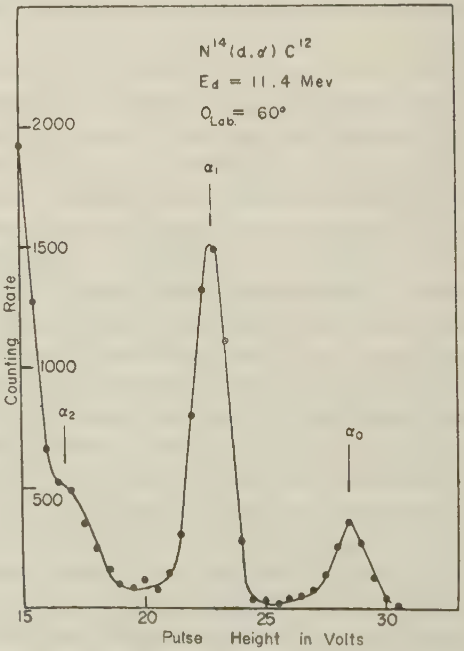

Fig. 2. Pulse-height spectrum of alpha-particles emitted at $\theta_{lab.}=60°$ from a melamin target bombarded with 11.4 MeV deuterons.

were produced by the reactions (*d*, *p*), (*d*, *d*) and (*d*, *d′*), the thickness of the CsI(Tl) crystal was chosen so thin as to be nearly equal to the range of the highest energy alpha-particle group from (*d*, *α*) reaction with 11.4 MeV incident energy at 90° in the laboratory system. At the forward angles smaller than 90°, aluminum absorbers were inserted in front of the scintillator until the pulse height of the highest energy alpha-particle group reached a maximum at each angular position. Actually CsI(Tl) crystals of 50 or 40 mg/cm² and 17 mm ×20 mm were used in the O^{16} experiments, but these were replaced by the crystals of 80 or 90 mg/cm² in other runs. The output pulses were amplified, shaped, and then analysed by a multichannel pulse height analyser. In the case of earlier measurements for $O^{16}(d, \alpha_0)N^{14}$(g'nd.) and $O^{16}(d, \alpha_1)N^{14*}$ (2.31 MeV state), a commercial 20-channel pulse height analyser was used, and in another experiments this was replaced by a 30-channel pulse height analyser, which had been constructed in our laboratory.

In order to identify the levels in the (*d*, *α*) reaction, the author used the range-energy relation for protons in aluminum[9] and the fact that the CsI(Tl) crystal responds linearly to the *α* particle energy loss in crystal[10]. Using alpha particles from the reaction $O^{16}(d, \alpha_0)N^{14}$ and $O^{16}(d, \alpha_2)N^{14*}$(2nd.), a measure-

ment was carried out on the CsI(Tl) crystal, which were used in this work, to obtain the pulse height ratio as a function of the energy of the emergent alpha particles. Then the comparison was performed between the output voltage from a linear amplifier and the results calculated kinematically.

A mylar film (0.8 mg/cm^2), was used in the measurements of $O^{16}(d, \alpha)N^{14}$ reaction, and a teflon film (0.9 mg/cm^2) was used in the $F^{19}(d, \alpha)O^{17}$ reaction. These targets are essentially $C_5H_4O_2$ and CF_2 respectively. The alpha-particle group under investigation was not contaminated with alpha particles of the same energy from reactions on other constituents. These substances were not so strong under deuteron bombardment that the calibrations were employed frequently for each run. The targets for the $N^{14}(d, \alpha)C^{12}$ and $P^{31}(d, \alpha)Si^{29}$ reactions, were prepared as follows; A melamin film ($C_3H_6N_6$, 2.2 mg/cm^2) was painted uniformly on the myler film (0.8 mg/cm^2), and commercial red phosphor powder (0.3 mg/cm^2) was molded uniformly in a thin polystylene film (1.0 mg/cm^2). These targets were supported by a 3 cm×3 cm frame, and were placed in the center of a cylindrical scattering chamber at 45° to the incident beam.

§ 3. Result

In Figs. 1 to 6 are shown the typical CsI(Tl) scintillation counter spectra obtained by the targets mentioned above, and the expected positions of peaks corresponding to the discrete states in the residual nuclei.

The alpha-particle group from $F^{19}(d, \alpha_0)O^{17}$ (g'nd.) and that from $F^{19}(d, \alpha_1)O^{17*}$(1st.) were not well resolved. In the results of $P^{31}(d, \alpha)Si^{29}$ experiments, the groups leading to the excited states could not be resloved adequately, except

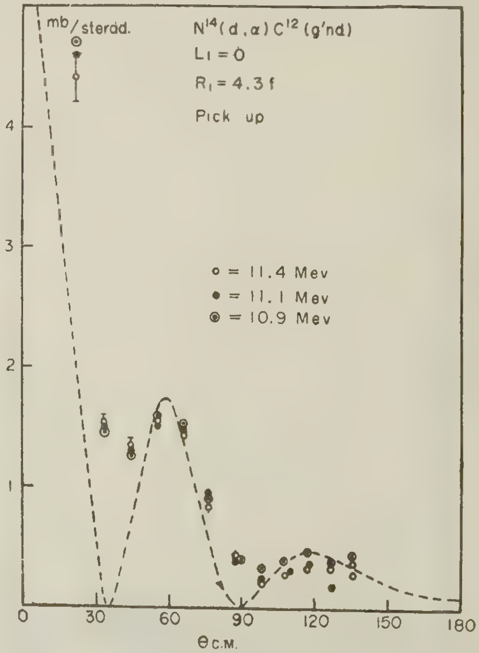

Fig. 8. Differential cross sections for the $N^{14}(d, \alpha_0)C^{12}$ (ground state) reaction. The dotted curve was calculated for pick up process with $r_1=4.3$ *f*., and $l_1=0$.

the group corresponding to the transition the ground state of Si^{29}.

The observed angular distributions for (d, α) nsitions induced by the deuterons of about MeV, which correspond to the ground and first excited states of the residual nuclei shown in Figs. 7 to 12.

The indicated relative errors of differential ss sections were due to the counting sta- tics, uncertainty in separation of alpha- rticle groups, and the background substrac- n, and the overall errors did not exceed 10%. The estimated errors in the absolute fferential cross sections are as follows: oxy- n target ±70%, nitrogen target ±80%, orin target ±50% and phosphor target 70%.

To assert the existence of the yield leading the first excited state ($T=1$) in N^{14}, almi- um absorbers (3 mg/cm^2 and 5 mg/cm^2) were serted respectively in front of the CsI(Tl) ystal, and the measured spectra are shown Figs. 1 and 5. The spectra without almi- um absorber are shown in Fig. 6. In all ses, the forbidden group appeared, and the eld for this state was much less than the

§ 4. Discussion

The angular distributions investigated in this work show strong forward peaking and oscillatory behavior. Some of them have another peak in the backward direction. In addition to these facts, the large energy dependency of the angular distribution was not observed except for the $O^{16}(d, \alpha)N^{14}$ reaction. Accordingly, it is reasonable to assume that the direct interaction process is playing an important role.

The fits to these angular distributions were made with the theoretical differential cross sections derived by Butler[3] for direct interaction, in the same way as, for example, a (d, p) reaction. The theoretical curves calculated with the formula derived by Butler, in which the alpha-particle was treated as a single particle, showed good agreement with experimental results. The effect of internal structure of alpha-particle was not considered in the calculation. In our treatment, the deuteron and alpha-particle were also considered as single particles even around the nucleus. The used expression for the theoretical differentia cross section was,

$$\frac{d\sigma}{d\Omega}\propto|F_1(K_1)\,W\{j_{l1}(Q_1r),\,h_{l1}(i\kappa_1r)\}_{r=r_1}|^2 \qquad (1$$

where $F_1(K_1)$ is a form factor. Q_1 and κ_1 are related to the appropriate momentum transfer vector defined below and binding energy. r_1 is the interaction radius, and l_1 is the change of angular momentum. The allowed l_1-values are found by the selection rule.

$$I_f=I_i+l_1+S \qquad (2$$

Here I_i is the spin of the target nucleus, I_f is the spin of the final state and S is the resultant spin of the incident and emerging particles. l_1 must be odd as the parity is changed.

For a given (d, α) reaction, the both processes of "Knock out" and "Pick up" were considered, and these processes are characterized respectively as follow; "Knock out"

$$\left.\begin{aligned} Q_1&=\frac{M_f}{M_i}\left[K_\alpha-\frac{M_i}{M_f}K_d\right]\\ \kappa_1&=\frac{1}{\hbar}(2M_\alpha\mathcal{E}_{\alpha i})^{1/2}+(2M_d\mathcal{E}_{df})^{1/2}\} \end{aligned}\right\} \qquad (3)$$

"Pick up"

$$\left.\begin{aligned} Q_1&=K_\alpha-\frac{M_f}{M_i}K_d\\ \kappa_1&=\frac{1}{\hbar}(2M_d\mathcal{E}_{di})^{1/2} \end{aligned}\right\} \qquad (4)$$

where M_i, M_f, M_d and M_α are the masses of the initial nucleus, final nucleus, deuteron and alpha-particle. $\mathcal{E}_{\alpha i}$, $\mathcal{E}_{di}$ and $\mathcal{E}_{df}$ are the binding energies, respectively, of alpha-particle in the initial nucleus, a deuteron in the initial nucleus, and a deuteron in final nucleus corresponding to the ground or the first excited state.

To get better agreement with the large cross sections at backward angles in the experimental results, the interaction which have been neglected in the theory mentioned above, must be considered. Therefore, the heavy particle stripping interaction[11] was added to the so-called ordinary direct interaction process. These two processes are coherent to each other, so that interference occurs between them. The differential cross section including heavy particle stripping is

$$\frac{d\sigma}{d\Omega}\propto|F_1(K_1)\,W\{j_{l1}(Q_1r),\,h_{l1}(i\kappa_1r)\}_{r=r_1}$$
$$+A\cdot F_2(K_2)j_{l2}(Q_2r_2)|^2 \tag{5}$$

ere A is an adjustable constant and the subcript 1 and 2 refer to knock out (or pick up) nd heavy particle stripping respectively. Vhen these are evaluated, the theoretical ifferential cross section becomes,

$$\frac{d\sigma}{d\Omega}\propto|F_1(K_1)\,W\{j_{l1}(Qr),\,h_{l1}(i\kappa_1r)\}_{r=r_1}|^2$$
$$+a\cdot F_1(K_1)F_2(K_2)\,W\{j_{l1}(Q_1r),\,h_{l1}(i\kappa_1r)\}$$
$$\times j_{l2}(Q_2r_2)\cos\beta$$
$$+b\cdot|F_2(K_2)j_{l2}(Q_2r_2)|^2 \tag{6}$$

vhere $\cos\beta$ arises from the transformation rom the heavy particle stripping axis of uantization K_2 to the knock out (or pick up) xis K_1, and β is the angle between K_1 and K_2, and " *a* " and " *b* " are adjustable constants.

The parameters used in the differential ross section for heavy particle stripping are

$$\left.\begin{aligned} Q_2&=K_d+\frac{M_d}{M_f}K_\alpha \\ K_2&=K_\alpha+\frac{M_\alpha}{M_i}K_d \end{aligned}\right\} \tag{7}$$

nd the form factor is calculated by the folowing equation.

$$F_2(K_2)=\int_0^\infty \psi_l(r)j_2(K_2r)r^2dr\,. \tag{8}$$

Iere $\psi_l(r)$ is the internal wave function of he alpha-particle in the initial nucleus, and is the orbital angular momentum of alphaarticle in the initial nucleus relative to the ore. In this case alpha-particle was treated s single particle. In almost all cases, the implified $\psi_l(r)$ was used in the calculation or convenience, so that $F_2(K_2)$ varies so slowly ver the angles that it has little effect on he final results.

The dotted curves calculated by Eq. (1) for ll reactions studied in this work with " Knock ut " or " Pick up " for all allowed angular nomentum transfers and for several values f the interaction radii are shown in Figs. 8 o 13. Some of them were lifted by adding n isotropic contribution to the theoretical ross section. A chief fraction of this additional ross section probably is due to the compound uclear process and the rest may be caused by he interference between various direct interctions or between direct interaction and comound nuclear process.

On the whole, a good agreement was obtained between theoretical curves and the experimental results for positions of maxima and minima, except for their height, and the marked disagreement between them appeared in the shapes over the backward angles.

Table I. Comparison of the positions of maxima and minima of experimental differential cross sections from (*d*, *α*) reactions with the predictions of Eq. (1)

The final state	Maximum or Minimum	Alpha-particle angle in the center of mass system	
		Experiment	Theory
C^{12}(g'nd.)	Min.	~ 40°	37°
	Max.	~ 60°	60°
	Min.	~100°	90°
C^{12}(1st.)	Min.	35°	28°
	Max.	45°	45°
	Min.	75°	70°
N^{14}(g'nd.)	Max.	65°	65°
	Min.	90°	90°
	Max.	~120°	120°
O^{17}(g'nd.)	Min.	~ 32°	24°
	Max.	43°	44°
	Min.	65°	65°
	Max.	90°	88°
	Min.	102°	105°
O^{17}(1st.)	Min.	~ 67°	70°
	Max.	87°	90°
	Min.	~120°	120°
Si^{29}(g'nd.)	Min.	30°	30°
	Max.	50°	50°
	Min.	74°	75°
	Max.	84°	95°

In Table I are summarized the locations of maxima and minima of the experimental results and the predictions of a simplified calculation based on the Eq. (1). The solid curves in Figs. 8 to 13 were calculated by Eq. (6). It is recognized that these curves are in better agreement with the data over the entire range of angles studied with reasonable radii and l-values than those predicted by Eq. (1). However, the theoretical curves for heavy particle stripping can be reproduced with slight variation in the interaction radius for the other values of the change in angular momentum. This is caused by the fact that the minimum value of Q_2 is relatively large. Accordingly, it is impossible to distinguish between various

l_2-values for heavy particle stripping, though, the use of this interaction improves the fit to the data.

In addition to these attempts, we tried to make fit the data to the formula derived by Newns[5] for double stripping (or double pick up) process. An approximate expression derived on this assumption is.

$$\frac{d\sigma}{d\Omega}\propto \exp\left(\frac{K^2}{8\gamma^2}\right)\cdot|A(L)j_L(\kappa r_0)|^2 \tag{9}$$

where the exponential term depends upon the internal motion of incident particle and corresponds to the form factor introduced in deuteron stripping. $A(L)$ is a constant and can be determined by fitting the theoretical curve to the experimental results, and r_0 is interaction radius. L is the total orbital angular momentum transfer in final nucleus by nucleons and is defined as follow.

$$\boldsymbol{L}=\boldsymbol{l}_p+\boldsymbol{l}_n \tag{10}$$

Here l_p and l_n are orbital angular momenta of proton and neutron which are captured by target nucleus. Between the spin of initial state I_i and that of final state I_f, the selection rule is required

$$|I_f-I_i|-1\leqq l_p+l_n\leqq I_i+I_f+\frac{1}{2}+\frac{1}{2} \tag{11}$$

and there is a parity change only when L is odd. The momentum transfer vectors K and k are,

$$\left.\begin{aligned}\boldsymbol{K}&=\frac{1}{2}\boldsymbol{K}_\alpha-\boldsymbol{K}_d\\ \boldsymbol{k}&=\boldsymbol{K}_\alpha-\left(\frac{M_f}{M_i}\right)\boldsymbol{K}_d\end{aligned}\right\} \tag{12}$$

The results obtained by Eq. (9) are shown in Figs. 14 and 15. Though more detailed discussion is given in latter section, it may be noted that the curves calculated by Eq. (9) illustrate better agreement than that obtained by Eq. (1) for this reaction. In the following we shall make further detailed discussions on individual targets.

4.1 $O^{16}(d, \alpha)N^{14}$(g'nd.)

The result of angular distribution for the transition to the ground state N^{14} was given by Freemantle[12] et al., at deuteron bombarding energy of 19 MeV, which was nearly symmetric about 90°. Fischer and Fischer[13] showed that the angular distribution observed by Freemantle could be fitted with a curve derived from Eq. (1) with $r_1=4.2f.$ and $l_1=0$. Recently, Browne[7] measured the angular distribution and excitation function of the alpha particle group leading to the ground state of N^{14} with bombarding energy up to 7.5 MeV. The observed angular distribution at 7.03 MeV was not symmetric about 90°, and the excitation function for the group leading to ground state varied rapidly with bombarding energy.

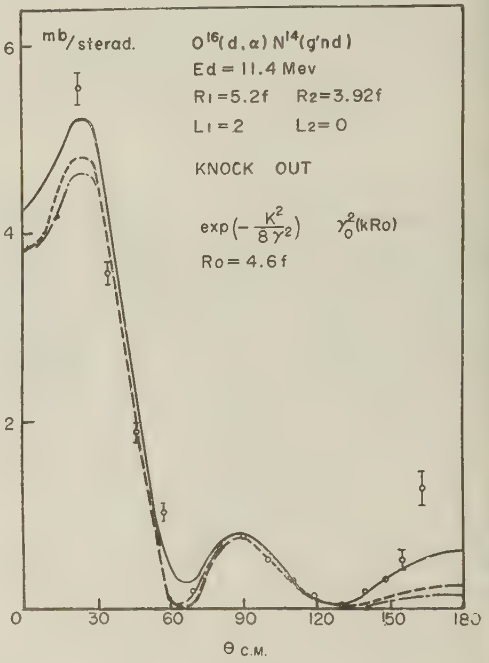

Fig. 13. Differential cross section substracted the isotropic part from the observed data of the $O^{16}(d, \alpha_0)N^{14}$ (g'nd.) reaction. The dotted curve was calculated for knock out process with $r_1=5.2f.$, and $l_1=2$. The solid curve included heavy particle stripping process with $r_1=5.2f.$, $l_1=2$, $r_2=3.92f.$, and $l_2=0$. The dashed curve was calculated for double stripping process with $r_0=4.6f.$ and $L=2$.

More recently Dalton et al.[15] investigated this reaction at 6.8, 7.1, 7.2 and 8.9 MeV, and the observed angular distributions at 6.8 and 8.9 MeV showed a forward peak. Especially the result at 8.9 MeV was essentially similar to the distributions obtained in the present work. Therefore the reaction mechanism governing this transition is explained more easily on the base of direct-interaction process than that of compound nucleus formation. The distributions investigated at various bombarding energies between 10.5 and 11.4 MeV are illustrated in Fig. 7. As shown in Fig. 13 fairly good agreements were obtained between distribution curve obtained at 11.4 MeV and the theoretical curves derived from Eq. (1) with $l_1=2$, $r_1=5.2f.$, and from Eq. (6) with $l_1=2$, $r_1=5.2f.$, $l_2=0$, $r_2=3.92f.$, if the isotropic part is subtracted from the experimental curve. It is recognized that relatively large cross sections in back ward angles suggest the existence of heavy particle stripping process. The yields, however, change too rapidly with bombarding energies to be accounted for by the heavy particle stripping alone. If one ignores the variation of interaction radius deduced from the data and Eq. (6), the main feature of these distributions can be represented theoretically. Moreover, the curve calculated from Eq. (9) with $L=2$, $r_0=4.6f.$, was nearly the same in shape with the curve obtained by Eq. (1), and the contribution from anther L-value, namely, $L=0$, was negligible in the angular distribution at 11.4 MeV.

On the other hand, it is remarkable that the total cross section shown in Fig. 14 obtained by integrating the angular distribution curves shows gradual change with bombarding energy and reaches a maximum at 10.7 MeV, and the shape of the angular distribution at 10.7 MeV is slightly different from others.

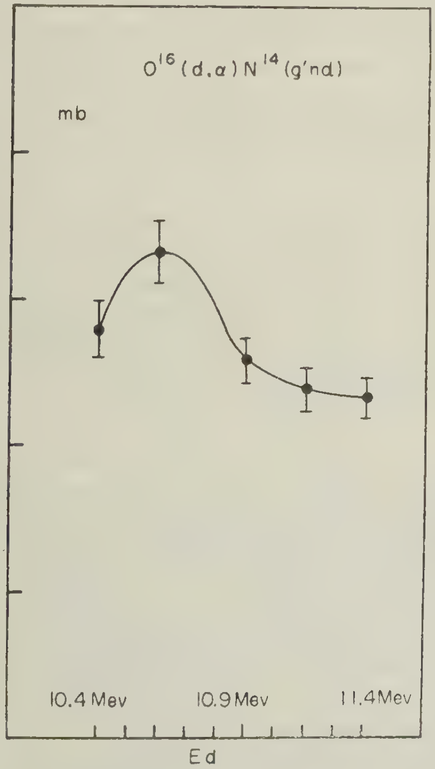

Fig. 14. Energy dependence of the total cross sections for the $O^{16}(d, \alpha_0)N^{14}$ (ground state) reaction.

Accordingly, it is expected that a direct process does play a leading role, and the process of compound nucleus formation undertakes a subsidiary role.

4.2 $O^{16}(d, \alpha_1)N^{14*}$ ($T=1$, 1st.)

The investigations relating to the 2.31 MeV level of N^{14} by (d, α) reaction was reported in detail in references 6 and 7. On the small appearance of these forbidden group, the detailed explanation was given by Browne[7] and by Lane and Thomas[15]. The violation of the isotopic spin selection rule was not observed clearly at 8.9 MeV deuteron bombarding energy, though the yield curve of the 2.31 MeV level indicated the excistence of this forbidden group up to 7.5 MeV bombarding energies. The excitations of compound nucleus with the deuteron bombarding energies of 8.9 MeV and 7.5 MeV are about 15 MeV and 14 MeV. In the latter case, the situation of compound nucleus are expected to exist in the region which is intermediate of those satisfying criteria (5.2) and (5.3) in the paper of Lane and Thomas[15]. The yield of the forbidden group shows resonance-like anomalies at 6.2, 6.7 and 7.2 MeV[7),8]. It is possible to assume that disappearance of this forbidden group at 8.9 MeV is due to the isolated resonances, so that the situation of the states excited with the deuteron bombarding energy of 11 MeV is expected to be similar to the situation excited with 7.5 MeV deuteron. Certainly a minor break-down in the isotopic spin selection rule was observed at 11.4 and 11.3 MeV as illustrated in Figs. 1, 5 and 6. Moreover, the yield of this forbidden group could be observed at 45° in the laboratory system at 11.2, 11.1, 10.7 and 10.6 MeV bombarding energies, with the comparable order to the intensity at 11.3 MeV.

4.3 $N^{14}(d, \alpha_0)C^{12}$(g'nd.) and $N^{14}(d, \alpha_1)C^{12*}$(1st.)

Previous study on the $N^{14}(d, \alpha)C^{12}$ reaction was made by Gibson and Thomas[16] at 8 MeV. Fischer and Fischer[13] measured the angular distributions for this reaction at 21 MeV. These results show the forward peaking and oscillatory behavior. As illustrated in Figs. 8 and 9, the angular distributions investigated at 11.4, 11.1 and 10.9 MeV also show direct interaction feature distinctly.

When one attempts to compare these data

with the theoretical curve calculated by Eq. (1), it is expected qualitatively that the pick-up process would be more probable than knock out process for the $N^{14}(d, \alpha)C^{12}$ reaction in contrast to the $O^{16}(d, \alpha)N^{14}$ reaction. Then the fits to the angular distribution are shown in Figs. 8 and 9, with reasonable interaction radii.

In the case of transition to ground state, considerable energy dependency of the angular distribution in the region greater than 90° may be due to the similar reason as discussed in previous section.

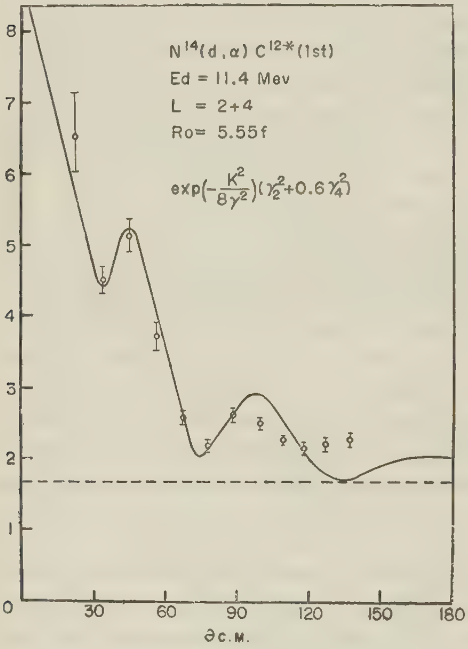

Fig. 15. Theoretical fit to the differential cross section of $N^{14}(d, \alpha_1)C^{12}$ (4.44 MeV state) using Eq. (9) with $L=2+4$ and $r_0=5.5f.$.

The distribution corresponding to the first excited stated deviates considerably in the forward angles from the theoretical ones which are obtained from Eqs. (1) and (6) by using one allowed l_1-value. This marked discrepancy may be reduced by summing up for all allowed l_1-values in Eq. (1). In fact, as illustrated in Fig. 15, the curve calculated by Eq. (8) with $r_0=5.55f.$, $L=2$ and 4, and $[A(4)/A(2)]^2=0.6$, shows a better agreement with the datum at forward angles than the curve derived from Eq. (1) with $r_1=5.4f.$, $l_1=0$, for pick up process.

4.4 $F^{19}(d, \alpha_0)O^{17}$(g'nd.) and $F^{19}(d, \alpha_1)O^{17*}$(1st.)

Measurements of the angular distributions of the alpha-particle group leading to the ground and low-lying state in O^{17} were not reported before this study. However, remarkable theoretical studies were made by several authors[17),18),19)] on the character of the ground and low-lying states. According to their interpretation, these states are described successfully on the bases of the shell[17),18)] and collective models[19)], and F^{19} is treated as a nucleus which has three particles outside the O^{16} core closed shells. Therefore, pick up process is more preferable than knock out process for the $F^{19}(d, \alpha)O^{17}$ reaction.

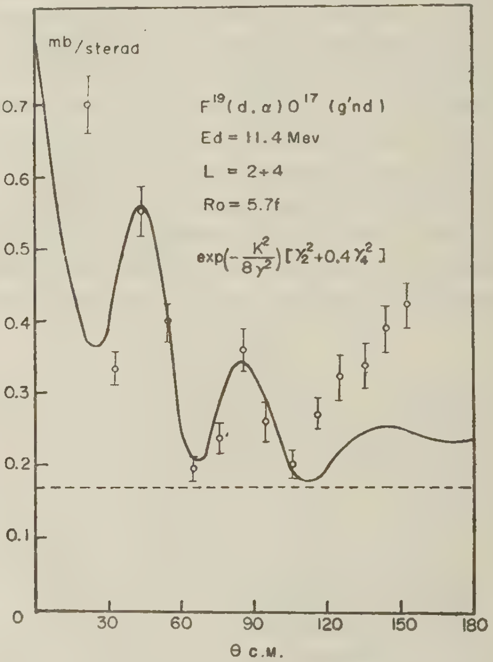

Fig. 16. Theoretical fit to the differential cross section of $F^{19}(d, \alpha_0)O^{17}$ (ground state) using Eq. (9) with $L=2+4$ and $r_0=5.7f.$.

Among the angular distributions of alpha-particle groups leading to the ground and first excited states, our data corresponding to the transition to ground state in O^{17} exhibit good agreement with the curve calculated from Eq. (6) with $r_1=5.2f.$, $l_1=2$, $r_2=4.55f.$, $l_2=1$ in pick up case. A better agreement could be obtained with the curve calculated by Eq. (9) with $r_0=5.5f.$, $L=2$ and 4, and $[A(4)/A(2)]^2=0.33$ as shown in Fig. 16.

Since the observed angular distribution of the $F^{19}(d, \alpha_1)O^{17*}$(1st.) reaction shows that the first maximum is smaller than that of the second maximum, the curves given by Eqs. (6) and

(9) did not show any agreement with the shape of the theoretical curve for any reasonable choice of parameter. The marked disagreement in the neighborhood of the secondary maximum may be caused by either the interference between the direct and compound nuclear process or by the fact that the used differential cross sections rest on gross simplification, so that, the disagreement between datum and curve may not be said to be real one.

4.5 $P^{31}(d, \alpha_0)Si^{29}$(g'nd.) and $P^{31}(d, \alpha_1)Si^{29*}$(1st.)

The ground and low-lying state of P^{31} and Si^{29} had been adequately characterized on the asumption of a strong-coupling collective model by Broude, Green and Willmott[21] and by Bromley[20] et al.. The ground state of P^{31} was interpreted as a base of $K=1/2$ (Nilsson orbit 9)[22] rotational band with negative (oblate) deformation parameter $\delta=-0.15\sim-0.3$. Here K, the quantum number introduced by Bohr and Mottelson[23], is the angular momentum along the nuclear symmetry axis. On the other hand, in the case of Si^{29}, the sequence of states corresponding to the ground, 2.03 and 2.43 MeV levels were explained as a rotational band for $K=1/2$ (Nilsson orbit 9). The state at 1.28 MeV was assigned as a $K=3/2$ (Nilsson orbit 8) rotational spectrum. Moreover, it was demonstrated that Si^{29} has also an oblate shape with negative deformation parameter $\delta=-0.15$.

From these facts, the probability leading to the 1.28 MeV state by the (d, α) reaction is expected to be smaller than the probability corresponding to the transition to the $K=1/2$ rotational states in Si^{29}. In order to excite the 1.28 MeV state via direct-interaction process, the reconstruction must be required not only in core but also for the structure of extra-particles.

Adequate separation in the pulse height spectrum for the alpha-particle group leading to 1.28 MeV state in Si^{29} could not be obtained as illustrated in Fig. 4, but the group corresponding to 2.03 MeV state appeared at all observation angles with intensity comparable to the ground state yield.

In Fig. 12 is shown one of the fits of data for the $P^{31}(d, \alpha_0)Si^{29}$(g'nd.) reaction. The theoretical curve given in the figure for pick up process corresponds to $r_1=5.25f.$, $l_1=0$, $r_2=6.24f.$ and $l_2=2$. The curve for the knock out process with $r_1=5.6f.$, $l_1=0$, $r_2=6.24$ and $l_2=2$ was practically identical with the above one.

Before the discussion is concluded, the author wishes to emphasize that the preceding discussions on the angular distributions are only qualitative, so that further works both experimental and theoretical, are required in order to derive quantitative results. The angular distribution for the (d, α) reaction on light nuclei with intermediate bombarding energy, may, however, be explained qualitatively on the assumption of double pick up process, such as the theory derived by Newns. Such theory will become one of the powerful tools in nuclear spectroscopy in the further investigation for (d, α) reaction.

I would like to express my thanks to Professor T. Wakatsuki and Assistant professor S. Yamabe for their continued encouragement and helpful suggestions, and to Professor Y. Oda for his advice during the early part of this experiment. For useful discussions and cooperations I am indebted much to M. Takeda, S. Kato and the member of the cyclotron group. The valuable discussions on the theory with Dr. M. Sano and T. Kammuri were indispensable. My thanks are also due to Dr. H. C. Newns for communicating the results of his work on the double stripping process.

Emission of ^{8}Li, ^{9}Li and ^{8}B Fragments from Stars Produced by 4.3 Gev π^--Mesons in Nuclear Emulsion

By Kuni IMAEDA*, Mitsuko KAZUNO* and Nobuo ITO**

Department of Physics, Yamanashi University, Kofu, Japan

(Received May 11, 1960)

9.300 stars with more than 5 black prongs were examined to study ^{8}Li, ^{9}Li and ^{8}B fragments emitted from these stars. Thus, we found 90 examples of hammer tracks produced by ^{8}Li or ^{8}B fragments, 11 examples of tracks produced by $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}+e^-\rightarrow{}^4\mathrm{He}+{}^4\mathrm{He}+n+e^-$ and the one by $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}+e^-\rightarrow{}^5\mathrm{He}+{}^4\mathrm{He}+e^-$.

The experimental result of angular distribution, energy distribution, and frequency of emission of these fragments are given. Comparison is made between the experimental result and the prediction of evaporation theory on the frequency of emission of these fragments. The effect of the ^{8}B fragments on the estimation of the Coulomb barrier of the residual nucleus for ^{8}Li fragment is discussed.

§1. Introduction

Hammer track was first reported by Occhialini and Powell[1)] and was established to be due to a ^{8}Li fragment coming out of a nuclear disintegration and decaying at rest into two alpha-particles and an electron by Franzinetti and Payne[2)] and other. A similar event which is due to a ^{9}Li fragment decaying at rest into two alpha-particles, a neutron and an electron was reported by Fry[3)] and several authors[4)]. Similar event should also be due to a ^{8}B fragment, and this was first pointed out by Alvarez[5)] and has shown by Gilbert[6)].

Many investigations were performed on the emission of ^{8}Li fragments and its mechanism of emission. But relatively few experiments have described at the same time the distinction between ^{8}B fragment and ^{8}Li fragment[7)].

The aim of this paper is to investigate the relative freqnencies and characteristics of these ^{8}Li, ^{9}Li and ^{8}B fragments emitted from stars produced by 4.3 GeV π^--mesons.

Investigated decays are:

(1) $^8\mathrm{Li}\rightarrow{}^8\mathrm{Be}^*+e^-\rightarrow{}^4\mathrm{He}+{}^4\mathrm{He}+e^-$,

(2) $^8\mathrm{B}\rightarrow{}^8\mathrm{Be}^*+e^+\rightarrow{}^4\mathrm{He}+{}^4\mathrm{He}+e^-$,

(3) $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}^*+e^-\rightarrow{}^4\mathrm{He}+{}^4\mathrm{He}+n+e^-$,

and

(4) $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}^*+e^-\rightarrow{}^5\mathrm{He}+{}^4\mathrm{He}+e^-$.

§2. Experimental Procedure and Results

A stack of Ilford G5 emulsion pellicles of 3″×4″, 600 μm thickness 36 sheets have exposed to the 4.3 GeV π^--meson beams from Bevatron at Berkeley. After the exposure, the emulsions were processed by amidolbisulphite temperature development method. Area scanning was made under 150 magnification of microscope to pick up double stars, hyperfragments, hammer tracks and ^{9}Li hammer tracks. The events were tentatively classified by visual criteria, into hammer tracks, ^{9}Li hammer tracks, hyperfragments and others. Hammer track includes those produced by ^{8}B fragment.

The definition of the hammer tracks and ^{9}Li hammer tracks are as follows. Two tracks by helium nuclei (^{4}He or ^{5}He) and a track by an electron or a positron associate with the common centre where ^{8}Li or ^{8}B or ^{9}Li fragments stopped. The experimental determination that an apparent hammer track or an apparent ^{9}Li hammer track are those produced by ^{8}Li or ^{8}B fragments or ^{9}Li fragments, respectively, was made by the following criteria.

(A) The criteria for the ^{8}Li and ^{8}B hammer tracks

(a) Two alpha-particles should be emitted in opposit direction and their ranges in emulsion should be equal.

(b) The experimental Q-value of the decay obtained from the sum of the energy of the two alpha-particles should agree with the Q-

---

** Now at Institute of Polytechnics, Osaka City University, Osaka, Japan.

vaule of the decay of an excited ^{8}Be nucleus into two alpha-particles.

(c) An electron track for ^{8}Li or a position track for ^{8}B shuld be associated at the point of decay of the fragment.

All the hammer tracks analysed in this paper satisfy the criteria (a) and (b). And out of 90 hammer tracks 8 events are missing the electron track, and these may be due to the crowded prongs of the parent star or short available path length for electron track in the same emulsion. The distribution of the Q-values of 8 events are in good agreement with those which have an electron track. There remains, however, some possibilities that the tracks are due to hyperfragments, but such a possibility can be neglected, because probability that hyperfragments satisfy the creteria (a) and (b) are extremely small.

In the course of analysis, we found out two examples which satisfy the criteria (a) and (c) but not (b). Their Q-values, assuming the decay (1) are 1.75 MeV and 1.5 MeV, respectively. But there are no levels of the excited ^{8}Be nucleus corresponding to the values. There was doubt about these hammer tracks, because the two tracks are too short to determine exactly that the tracks satisfy the criteria (a) or not.

After the examination, we concluded that the events are due to ^{9}Li fragments. The experimental Q-values are well fit to the decay of excited ^{9}Be nuclei and included in ^{9}Li hammer tracks.

(B) Criteria for ^{9}Li hammer tracks.

(d) An electron track should be associated with the decay for all ^{9}Li hammer tracks. In the case of the decay (3): $^9\text{Li}\rightarrow{}^4\text{He}+{}^4\text{He}+n+e^-$.

(e) Two alpha-particles are in general neither collinear nor equal range.

(f) By assuming that the event is due to the decay scheme (3) and the magnitude of the momentum of the neutron is equal to the sum of that of the two alpha-particles, the experimental Q-value obtained should agree with the Q-value calculated of the decay of an excited ^{9}Be*: $^9\text{Be}^*\rightarrow{}^4\text{He}+{}^4\text{He}+n$.

In the case of the decay (4): $^9\text{Li}\rightarrow{}^5\text{He}+{}^4\text{He}+e^-$.

(g) As expected from the decay of excited ^{9}Be* nucleus into ^{4}He and ^{5}He nuclei, two tracks of the alpha-particles should be collinear and their ranges are such that the momenta of the ^{4}He and ^{5}He particles should be equal in magnitude and opposite in direction.

(h) The experimental Q-value of the decay of an excited ^{9}Be nucleus into a ^{4}He nucleus and a ^{5}He nucleus should agree with the Q-value calculated from the decay scheme (4).

Mean	13.7	9.5	2.7		88	95.2	1.02±0.15	2	11	1
Total				9304						
Total No. of Hammer					97.4				14.5	

All the ^{9}Li hammer tracks used are accompanied by an electron track and could be definitely distinguished from hyperfragments.

The number of the ^{8}Li, ^{8}B and ^{9}Li hammer tracks are shown in Table I.

There may be, however, some ^{9}Li hammer tracks whose electron tracks could not be observed and in this case it was excluded from ^{9}Li fragment. Thus, the corrections were made by assuming the same missing probability of the electron track as in the case of ^{8}Li hammer tracks. Also the correction were made in Table I for the hammer tracks whose prongs do not end in the same emulsion sheet and cannot be picked up as hammer tracks.

In order to distinguish between ^{8}Li and ^{8}B hammer tracks, attempt was made to distinguish ^{8}B hammer tracks from ^{8}Li hammer tracks.

The δ-ray measurement were performed on all the hammer tracks longer than 200 μm and the dip angle of less than 56° in unprocessed emulsion. The experimental number of δ-rays of more than two grains, and of more than three grains are shown in Table II and III.* The number of δ-rays attached to track No. 10 is distinctly different from the others.

The total number N_δ of δ-rays attached to a track of the range R of a particle of the charge Z and the mass M is expressed as follows:

$$N_\delta = M \cdot G(RZ^2/M) \qquad \text{(A)}$$

where $G(\quad)$ is a function which depends only on (RZ^2/M).

The range R_{Li} and R_{B} of the tracks of ^{8}Li and ^{8}B fragments, are such that the tracks contain the same number of δ-rays, then the expression (A) shows that, as the mass is the same, the range is inversely proportional to the square of charge: $R_{\text{Li}}/R_{\text{B}} = (Z_{\text{B}}/Z_{\text{Li}})^2 = (5/3)^2$.

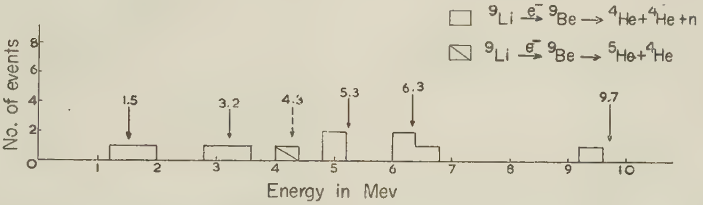

Fig. 1. Q-value obtained of the decay of ^{9}Be (produced by β- decay of ^{9}Li) into ^{4}He+^{4}He+n+Q and ^{4}He+^{5}He+Q.

Assuming that the track No. 10 is due to a ^{8}B fragment, the expected curve for δ-rays obtained of ^{8}Li from those of track No. 10 is shown in Fig. 2.

That the width for ^{8}B fragment is larger than that for ^{8}Li fragment results in under estimate of the number of δ-rays of more than two grains in the track of ^{8}B fragment. Taking into account of the fact, the result agrees with that the track No. 10 is due to a ^{8}B fragment.

For shorter tracks, the profile measurement were made on all the hammer tracks whose dip angles are less than 35° and the length exceeds 60 μm. The tracks were divided into 5 micron cells and for each segment of the track, the mean width was measured under the microscopic magnification 1.500 and summed up those values for each track.

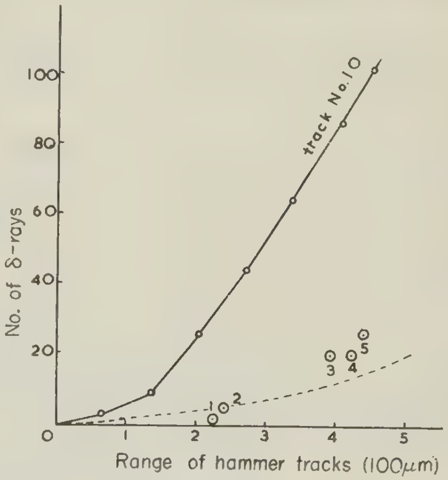

Fig. 2. The number of δ-rays in the tracks of hammer. ---- indicates the number of δ-rays for Li fragments expected from Z^2 law and assuming the track No. 10 is due to a ^{8}B fragment.

---

* (Note by the Editor) These tables are missing here owing to an accident; they will be printed in the Errata reaction of the forthcoming issue.

Thus, we get a measure of area on each track. The values obtained are plotted in Fig. 3. The area is not depend on the dip angle of track of the dip angle less than 35°[9]. The distribution shows that track No. 15 is distinctly different from the other group. The mean values of the group is 0.95±0.08 μm^2. The value for the track No. 15 is 1.246 μm^2 and the value is deviated more than twice the standard deviation.

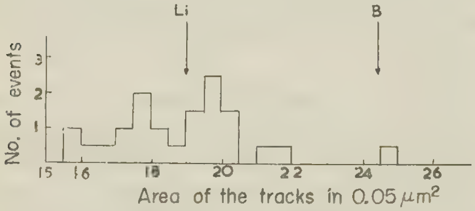

Fig. 3. Profile measurement (area of the tracks of 60 μm track length).

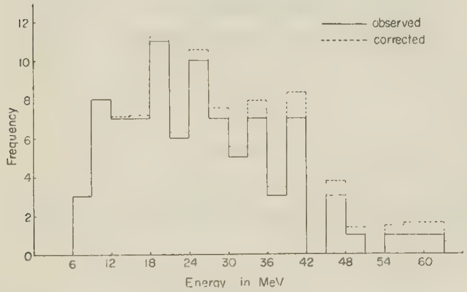

Fig. 4, Energy distribution of ^{8}Li fragments emitted from stars produced by 4.3 GeV π^--mesons in emulsion.

From the mean value of the group of 0.948 μm^2 for ^{8}Li fragment, and applying $z^{1/2}$ law of the track width, we obtain the track width for ^{8}B fragment, 1.22 μm^2 which is in good agreement with the observed value of 1.25 μm^2. Thus, the track No. 15 is concluded to be due to a ^{8}B fragment. Our result also agrees with 1.27 for the ratio of the area of 100 μm tracks of ^{8}B and ^{8}Li fragments which was obtained by O. Skjeggested et al.[7].

The frequency of emission of ^{8}Li, ^{8}B and ^{9}Li fragments in stars of different number of black prongs are given in Table I. The corrections for the hammer tracks which are escaped from emulsion before decaying at rest are made in Appendix (I) and included in Table I.

The energy distribution of 88 ^{8}Li fragments assuming that all the hammer tracks are produced by ^{8}Li fragments and that of 12 ^{9}Li fragments are shown in Fig. 5 and in Fig. 6, respectively. The angular distribution of ^{8}Li fragments and ^{9}Li fragments to the incident π^--meson beam are shown in Fig. 7. The energy distribution of ^{8}Li and ^{9}Li fragments in the backward direction as well as the forward direction with regard to the direction of the incident π^--meson are shown in Fig. 8. The ratio of the number of ^{8}Li fragments emitted in the forward to backward obtained is 1.29±0.26 for all fragments and 2.4±0.9

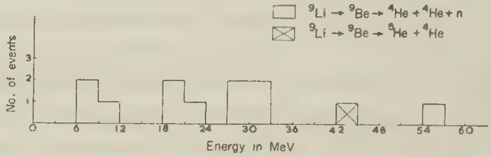

Fig. 5. Energy distribution of ^{9}Li fragments.

for energy greater than 30 MeV.

§ 3. Discussion

Frequency of emission of ^{8}B fragment

Based on the observed ^{8}B fragment, an estimate of the total number of ^{8}B fragments is made. The number of fragment A of the energy between E and $E+dE$ emitted from nucleus of the temperature T at rest is given as follows:

$$\text{(I)}\quad dN_{\rm A}=N_{\rm A}\frac{E_{\rm A}-V_{\rm A}}{T^2}\exp\left(-\frac{E_{\rm A}-V_{\rm A}}{T}\right)dE_{\rm A},$$

where $N_{\rm A}$, $V_{\rm A}$ are the total number, the height of Coulomb potential for fragment A.

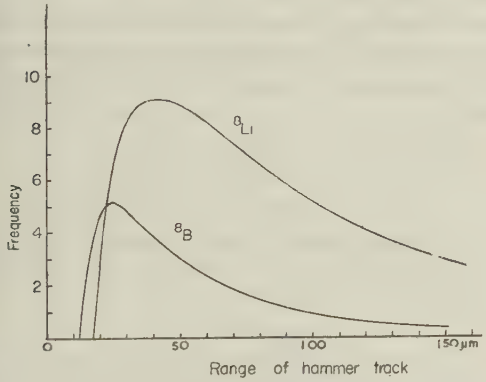

Fig. 8. Range distribution of hammer tracks of the mixture of ^{8}Li fragments and ^{8}B fragments with the ratio of 10:3.

According to (I), when $E_{\rm B}-V_{\rm B}=E_{\rm Li}-V_{\rm Li}$ holds, the ratio of the number of ^{8}B and ^{8}Li fragments of the energy greater than $E_{\rm B}$ and $E_{\rm Li}$, respectively, is equal to the ratio of the total number of ^{8}B and ^{8}Li fragments i.e. $N_{\rm B}/N_{\rm Li}$. Putting for $V_{\rm Li}=7$ MeV and 8 MeV and $E_{\rm B}=40$ MeV (which is the energy of ^{8}B fragment distinguishable from ^{8}Li fragment) and taking into account of the experimental restriction for the identification of ^{8}B fragments, we get $N_{\rm B}/N_{\rm Li}=0.1\sim0.3$. The result is in conformity with that obtained by Skjeggested *et al.* and also the prediction from the evaporation theory which gives the ratio $N_{\rm B}/N_{\rm Li}=1/3.2$ for $T=10.3$ MeV. (Appendix II)

In order to know the contribution of ^{8}B fragment, the range distribution of hammer tracks when the ratio $N_{\rm B}/N_{\rm Li}$ is equal to 0.3, is given in Fig. 9. The best fit curve to the experimental distribution is given by $T=10.3$ MeV and $V_{\rm Li}=8.0$ MeV.

As can be seen from Fig. 8, the low energy cut in the range distribution is determined by that of ^{8}B fragment. The height of Coulomb potential thus obtained from the low energy end of the distribution correspond to that of ^{8}B and not to that of ^{8}Li fragments as ordinarily assumed.

This conclusion is scarcely affected by the motion of the emitting nuclei and the tunnel effect of the evaporating fragments through barrier.

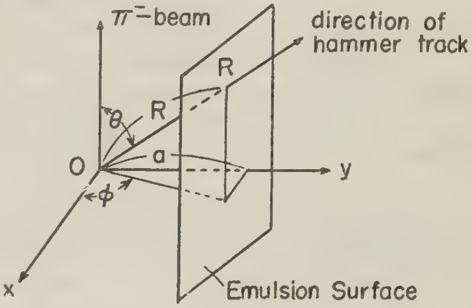

Fig. 9.

The above conclusion, however, depends on the ratio $N_{\rm B}/N_{\rm Li}$ and the number of hammer tracks observed in the experiment. In the case where $N_{\rm B}/N_{\rm Li}=0.1$, and the number of hammer tracks observed is less than 100, which is not incompatible with the present experimental results, the possibility of observation of ^{8}B fragments which range is less than that of the shortest ^{8}Li fragments will be small as the observed number of hammer tracks decrease and the value of the potential thus obtained become more likely to be that of ^{8}Li fragment rather than that of ^{8}B fragment.

The ratio $N_{\rm B}/N_{\rm Li}=0.1\sim0.3$ is also in agreement with that of Skjeggested *et al.* But the experimental result obtained so far is not sufficient to draw any difinite conclusion on the potential barrier, and the further experiment is desirable.

Frequency of emission of ^{9}Li fragment

The frequency r_2 of emission of ^{9}Li fragment relative to that of ^{8}Li fragment is 0.15 ±0.05. The value is much higher than that expected from the one by 950 MeV proton by Munir *et al.* in which a ^{9}Li fragment in 50 ^{8}Li fragments.

One of the reason for this is due to the dependence of the frequency on the temperature of emitting nuclei. But the temperature is not sufficient for the explanation of the difference between the two experiments. But the evaporation theory gives the ratio $N(^9\mathrm{Li})/N(^8\mathrm{Li})=1/17.8$ or $1/10.7$ for the spin of ^{9}Li is 1 or 2, respectively. (Appendix II) The value is in conformity with our experimental value of 0.15.

§ 4. Conclusion

1. 90 examples of hammer tracks observed in which two ^{8}B fragments are identified.

2. 12 examples of ^{9}Li fragment decays are observed. 11 examples of which are the decay of $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}+e^-\rightarrow{}^4\mathrm{He}+{}^4\mathrm{He}+n+e^-$, and an example is the decay of $^9\mathrm{Li}\rightarrow{}^9\mathrm{Be}+e^-\rightarrow{}^5\mathrm{He}+{}^4\mathrm{He}+e^-$.

3. Frequency of emission of ^{8}Li fragment is estimated to be $(0.94\pm0.11)\times10^{-2}$ and that of ^{9}Li fragment is $(0.15\pm0.05)\times10^{-2}$ per star, respectively.

4. Frequency of emission of ^{8}B fragment is estimated to be $(0.1\sim0.3)\times10^{-2}$ per star of heavy nuclei.

5. Frequency of emission of ^{9}Li fragment is in conformity with that of evaporation theory.

6. The height of Coulomb potential determined from the shortest range cut off of the range distribution of hammer track is more likely to be that of V_{B} and not V_{Li}. The value obtained is $V_{\mathrm{Li}}=(3/5)V_{\mathrm{B}}=8$ MeV.

7. $N(\text{forward})/N(\text{backward})=1.30\pm0.26$ for all ^{8}Li fragments, and 2.4 ± 0.9 for ^{8}Li of the energy greater than 30 MeV.

As ^{8}B and ^{9}Li nuclei are isobar and isotope of ^{8}Li nucleus, the study of ^{8}B and ^{9}Li fragments emitted from stars will give another light to the mechanism of emission of those fragments from nuclear disintegration. Care should be paid for the distinction between these hammer tracks, hyperfragments and strange particle when the energy of primary goes up and is sufficient for the production of these particles.

We are very grateful to Professor E. J. Lofgren who arranged the exposure of the stack and to Dr. W. W. Chupp and Dr. T. Kotani who exposed the stack in perfect conditions.

Appendix I. Correction factors for the hammer tracks escaped from emulsion

The coordinate is taken as in Fig. 9.

Then, the fraction of hammer tracks whose residual range is $R\,\mu$m and emitted from stars at a depth of a in a direction of θ to the incident π^--meson, escape from the surface of the emulsion is $(2/\pi)\cos^{-1}(a/R\sin\theta)$.

The fraction of the escaping hammer tracks of the residual range of $R\,\mu$m and emitted in the direction θ from the stars which are uniformly distributed from the depth 0 to $D\,\mu$m is

$$2R\sin\theta/(\pi D)$$

where we have assumed that D is larger than R and no hammer tracks which range exceeds $D\,\mu$m. The energy distribution of the fragments is given by the evaporation theory:

$$dN=\frac{E-V}{T}\exp\left(\frac{E-V}{T}\right)d\left(\frac{E}{T}\right).$$

Then, the fraction of the hammer tracks of all the energy but emitted in a specified angle θ is

$$\text{(II)}\qquad I=\int_{E=V}^{\infty}\left(\frac{2R}{\pi D}\sin\theta\right)dN\Big/\int_{E=V}^{\infty}dN$$

where R and E are given by the range-energy relation:

$$R=kE^{l}\,,\qquad l\simeq3/2\,,$$

where k is a constant.

Integrating (II), we obtain

$$I=\frac{2}{\pi}\left(\frac{R_v}{D}\right)\left(1+\frac{l(l+1)}{(V/T)}+\varepsilon\right)\sin\theta\,,$$

where

$$\varepsilon=\frac{(l+1-(V/T))l(l-1)}{(V/T)^{l}}e^{V/T}\int_{\sqrt{V/T}}^{\infty}x^{l-2}e^{-x}dx\,,$$

and R_v is the range of hammer tracks of the energy corresponds to V of the Coulomb barrier height, ε is small compared with 1.

Summing up for all directions, we get, assuming the isotropic distribution of emission of the fragments from stars,

$$C=\frac{R_v}{2D}\left(1+\frac{l(l+1)}{(V/T)}+\varepsilon\right).$$

Now, putting for $l=3/2$, $V=9.7$ MeV, and $T=10.3$ MeV, we obtain for $C=0.075$ for ^{8}Li and 0.025 for ^{8}B fragment.

The correction for the number of the fragments is given by

$$N_{\mathrm{corr.}}=N_{\mathrm{observed}}/(1-C)\ .$$

Appendix II

According to evaporation theory, the probability N_A per unit time for the emission of a particle A with kinetic energy $E \geqq V_A$ is[7]

$$N_A=kT^2\exp\{(-V_A+b_A+DF)/T\}\ ,$$

where $k=\sigma_0 gm/\pi^2\hbar^3$, σ_0=geometrical cross-section of the residual nucleus, m=mass of the emitted particle, b_A=binding energy of the emitted particle, V_A=height of the Coulomb potential barrier, T=nuclear temperature of the residual nucleus, F=Helmholtz free energy of the residual nucleus of $A(N, Z)$, ΔF the difference between F of the nucleus before and after the emission of that of the nucleus.

F of a heavy nucleus $A(N, Z)$, is given by, based on Fermi-gas model of nucleus,

$$F=A[-\alpha+\beta(\Theta-\Theta_0)^2-0.07(1+1.2\Theta^2)T^2]$$

where $\Theta=(N-Z)/A$ and Θ_0 is the value of Θ for the most stable nucleus of mass A, α =8.5 MeV, β=22.3 MeV, and is well represented by the semi-empirical formula:

$$\Theta_0=\frac{A^{2/3}}{A^{2/3}+132}\ .$$

Taking Br^{80}_{35} as a mean nucleus of the characteristics of the evaporating heavy nucleus in emulsion, we find for V_{Li}=8 MeV,

$$r_1=\frac{N(^8\mathrm{B})}{N(^8\mathrm{Li})}=\exp\left[\frac{1}{T}(-12.8+0.011T^2)\right],$$

$$r_2=\frac{N(^9\mathrm{Li})}{N(^8\mathrm{Li})}=\frac{g_{^9\mathrm{Li}}}{5}\exp\left[\frac{1}{T}(-15.2-0.09T^2)\right],$$

where $g_{^9\mathrm{L}}=3$ or 5, according to the spin of ^{9}Li equal to 1 or 2.

For T=8, 9, 10.3 MeV, we obtain $r_1=1/4.8$, 1/3.9 and 1/3.2 and $r_2=g_{^9\mathrm{Li}}/13.0$, $g_{^9\mathrm{Li}}/11.7$ and $g_{^9\mathrm{Li}}/10.7$, respectively.

X-ray observations on Cleavage Faces of LiF Single Crystals

By Mitsuru YOSHIMATSU
Rigaku Denki Co Ltd., Haijima, Akijima City, Tokyo
and Kazutake KOHRA
Institute of Physics, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo

(Received January 9, 1960)

Cleavage faces of LiF single crystals were studied by the Berg-Barrett method of X-rays. (i) Boundary lines of subgrains with small tilt angle show the intensity enhancement. The intensity enhancement is also seen for boundaries lying closely to the surface. (ii) As to deformations produced by cleaving, more informations such as slip directions are obtained than in etce-pit photographs. (iii) Furthermore, outcrops of individual dislocations arrayed in a boundary line or scattered in the interior of a grain are resolved. Dislocation half-loops lying closely to the surface in a slip line are also observed. In each type of the defects above mentioned the direction of Burgers vector is determined.

§ 1. Introduction

X-ray diffraction microscopy which presents us topographical information about lattice defects in a crystal has been recently developed to such an extent that individual dislocations have been able to be detected[1]. In comparison with light and electron microscopy, X-ray diffraction microscopy has several advantages: specimens do not suffer from any change of state with such a treatment as etching or decoration; they need not be so thin as in electon microscopy; and furthermore the direction of the dislocation Burgers vector can be determined. In X-ray microscopy, three different natures of diffraction are utilized to discriminated distorted region from the perfect one, or to obtain the image contrast; that is, (i) enhancement of integrated intensity or reduction of primary extinction; (ii) displacement of diffraction angle (in order of second) and (iii) decrease or disappearance of anomalous transmission. With the use of (i), Lang[2] established a fine technique to observe clearly dislocation lines in the interior of crystals. With the refined Berg-Barrett mehtod[3] where the nature of (i) is also used, Newkirk[4] observed outcrops of individual dislocations at the surface of Fe-Si single crystal, and furthermore fine structures of plastic deformations and dislocation outcrops at the cleavage face of a slightly compressed LiF single crystal. Bonse and Kappler[5] studied outcrops of dislocations at the surface of a Ge single crystal wifh the double crystal spectrometer using (ii), where the fine structure of the image was compared with the theory. With the use of (iii) Borrmann et al[6] observed dislocation lines in the interior of Si single crystal with a point source of X-rays, while Bardt and Hosemann[7] and Gerold and Meyer[8] observed dislocation lines with a parallel beam arrangement, the latter having also obtained the stereographic pattern. By the same technique one of the author and his coworkers showed that the anomalous transmission phenomenon was useful to detect lattice defects or strain field caused by other sources than the dislocation, that is, the strain field produced by external force in a Ge single crystal[9] and the layer structure probably due to oxygen in a Si single crystal[10], the latter of which had been observed by Dash with the decoration technique and infra-red microscopy[11].

We have observed cleavage faces of LiF single crystals by the refined Berg-Barrett method as Newkirk*. This method needs neither any special micro-focus X-ray tube as the one of Lang, nor any complicated instruments as the one of Bonse or Lang.

The surface of LiF single crystal has been intensively studied especially using the chemical etching technique[13]. As mentioned above, a general study of LiF single crystals by X-ray microscopy has been reported by Newkirk. While Newkirk studied mainly plastic deformations procuced by a slight compression, we studied more details of lattice defects on surfaces as cleaved, such as grain boundaries, plastic deformations produced by cleaving, individual dislocation outcrops found at the subgrain boundary or within the subgrain and dislocation half-loops lying near the surface.

---

* The preliminary report has been given[12].

§ 2. Experiments

a. *Apparatus*

The experimental arangement is shown in Fig. 1. The distance between the specimen and the photographic plate was made as small as possible to obtain the high resolution from the reason described in § 2c. The LiF single crystals were purchased from the Harshaw Chemical Company. The usual sealed-off X-ray tube of Cr target with the focal size 1×10 mm was used and operated at 40 KVP and 10 mA. For the case of high magnification (about 100 times), high resolution spectrographic plates 649-0 of Kodak were used, where the exposure time was several hours.

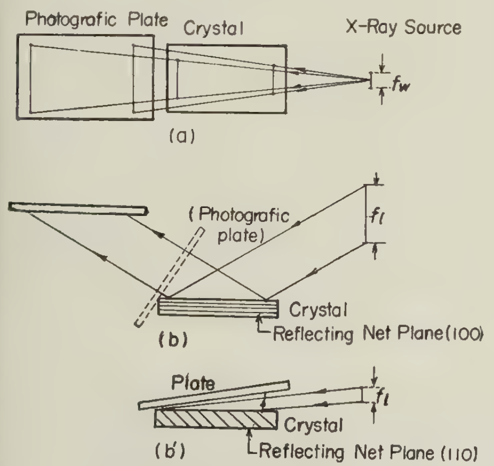

Fig. 1. Experimental arrangement.
(a) Projection on the plane perpendicular to the incident plane.
(b) Projection on the plane parallel to the incident plane. For the (200) reflections, the photographic plate is put at the position indicated with the dotted line.
(b′) Projection is the same as in (b), but for the case of {220} reflections.

In the present experiment, the apparent focal size is $f_w=1$ mm and $fl=1$ mm, the true focal size being 1×10 mm².

In order to obtain the good image contrast, a foil of Be 0.2 mm thick was used instead of black paper for shielding the photographic plate from the light and cleavage surfaces as flat as possible were used.

b. *Direction of Burgers vector and reflecting plane*

For the LiF crystals, the slip planes are {110} and the slip directions or the direction of the Burgers vector are ⟨110⟩ as shown in Fig. 2. It is usually known that the reduction of extinction is the strongest, when the reflecting plane is normal to the direction in which the lattice distortion is the strongest. Accordingly it is expected that the image contrast is the largest when the Burgers vector directs normal to the reflecting plane. For this reason the {220} reflections were mainly utilized as in case of Newkirk. The (200)

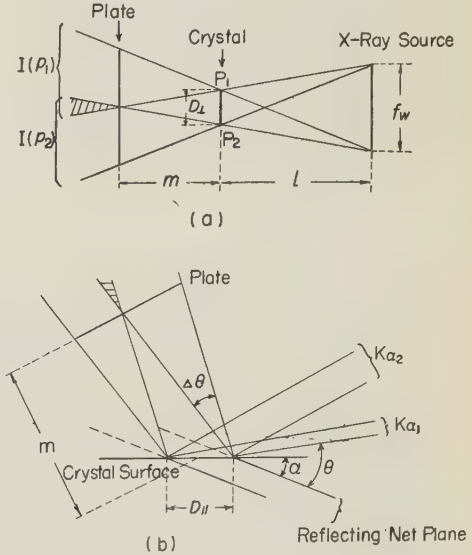

Fig. 3. Schematic diagram showing resolution of the image.
(a) Projection on the plane perpendicular to thd incident plane. In the hatched region, the two images $I(p_1)$ and $I(p_2)$ can not be separated.
(b) Projection on the plane parallel to the incident plane. The difference in the direction of K_{α_1} and K_{α_2} is exaggerated.

$\boldsymbol{D}_\perp$ and $\boldsymbol{D}_{//}$ are the component of the shortest separable distances in the direction perpendicular and parallel to the incident plane respectively.

l and m are the distances from the crystal to X-ray source and to the photographic plate respectively. θ is the Bragg angle, α, the angle between the reflecting plane and the crystal surface, $\Delta\theta$, the angle of dispersion K_{α_1} and K_{α_2}, f_w, the apparent X-ray focal width.

reflection was also sometimes used for comparison. In Table I the angles between the reflecting planes used and various slip directions are given. In the present experiment the {220} reflections have also the advantage that the image is hardly distorted: the magnification in the direction parallel to the incident plane is usually only several per cent larger than in the direction perpendicular to the incident plane.

In the experiment four planes of {220}, that is, $(2\bar{2}0)$, (220), (202) and $(20\bar{2})$, can be practically used as the reflecting plane. The direction (not sign) of the Burgers vector will be determined by knowing the reflection plane giving the strongest contrast. This is, how-

ever, possible only if the Burgers vector direction is [110], $[1\bar{1}0]$, [101] or $[10\bar{1}]$, but not if the direction is [011] or $[01\bar{1}]$. In the latter case, the image contrast is expected to be the same for above four reflections, and it cannot be determined to which direction the Burgers vector is parallel.

c. *Instrumental resolving power*

One of the factors limiting the resolution of the image is the grain size of the photographic plate. We can practically use the special plate, for example, Kodak 649-0, the grain size of which is smaller than 1μ, at the cost of a long exposure.

Another factor determining the resolution is the diffuseness of the image of an isolated defect such as a dislocation outcrop or a dislocation line. This factor is further classified into the one due to the state of defects, and the one due to the experimental arrangement.

The fomer is dependent of the aggregating state of dislocations, the relative direction of the Burgers vector to the reflecting plane and others. The latter is here called the instrumental resolving power, and involves the factors such as the property of the incident beam source, and the relative position of the source, specimen and the photographic plate. The former is an important but complicated problem, and will be mentioned a little in § 5a and § 6, but should be studied in detail in the

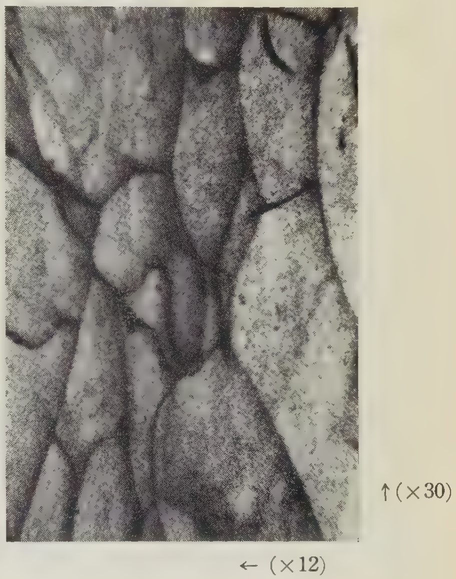

Fig. 5. Subgrain boundaries showing the asymmetric intensity distribution. (200) reflection.

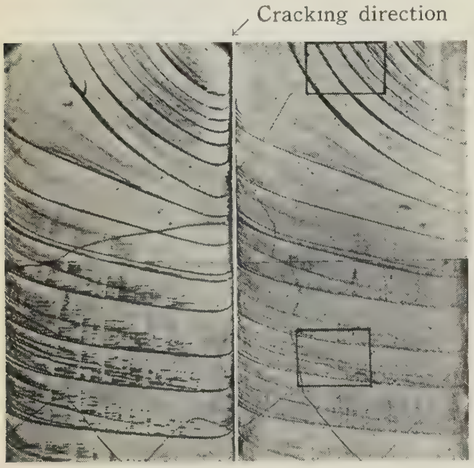
(geometrical divergence, spectral distribution of the wave length), dimension of the X-ray future. Here we consider only the latter.

The instrumental resolving power can be roughly estimated by the following consideration for two components parallel and perpendicular to the indident plane. The schematic diagramm is given in Fig. 3. Here the case that the diffracted rays lie in the incident plane is considered for simplicity. This condition is realized in our experiment. The shortest separable distances of two points lying on the crystal surface are given for two components respectively as follows:

$$D_{//}=\frac{m\Delta\vartheta}{\sin(\vartheta+\alpha)}, \qquad (1)$$



(a) (202) ↓ (b) (220) ← (×8)

and

$$D_\perp = \frac{m}{l+m} \doteqdot \frac{m}{l} f_w . \qquad (2)$$

As seen from (1), $D_{//}$ may be considered to be mainly determined by the divergence of $K\alpha_1$ and $K\alpha_2$, when m is given. It is practically meaningless that $D_\perp$ is far smaller than $D_{//}$. Therefore f_w needs not be very small, and

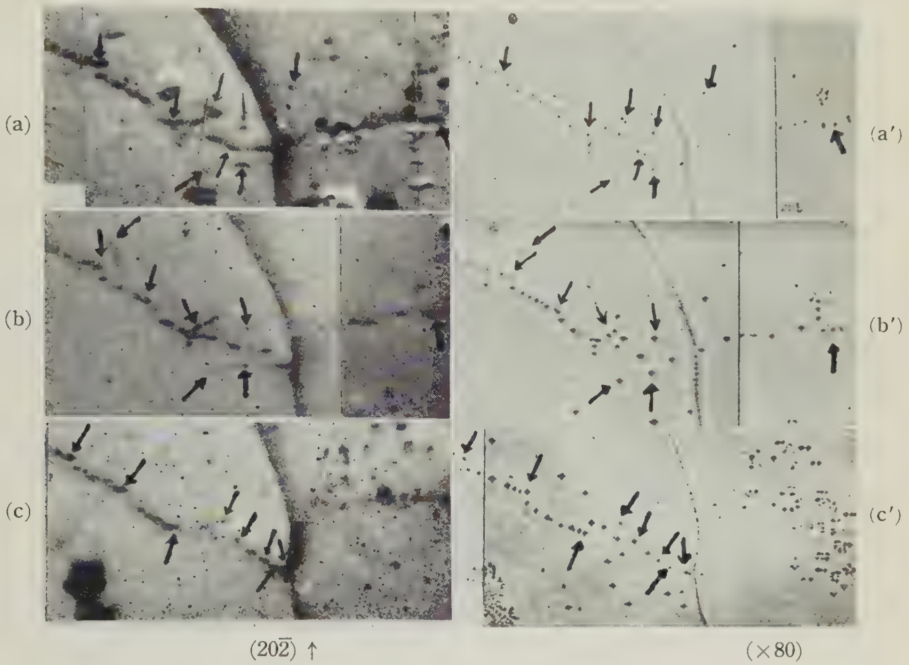

Fig. 11. Charge of X-ray and etch-pit photographs with chemical polishing.
(a) The cleaved face was chemically polished for 10 min., (b), chemically polished further for 5 min. after having been etched to obtain the etch-pit pattern, (c), furthermore chemically polished for 15 min. after (b).

we can use the usual X-ray tube of the focal size 1×10 mm. In the present experiment, the following dimensions were used: $m=0.2\sim1.0$ mm, $l=150$ mm and $f_w=1$ mm. For the {220} reflections we have $\vartheta=53.5°$ and $\alpha=45°$, and for the (200) reflection $\vartheta=34.7°$ and $\alpha=0°$. With $\Delta\vartheta(\mathrm{K}\alpha_1, \mathrm{K}\alpha_2)=2\times10^{-3}$ radians, and $m=0.5$ mm, we have from (1) and (2) $D_{//}=1.0\mu$ and $D_{\perp}=3.3\mu$ for {220}, and $D_{//}=1.8\mu$ and $D_{\perp}=3.3\mu$ for (200). The order of resolutions may be said to be several microns.

§ 3. Subgrain Boundaries

a. *Intensity enhancement at the subgrain boundaries.*

When the crystal is of high quality, the network pattern with the enhanced intensity is observed on the diffraction photograph

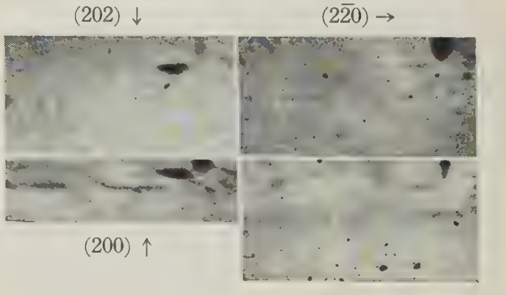

Fig. 15. X-ray photographs of a part (left) of Fig. 14 with different reflections. The chemical stage is the same to the one of Fig. 14 (c).

from the cleavage face. A series of photographs for various net planes from a face are shown in Fig. 4. From the etch-pit photograph the network was confirmed to correspond to the subgrain boundary on which etch pits were arryed, as seen in Fig. 11. As will be mentioned in § 5a, the boundary line could be also resolved in individual dislocations even in the diffraction photograph, if the dislocation density is sufficiently low. The intensity enhancement at the boundary is attributed to the reduction of the extinction effect due to the strain field around the dislocation array.

It is known[14] that if the dislocation density at the boundary is sufficiently high and accordingly the tilt angle is sufficiently large, the intensity enhancement as mentioned above is not seen at the boundary, but the intensity anomaly of another type appears. The images of grains shift against each other, being separated from or overlapped each other according to the sense of the tilt agnle. In the former case the region of zero intensity appears, while in the latter case the intensity enhancement is seen as the result of overlapping, but the enhancement is not so remarkable and the region is usually not so narrow as in case of the small tilt-angle boundary. As the case of the large tilt-angle boundary has been studied by many investigators, it will not be considered in the present paper.

b. *Change in the intensity contrast with the reflecting planes.*

As seen in Fig. 4, the intensity contrast of the boundary is remarkably changed with the different reflecting planes.

Most boundaries have the strongest intensity for one reflecting plane, for example, the lines 1 and 10 for the (202) reflection, 5 and 9 for $(20\bar{2})$, 3, 6 and 8 for (220) and 7 for $(2\bar{2}0)$. From the reason mentioned in § 2b. it can be concluded that the Burgers vectors of dislocations for these lines are normal to the reflecting planes giving the strongest contrast, respectively. On the other hand, some boundaries, for example, 1′ and 4, do not show any remarkable intensity change with different planes. In this case the Burgers vector of dislocation is considered to be normal to eithe (011) or $(01\bar{1})$ plane, neither of which can be used as the reflecting plane in the experiment.

Some lines have almost equal intensity for two reflections, for example, the line 2 for the (220) and $(2\bar{2}0)$ reflections. This facts cannot be explained by the consideration in § 2b. Some other factors, such as the coexistence of dislocations with different Burgers vector directions, the difference of the strain field between an isolated dislocation and a dislocation assembly or a boundary wall, seem to be considered. Some considerations in relation to these problem will be given in § 5 and § 6.

c. *Intensity enhancement in the whole region of subgrain and asymmetric intensity distribution of the boundary line*

It is to be noted that some small subgrains show the intensity enhancement in the whole region: for example, grains indicated with I, II, III and IV in Fig. 4(e) show the intensity enhancment in Fig. 4(f), which was taken from the matched face of the piece making the pair with the one of Fig. 4(a)∼(d).

It is also noticed that some boundary lines show the asymmetric intensity distribution in the direction normal to the line, being diffuse at one side, while sharp at another side. This tendency is more clearly seen in another photograph, Fig. 5.

To explain these phenomena the following experiment was carried out. After the cleavage face, from which Fig. 4f was taken, was chemically polished with the NH_4OH (2% in volume) solution following Gilman[15], the X-ray photograph was taken again. This procedure was twice repeated. The thicknesses of layers removed at both polishings are estimated to be about 12 and 5μ respectively. Corresponding patterns are given in Fig. 6. The change of the pattern is especially remarkable for the small grains having the intensity enhancement as above mentioned: Grains II and IV have disappeared already with one time polishing, and grains I and III become smaller. From this fact it can be concluded that the boundary walls of these subgrains found themselves so closely to the surface (at the deepness of ten μ in order) that X-rays reflected at the boundary walls are less absorbed in the path, resulting in the intensity enhancment for the whole subgrain.

The asymmetric intensity distribution of the boundary line is also explained in the similar way: the boundary wall lies much inclined to the surface, and accordingly lies very closely to the surface.

§ 4. Plastic Deformations produced by Cleaving

Besides the network pattern of subgrain bondary, another type of patterns as shown in Fig. 7 was sometimes observed, which seems, at first sight, to be consisted of parallel streaks (horizontal and vertical) and curved lines. As a general tendency the pattern of this kind appeared more clearly when the cracking speed was lower. Similar patterns were taken and studied by Gilman[15] with the etch-pit technique, and the X-ray diffraction photograph of the pattern was also taken by Newkirk.[15]* We examined the pattern of the X-ray photograph in more detail and especially tried to obtain some complementary informations to those from the etch-pit photograph.

The appearance of the streak pattern is changed noticeably with different reflecting planes, that is, only horizontal parallel streaks are seen for (202) or $(20\bar{2})$ reflection, while only vertical ones for (220) or $(2\bar{2}0)$. It can be concluded that the plastic deformations produced by cleaving are consisted of four kinds of slip: the [101] direction in the $(10\bar{1})$ plane and $[\bar{1}01]$ in (101) for the horizontal streaks, and [110] in $(1\bar{1}0)$ and $[1\bar{1}0]$ in (110) for the vertical streaks.

As another feature, a group of curved lines like the wave front is observed. Both kinds of horizontal and vertical streaks above mentioned are broken at the curved line. According to Gilman, when the propagation speed of cracking is slowed down or stopped, many dislocations are generated. The curved lines correspond to the crack fronts at various instants. For comparison, the enlarged photographs of two regions in Fig. 7(b) and the corresponding etch-pit photographs are given in Fig. 8.

The etch pit photographs was taken after the cleaved surface was etched, in order to obtain the clear pattern of etch pits. Therefore the exact comparison can not be made, but some essential differences of both patterns are clearly seen. Needless to say, at first, the information as to the Burgers vector direction is obtained only from the diffraction photograph. Secondly, in the diffraction photograph the spotty images of the dislocation outcrops can be hardly observed, but the streaks are only observed. These facts suggest that a streak corresponds to one or a few dislocation lines, which lie very closely to the surface. A similar case will be mentioned in § 5(c). The concept that the defects responsible for the streaks are very shallow is also supported by the experimental fact that the streaks disappears with a slight chemical etching or with the heat-treatment such as at 400°C for 20 min., as seen in Fig. 9.

§ 5. Dislocation Outcrops and Dislocation Half-Loops

In the diffraction photograph from the LiF single crystal, outcrops of individual dislocations are usually difficult to be observed, because the dislocation density is generally not so low as in case of Ge and Si. In the present experiment, however, individual dislocation outcrops, arrayed in the subgrain boundary or scattered in the interior of the subgrain, could be resolved. Furthermore, the image of dislocation half-loops was also confirmed.

In Fig. 10 a general view of the diffraction photograph of a specimen is given, three regions of which were enlarged to study various types of dislocations.

a. *Dislocations in the subgrain boundary*

In Fig. 11 the diffraction as well as etch-pit photographs of the region I of Fig. 10 are given, where the change of the pattern with successive chemical polishing is also shown. The chemical polishing was carried out as follows. At first the cleaved face was chemically polished in the same way as in § 3c to obtain the photographs of good contrast by removing the distorted layer produced on cleaving. Then the X-ray photograph (Fig. 11(a)) was taken. Next, the surface was slightly etched by Gilman's method, to obtain the etch-pit photograph (Fig. 11(a′)). Repeating this procedure, a series of photographs were obtained. The times of chemical polishing were 10, 5 and 15 minutes, respectively, which means that the layers about 8, 4 and 12μ respectively were removed at each polishing. The thickness of the layer taken away with the etching before obtaining the etch-pit photograph is considered to be negligible, because the time of etching was a few minutes.

---

* Furthermore it is seen in Fig. 7(a) that horizontal streaks are broken at some white lines running about vertically. The latter lines are likely to be the cleavage step.

As seen in the diffraction photographs, Fig. 11 (a), (b) and (c), the boundary running nearly horizontally is consisted of the array of points. One point corresponds sometimes to one etch pit and sometimes to an assembly of a few etch pits. The dimension of one point image, several microns, seems to limit the resolution. It is a little larger than the instrumental resolving power discussed in § 2c. This is probably because the resolution of the image becomes poorer by the effect of lattice distortion as mentioned in § 2c.

The distribution of dislocations near the cross-point of the boundaries is changed remarkably with etching in both diffraction and etch-pit photographs. The horizontal boundary line which is seen as one line in Fig. 11a, is divided into two boundaries in Fig. 11(c)*.

The image contrast of the dislocation outcrops in the diffraction photographs is varied sensitively with the reflecting plane, as shown in Fig. 12. These photographs were taken at the same stage of chemical polishing to the one of Fig. 11(c′). Among the series of the {220} reflection photographs, Fig. 11(c) and Fig. 12, the intensity contrast of the point image is the strongest for the $(20\bar{2})$ reflection**. From the consideration in § 2b, it can be said that the Burgers vector direction of the dislocation is $[10\bar{1}]$.

b. *Scattered dislocations in the interior of subgrains*

Outcrops of dislocations scattered in the interior of subgrains are usually difficult to be observed in the diffraction photograph. But with a careful treatment, they could be also observed as shown in Fig. 13, where the etch-pit photograph is also given for comparison. In both photographs, which were taken from the region II of Fig. 10, one-to-one correspondence could be established for many points.

The intensity contrast of these scattered isolated dislocations is generally far weaker than one of the dislocations arrayed in the subgrain boundary. This fact might be probably attributed to the following circumstances. According to the dislocation theory, the strain field around a single dislocation decreases more gradually than the one around the dislocation row or the boundary wall, and accordingly the strain gradient in the former is smaller than in the latter. On the other hand, it is usually known that the extinction effect is weaker or the intensity contrast is stronger when the strain gradient is larger.

c. *Dislocation array and half-loops*

In Fig. 14 the diffraction photographs from the region III of Fig. 10, are given together with the etce-pit photographs. The series of photographs were taken at the same stages of chemical polishing to these of Fig. 11.

The difference in appearance between the diffraction and etch-pit photographs is remarkable. while etch pits are observed to be arrayed nearly on a line in the etch-pit photograph, many streaks and a few points are observed in the diffraction photograph. The both ends of the streak were proved in most cases to correspond to etch pits.

It may be concluded that the streaks in the diffraction photograph is the image of the half-loop of the dislocation: the half-loop lies so closely to the surface that not only the dislocation outcrops but also dislocation loops themselves are observed. The appearance of the pattern in the diffraction as well as etch-pit photograph is changed remarkably with a slight etching of the order of ten microns.

For the left region of Fig. 14 the diffraction photographs were taken with (200) and various reflections {220} other than $(20\bar{2})$, as shown in Fig. 15, where the stage of chemical polishing corresponds to the one of Fig. 14(c). The intensity contrast is very weak for all reflections {220} in Fig. 15. Therefore it can be concluded that the Burgers vector direction of the dislocation loop is $[10\bar{1}]$. The slip plane is also considered to be parallel to (101). It is to be noted that the streaks or the etch pits are not arrayed exactly on a straight line, suggesting that the slip does not occur exactly in one plane.

§ 6. Conclusions and Discussions

The Berg-Barrett method of X-ray diffraction microscopy proved useful to study the defects on the surface or lying closely under the surface of single crystals. In favourable cases, individual dislocations could be resolved (§ 5).

---

* In Fig. 11(c′) it seems that other imperfections appear and mask the boundary.

** It is to be noted that the intensity contrast is not completely zero for other reflection than $(20\bar{2})$, being pretty strong for (202) and weak but still obserbable for $(2\bar{2}0)$ and (220).

As an advantage common to the X-ray diffraction microscopy, the specimen can be observed without disturbing the state of the specimen, being different from light microscopic observation by the use of etching or decoration. Accordingly the Berg-Barrett method is useful to study the surface phenomena, which might disappear by a slight etching or the heat-treatment necessary for decoration. Furthermore the X-ray diffraction microscopy is generally suitable for the study of structural changes of lattice defects. As an example, the polygonization process of bent crystals of LiF is being studied by us and will be reported in the near future.

Another advantage common to the X-ray diffraction microscopy, that the intensity contrast of the image is dependent of the relative direction of the strain gradient to the reflecting plane, was utilized to the fullness in the present study. In many cases, the Burgers vector direction of dislocation could be determined (§ 3b, § 4, § 5a and b).

For some cases (§ 3b), however, the change in intensity contrast of the boundaries could not be explained by the simple consideration mentioned in § 2. The dimension of the image is also a problem to be studied in the future, in relation to the resolution of the image (§ 2c). Theoretical considerations are necessary, taking account of factors such as the modified strain field arround the dislocation array, not a single dislocation, and the relative directions of the Burgers vector as well as the dislocation line to the reflecting plane.

The authors should like to express their sincere thankfulness to Profs. E. Fukushima, A. Ookawa and M. Sakamoto for their helpful discussions, and to Mr. Y. Shimura, president of Rigaku Denki Co. Ltd., for his interests and encouragements, and also to Mr. Y. Sugiyama for his technical assistance.

Study on the Ordered Phases with Long Period in the Gold-Zinc Alloy System

I. Survey of Crystal Structures and Calorimetric Measurement

By Hiroshi IWASAKI, Makoto HIRABAYASHI, Kunio FUJIWARA[†]
Denjiro WATANABE and Shiro OGAWA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received June 2 1960)

The crystal structures of the ordered phases in the Au-Zn alloy system have been studied in detail by means of X-ray and electron diffraction on single crystal samples, and the order-disorder and other kinds of phase transitions involved in the present system have also been studied by the measurement of specific heat.

The previously proposed structures of $Au_{3+}Zn$, Au_3Zn[H], Au_3Zn[R] have substantially been confirmed and that of Au_5Zn_3 only partly. Moreover, the details in these structures have been revealed: in $Au_{3+}Zn$ some type of the strong lattice modulation is present, and in Au_3Zn[R] the two types of structure, $Au_3Zn[R_1]$ and $Au_3Zn[R_2]$, certainly exist. The transition behavior of the alloys with changing temperature has been investigated on samples of various compositions and the thermodynamic data obtained are presented. The phase diagram of the Au-rich side of the present system is reasonably corrected by the present experiment. The orientation distribution of the ordered crystals formed in the originally disordered crystal and the nature of the transition, $Au_3Zn[H] \rightarrow Au_3Zn[R]$, are briefly discussed.

§ 1. Introduction

The formation of the ordered phases with long period in the gold-rich solid solution of the gold-zinc alloy system was first reported by Schubert and his collaborators in 1954[1]. The structures of these ordered phases are characterized by the presence of "anti-phase domains" with definite size, *i.e.* the long range order in the usual sense extends not over the whole crystal volume but only over small domains, and these domains are regularly arranged with a definite phase-shift relation to one another. Examples are found in CuAu II, Cu_3Pd, Ag_3Mg, Au_3Mn etc. Extensive studies by Schubert *et al.* on the gold-zinc alloy system[2),3),4)] by the X-ray powder method made clear the following facts: There are three kinds of the ordered phases with long period, a) $Au_{3+}Zn$*($=Au_4Zn$), b) Au_3Zn[H] and its room temperature modification Au_3Zn[R] and c) Au_5Zn_3. Frequency of the occurrence of anti-phase shift (or out-of-step) in terms of a fundamental face-centered cell**, *i.e.* "*Verwerfungsdichte*", shows a simple dependence on the valence electron concentration of alloys, the dependence being regarded as the characteristic nature of the ordered phases with long period. Recently, one of the present authors (H.I.) proposed[5)] that the phase Au_3Zn[R] is divided furthermore into two types of structure $Au_3Zn[R_1]$ and $Au_3Zn[R_2]$.

Some physical properties, such as electrical resistivity[6),7)], elastic moduli[7)] and thermal dilatation[8)], were measured by several workers on the gold-zinc alloys with various compositions in a wide temperature range, and, in particular, a detailed study using several experimental techniques was performed on Au_3Zn[9)]. These experiments contributed much to our understanding of the nature of the ordered phases and the phase transitions of them.

[†] Now at the Institute for Soild State Physics, Tokyo University, Tokyo.

* The convenient notation $Au_{3+}Zn$ was used by Wilkens and Schubert[3)], because this ordered phase stably exists in the composition range deviating appreciably from the ideal composition Au_3Zn towards Au-rich side, but the fundamental atomic arrangement of this phase is still based on A_3B-type ordered structure. The present authors followed their notation.

** For the meaning of this term, refer to our previously published papers, for example, (12).

However, in view of the complicated character of these ordered phases, a more detailed study on the crystal structures of them with single crystals, on their stable region in the phase diagram and, especially, on their thermodynamic properties seemed to be desirable. We therefore studied the crystal structures by electron diffraction on evaporated single-crystal-like films, and by X-ray diffraction on bulk single crystals. The order-disorder and other kinds of phase transitions involved in the present system were also studied by the measurement of specific heat, from which the changes in configurational energy and entropy were deduced and, at the same time, the type of the transitions could be concluded. In the present paper, the experimental results on the specimens with the composition range from about 15 to 45% Zn* are reported. The details of structure analysis on the ordered phases will be reported in the subsequent paper.

§ 2. Proposed Models for the Structures of the Ordered Phases

From the analysis of powder diffraction patterns of the alloys, Schubert *et al.* proposed the structure models for the three ordered phases in the gold-zinc alloy system, as are shown in the following figures. First, in Fig. 1 the structure of $Au_{3+}Zn$ is shown, which is a two-dimensional anti-phase domain structure ($L1_2VwVw^{\alpha}$) of the Cu_3Pd_{1+} type with an orthorhombic fundamental cell. There occur the anti-phase shifts (or, out-of-steps) simultaneously along two directions in the same region. Au_3Zn[H] is a simple, one-dimensional anti-phase domain structure ($L1_2Vw$) of the Ag_3Mg type with a tetragonal fundamental cell, as is shown in Fig. 2. In this structure, the shift occurs only along one direction. The structure of Au_3Zn[R] is somewhat complicated. The dimensions of its large orthorhombic unit cell are: a and $b \sim \sqrt{2}a_f$ and $c=4c_f$, where a_f and c_f are the axes of the fundamental cell. The atomic arrangement of Au_3Zn[R] is obtained from that of Au_3Zn[H] by shifting many of atoms at the face-centered positions in the latter structure. However, as mentioned before, according to one of the present authors (H.I.)[5] Au_3Zn[R] is divided into the two types of structure, $Au_3Zn[R_1]$ and $Au_3Zn[R_2]$. The latter corresponds to the structure proposed by Schubert *et al.*, while the former has an tetragonal symmetry with the a-axis nearly equal to the a-axis of, and with the c-axis twice the c-axis of the latter. Furthermore, $Au_3Zn[R_1]$ was shown to be an anti-phase structure of $Au_3Zn[R_2]$ with the period of out-of-step, measured in atomic distance, M, being unity. Both the structures are shown in Fig. 3. Au_5Zn_3 has a more complicated structure. According to Schubert *et al.*, the dimensions

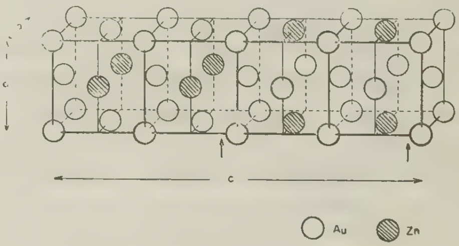

Fig. 2. Model of the one-dimensional anti-phase domain structure, Au_3Zn[H], with $M_3=2$. Out-of-steps occur at places indicated by arrows.

---

* In the present paper, all percentages refer to atomic per cent.

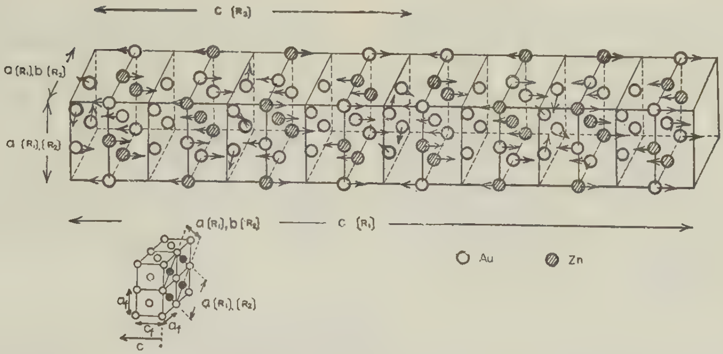

Fig. 3. Model of the ordered structures, Au_3Zn [R_1] and Au_3Zn[R_2]. The two *a*-axes of [R_1] coincide nearly with the *a*- and *b*-axes of [R_2], and the *c*-axis of [R_1] is twice that of [R_2]. Arrows show the directions of atom shift. Geometric relation between the axes of the large unit cell and of the fundamental cell is shown.

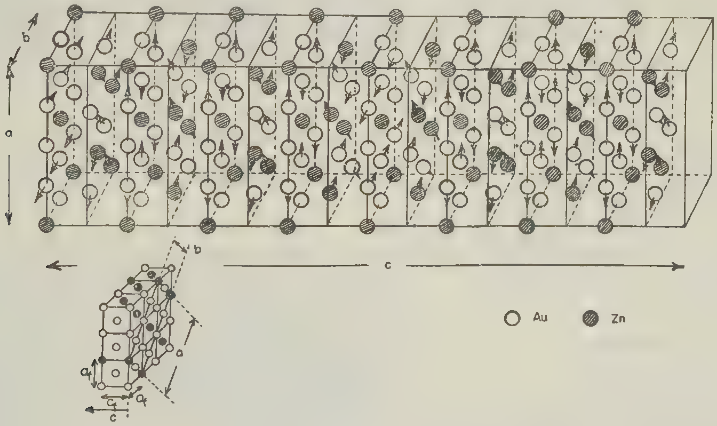

Fig. 4. Model of the ordered structure, Au_5Zn_3. Arrows show the directions of atom shift. Geometric relation between the axes of the large unit cell and of the fundamental cell is shown.

of the large orthorhombic unit cell are: $a=2\sqrt{2}a_f$, $b=\sqrt{2}a_f$ and $c=8c_f$, and, again, atoms in this structure are located at the slightly shifted positions from the face-centered positions, as indicated by arrows in Fig. 4.

§ 3. Experimental Procedures

Alloys were prepared from pure gold (99.99%) and electrolytic zinc (99.95%). In order to avoid oxidation and evaporation loss of zinc, melting and heat treatment of the alloys were always carried out in argon gas atmosphere.

a. Electron diffraction study

Single-crystal-like films for electron diffraction were prepared in the following way: First, well orientated thin gold films were obtained by evaporating gold on cleavage faces of rocksalt kept at high temperatures. Next, different amounts of zinc were evaporated on the gold films at room-temperature, and finally, they were annealed to allow alloy formation. The ordering treatments of the films were carried out at 120°C for a long time. The determination of the composition of films by the measurement of the lattice constant in the region of the *α*-solid solution (disordered state) was not carried out, because the heating of these films up to the disordered state might lead to evaporation loss of zinc.

b. Specific heat and X-ray diffraction study

Gold and zinc were melted together in carbon crucibles and rapidly poured into iron moulds. Each specimen was subjected to preliminary homogenization at temperatures immediately below the solidus for several hours. The composition was determined by chemical analysis.

Specific heat was measured by an adiabatic calorimeter of Nagasaki-Takagi type[10], changing temperature at the rate of about 2 degrees per minute. Specimens employed were cylinders of about 10 mm in diameter and 15 mm in length. To avoid a disturbance due to the heat of oxidation and evaporation of zinc, the vessel of the calorimeter was filled with argon. Before each measurement, the specimen was subjected to an ordering treatment for three or four weeks.

Single crystals were small rod of about 0.2 mm in diameter and 10 mm in length, grown in a thin ceramic tube by the Tammann-Bridgman method. Their composition was examined, when the quenching was effective, by measuring the lattice constant in the disordered state, and utilizing the known relation between the alloy composition and the lattice constant given by Owen and O'Donnell Roberts[11]. Oscillation photographs were taken with cylindrical cameras of 8 cm and 7 cm in diameter by rotating the samples around either a ⟨100⟩ or a ⟨110⟩ direction of the originally disordered cubic cell. Throughout the present work only filtered Cu radiation (wave length=1.5374 kx) was used.

§ 4. Experimental Results

a. Electron Diffraction Study

Seven single-crystal-like films with different compositions were employed, all of which had previously been subjected to the ordering treatment. In Photos. 1, 2, and 3 are reproduced a series of diffraction patterns taken from these films. Zinc composition gradually increases from Photos. 1 to 3. One can recognize gradual changes of the patterns in a rather complicated way. It should be noted that each pattern represents the intensity distribution on a {100} plane section of the reciprocal lattice of the originally disordered cubic cell, though there takes place a slight distortion, and also that the crystallographic axes of the fundamental cell of the ordered phase, which are no longer equivalent to each other on account of the lowered symmetry on ordering, are distributed along the three axes of the original cubic cell. In interpreting the patterns caution was furthermore taken on the possibility that the intensity distribution not lying on the {100} plane of the reciprocal lattice might appear in the pattern owing to bending or twisting of the films.

Adopting the proposed structures shown in § 2, it is able to calculate the intensity distribution in the reciprocal lattice for the ordered phases. In Figs. 5, 6 and 7 are shown the intensity distributions on a {100} plane section calculated by assuming three or sixfold superpositions of possible orientations of the ordered crystal. All the indices are asigned in terms of the original cubic cell.

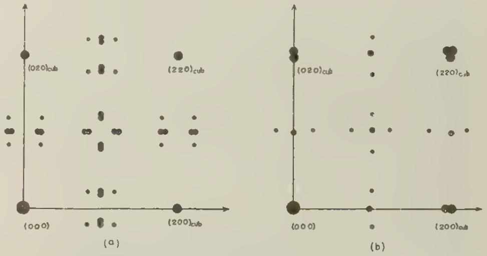

Fig. 5 (a) and (b). Six- and threefold superpositions of the intensity distribution on a {100} plane section of the reciprocal lattice of $Au_{3+}Zn$, (a), and Au_3Zn[H], (b), respectively.

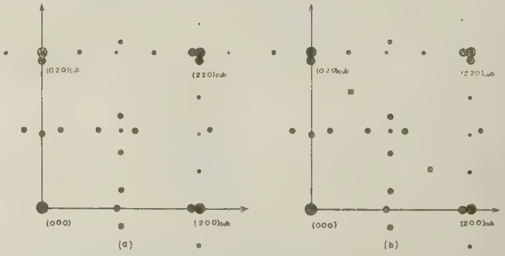

Fig. 6 (a) and (b). Three- and sixfold superpositions of the intensity distribution on a {100} plane section of the reciprocal lattice of Au_3Zn [R_1], (a), and Au_3Zn[R_2], (b), respectively.

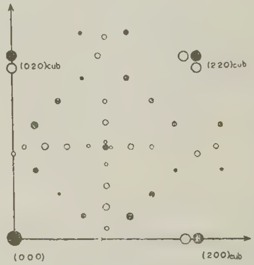

Fig. 7. Sixfold superposition of the intensity distribution on a {100} plane section of the reciprocal lattice of Au_5Zn_3.

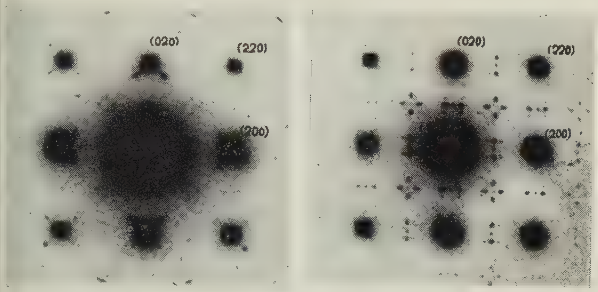
The characteristic splitting of the superlattice spots in Photo. 1 (a) can be accounted for by the intensity distribution of $Au_{3+}Zn$ shown in Fig. 5 (a). In Photo. 1 (b), the pattern of $Au_{3+}Zn$ is more clearly observed, though in the same photograph the faint pattern of $Au_3Zn[H]$ is superposed. Photo. 2 (a) shows a diffraction pattern very similar to that of the one-dimensional anti-phase domain structure of Ag_3Mg[12], indicating the fact that only the phase $Au_3Zn[H]$ (Fig. 5 (b)) is present. Photo. 2 (b) can be interpreted as a mixed diffraction pattern of the two phases, namely, $Au_3Zn[H]$ in larger and $Au_3Zn[R_1]$ in less amount. It is noticed in Photos. 3 (a) and (b) that the distribution of the *c*-axis of the ordered phase Au_5Zn_3 is unequal along the three directions, showing the preferential orientation of the *c*-axis in the direction of the film normal. This fact is in contrast to the case of the other ordered phases of the present system. The intensity distribution from an Au_5Zn_3 crystal with such a preferential orientation is shown by solid circles in Fig. 7, and diffraction spots due to the crystals with their *c*-axis lying in the film surface are shown by open circles. Taking the above fact into account, the diffraction patterns in Photos. 3 (a) and (b) are explained as the mixing of $Au_3Zn[R_2]$ and Au_5Zn_3.

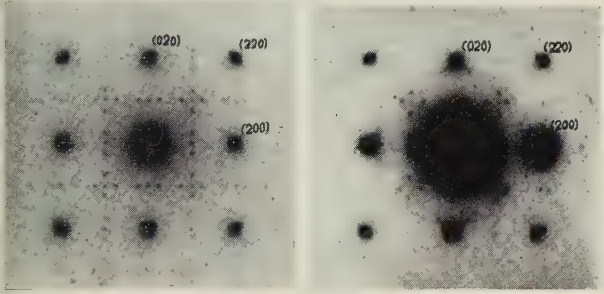
Similarly as in other ordered alloys with long period, such as CuAu II[13], Cu_3Pd[14], Au_3 Mn[15] etc., satellites flanking the direct spot can be observed in all the present diffraction patterns, though weak in their intensity. In the X-ray diffraction pattern, however, the satellite spots could hardly be detected around the direct spot.

The structure data obtained by electron diffraction are summarized in Table I.



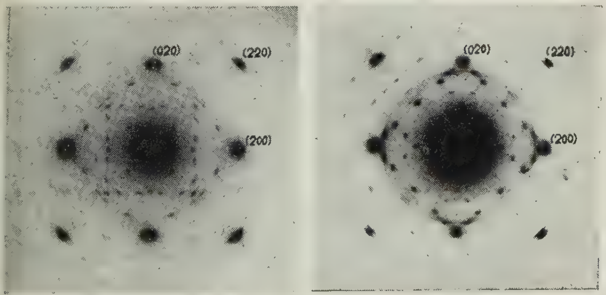
(a)　(b)

Photo. 1. Electron diffraction patterns of (a) $Au_{3+}Zn$ and (b) $Au_{3+}Zn+Au_3Zn[H]$. In (b), the former excels the latter in amount.



(a)　(b)

Photo. 2. Electron diffraction patterns of (a) $Au_3Zn[H]$ and (b) $Au_3Zn[H]+Au_3Zn[R_1]$. In (b), the former excels the latter in amount.



(a)　(b)

Photo. 3. Electron diffraction patterns of (a) $Au_3Zn[R_2]+Au_5Zn_3$ and (b) $Au_3Zn[R_2]+Au_5Zn_3$. In (a), the former and in (b), the latter excel the others in amount.

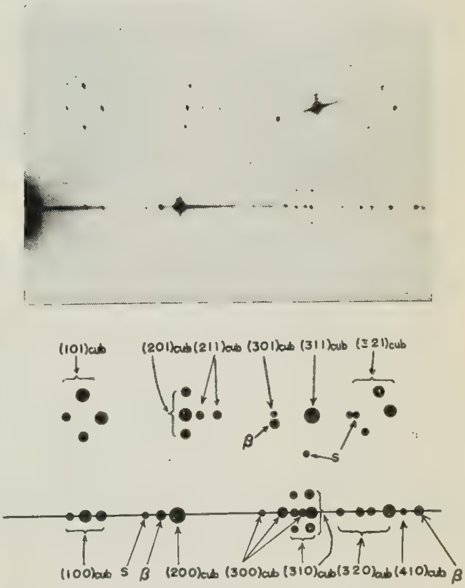


Photo. 4. X-ray oscillation pattern of $Au_{3+}Zn$ from the 19% Zn single crystal and its schematic diagram. $[001]_{cub}$. is vertical and oscillation angle is 30°. *s* and *β* represent satellite and *Kβ* spots, respectively.

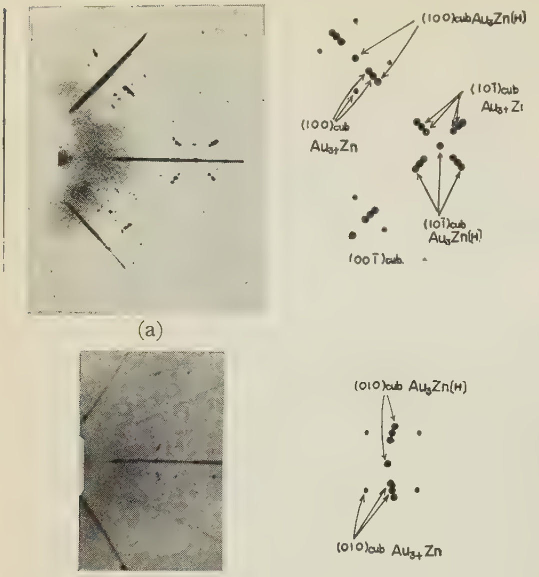

Photo. 5. X-ray oscillation patterns of $Au_{3+}Zn$+Au_3Zn[H] from the 20% Zn single crystal and their schematic diagrams. $[101]_{cub}$. is vertical and oscillation angles are 11° in (a) and 30° in (b). (a) $(100)_{cub}$. and $(10\bar{1})_{cub}$. superlattice spots. (b) $(010)_{cub}$. superlattice spots.

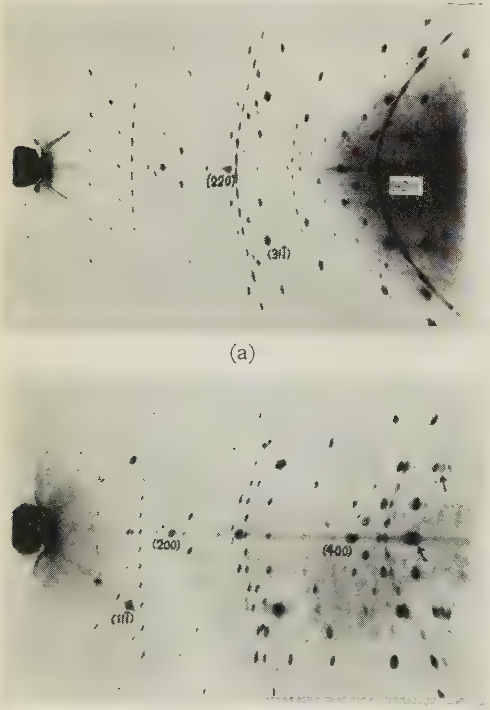

Photo. 6. X-ray oscillation patterns of (a) Au_3Zn [R_1] (23.5% Zn crystal) and (b) Au_3Zn[R_2] (26% Zn crystal). In both, the *c*-axis of the ordered crystal is vertical and oscillation angle is 80°. In (b), spots from a slight amount of Au_5Zn_3 are also observed. (indicated by arrows.)

b. X-ray Diffraction Study

X-ray diffraction study was carried out on single crystal samples. Since, unfortunately, single crystal with the composition range 30 to 40% Zn could by no means be prepared, the ordered phase Au_5Zn_3 was not studied by X-rays.

Photo. 4 shows the oscillation pattern of the crystal of 19% Zn, with the schematic diagram. Each superlattice reflexion splits in a characteristic group of spots, though some of groups

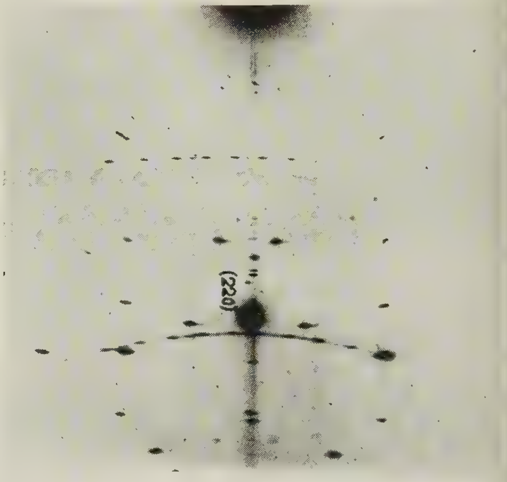

Photo. 7. X-ray oscillation pattern of Au_3Zn[R_1]+Au_3Zn[R_2] from the 24% Zn single crystal. In this crystal, the *c*-axis of the ordered crystal is distributed not only in vertical but also in horizontal orientation. Oscillation angle is 30°.

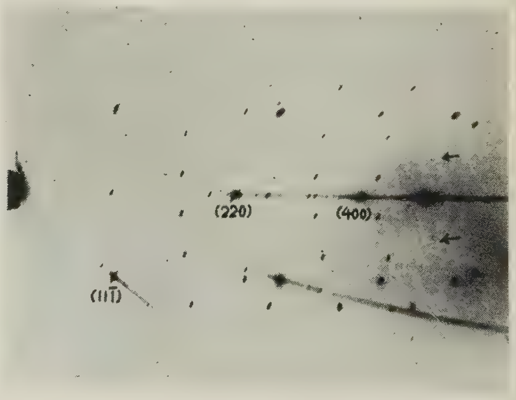

Photo. 8. X-ray oscillation pattern of Au_3Zn[H] from the quenched 26% Zn single crystal. The *c*-axis of the ordered crystal is vertical and oscillation angle is 60°. On account of incomplete quenching, transition into Au_3Zn[R] has slightly taken place. (Very weak spots indicated by arrows.)

*** It was not able to detect the fine structure of the diffraction spots due to an orthorhombic symmetry of $Au_{3+}Zn$.

**** Lattice constants could not be determined because of lack of the standard pattern.

ook incomplete. Here it must be noted that he present diffraction pattern can be accounted or by the only twofold superposition of the ingle crystal of $Au_{3+}Zn$ unlike the electron liffraction pattern. In Fig. 8 is shown the corresponding intensity distribution of $Au_{3+}Zn$. Examination of the diffraction pattern revealed he following fact: In Photo. 4, for example, he superlattice spots $(321)_{cub.}$ consist of four spots split crosswise, the vertical pair of spots being indexed as $(1+1/2M_1, 3, 2)$ and $(1-1/2M_1, 3, 2)$ and the horizontal pair as $(3+1/2M_1, -1, 2)$ and $(3-1/2M_1, -1, 2)$. In each of the pairs the asymmetry in intensity is recognized. Generally speaking, a spot at the higher diffraction angle side, $(h+1/2M_1, k, l)$ is always stronger than that at the lower angle side, $(h-1/2M_1, k, l)$ and this asymmetry becomes more conspicuous with increasing h. A similar

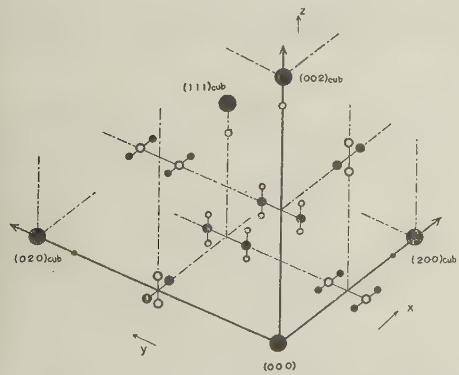

Fig. 8. Twofold superposition of the intensity distribution in the reciprocal lattice of $Au_{3+}Zn$. Solid and open circles represent the diffraction spots from the crystals with the following two orientations: in one, c-axis in y, a-axis in x direction, and in the other, c-axis in y, a-axis in z direction, respectively.

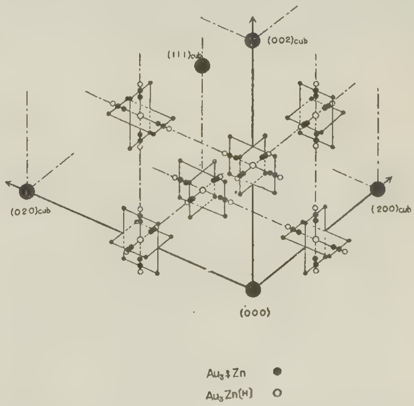

Fig. 9. Intensity distribution in the reciprocal lattice of the crystal, in which $Au_{3+}Zn$ and Au_3Zn[H] coexist. Solid and open circles represent the superlattice spots from $Au_{3+}Zn$ and Au_3Zn[H], respectively. The former corresponds to the sixfold, and the latter to the threefold superpositions.

asymmetry is also recognized in another set of split superlattice spots, (horizontal paris in $(310)_{cub}$. spots), which are generally indexed as $(h, k, l+1/2M_3)$ and $(h, k, l-1/2M_3)$. These two kinds of asymmetry were previously noticed by Wilkens and Schubert[3] in their powder diffraction pattern. In addition to the asymmetry in intensity, another fact was found in our diffraction pattern, that is, the appearance of the very weak satellite spots flanking the fundamental spots. The satellite spots are indicated as "s" in Photo. 4. They can be indexed as, for example, $(h+1/M_1, k, l)$ and $(h-1/M_1, k, l)$. Both the facts suggest a complicated atomic arrangemet in the structure of $Au_{3+}Zn$.

Coexistence of the two ordered phases $Au_{3+}Zn$ and Au_3Zn[H] is recognized in the diffraction patterns of the single crystal of 20% Zn shown in Photo. 5 (a) and (b). All spots may be classified into two groups as shown in Fig. 9, each group corresponding to the intensity distribution of the constituent ordered phase. In this case, the orientation of the ordered phase is equally probable in the directions of the three axes of the original cubic cell.

Photos. 6 (a) and (b) show the oscillation patterns of the single crystals of 23.5 and 26% Zn, respectively, and in both crystals the c-axis of the ordered crystal lies in the direction of the rotation axis, altough weak spots can be observed which are reflected from the crystals with the c-axis in the direction approximately perpendicular to the rotation axis. From Photo. 6 (a) the three-dimensional intensity distribution was directly obtained as shown in Fig. 10, and this corresponds to that of the tetragonal phase $Au_3Zn[R_1]$ with single orientation. Although the diffraction pattern in Photo. 6 (b) show apparently a fourfold symmetry about the c-axis, it seems to be reasonable to assume an orthorhombic symmetry for the structure, because spots at the higher diffraction angle, not seen in this pattern, show diffuse broadening which may be expected as a result of formation of an orthorhombic ordered crystal. Taking this fact into account, the intensity distribution is deduced from Photo. 6 (b) and is shown in Fig. 11, which accords with that calculated from the structure of Au_3Zn[R] of Wilkens and Schubert[4]. This structure was specified as $Au_3Zn[R_2]$. In spite of the resemblance between

corresponds to a "true" single crystal of the ordered phase without superposition of orientations. The dimension of this crystal is estimated to be about 0.5 mm. The intensity distribution shown in Fig. 12 corresponds to a typical one-dimensional anti-phase domain structure.

In Table II are summarized the structure data from X-ray diffraction.

c. *Specific heat measurement*

Twelve samples were employed to the specific heat measurement, their composition ranging from 14.9 to 38.4% Zn. Some of the measured Cp-T curves are shown in Figs. 13, 14 and 15. It is possible to interpret these curves by taking account of the results of the diffraction study.

Disordering of the phase $Au_{3+}Zn$ is seen as an anomalous peak *A* in both 14.9 and 18.1% samples. The transition energy is rather small and a fair amount of heat absorption remains even after the transition temperature has been passed, indicating the persistence of short range order. A peak *B* in 21.3% (also in 19.6%), which appears at the same temperature, 300°C, for both samples, may be considered as due to the reaction, $Au_{3+}Zn + Au_3Zn[H] \rightarrow \alpha$(disordered solid solution)$+ Au_3Zn[H]$, *i.e.* the peritectoid reaction[*]. In 26.1 and 27.3%, a very sharp peak *C* can be seen with the latent heat, indicating that the order-disorder transition in Au_3Zn is of the first order. In 21.3%, peak *C* due to the same transition is recognized, though less marked. Persistence of the short range order is again recognized in this transition, and the tendency is the more prominent, the nearer the ideal composition Au_3Zn is approached. Existence of the two phase region, the ordered and disordered phases, could not clearly be detected in the measurements. There appears another smaller peak *D* in 26.1 and 27.3%, which is an evidence of the transition between $Au_3Zn[H]$ and $Au_3Zn[R]$. That a small energy (about 210 cal./mol. at 27.3%) is associated in this case is consistent with the result of the diffraction study that no marked atomic diffusion but only slight shift of atoms is accompanied with the present transition. In the Cp-T curves of 29.9, 35.3 and 38.4%, a common peak *E* at about 300°C is interpreted as due to the decomposition of Au_5Zn_3 into $Au_3Zn[H] + AuZn$ (CsCl-type ordered phase), which is another peritectoid reaction. The latent heat of the order of about 90−30 cal./mol. was observed at 410°C in 29.9 and 35.3% as a sharp peak *F*, which corresponds to the eutectoid reaction, $Au_3Zn[H] + AuZn \rightarrow \alpha + Au_3Zn$. A small kink *G* in 38.4% may be due to crossing over the solubility limit of AuZn.

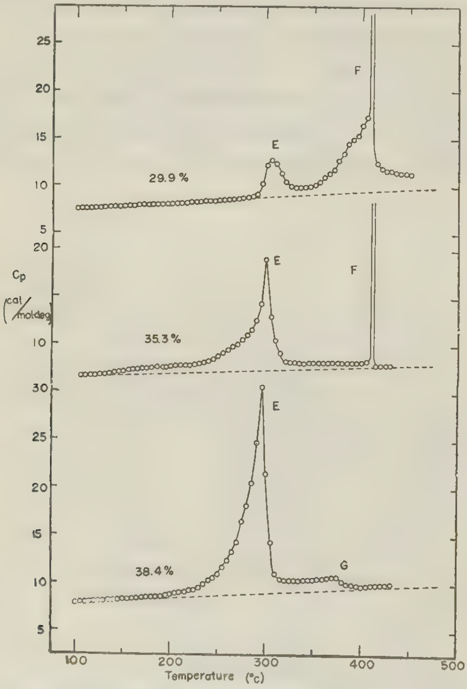

Fig. 15. Specific heat versus temperature curves of 29.9, 35.3 and 38.4% Zn alloys.

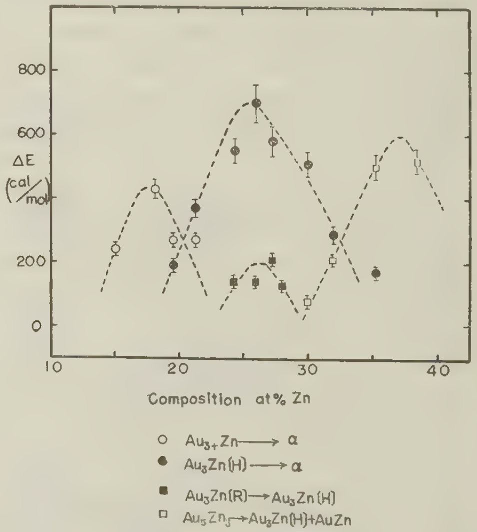

Fig. 16. Changes in configurational energy associated with various types of the transitions, plotted against the alloy composition.

[*] Latent heat was not observed, presumably because the reaction was too slow to be observed.

Energy changes associated with each type of the transitions are plotted against the alloy composition in Fig. 16.

§ 5. Interpretation and Discussion of the Experimental Results

On the basis of the information obtained from the diffraction study as well as from the calorimetric measurement, it is possible to construct the phase diagram of the gold-rich side of the gold-zinc alloy system, as is shown in Fig. 17, in which open circles represent the transition temperatures obtained from the present measurements, though these temperatures were obtained from the heating experiments only. It should be noted that the transition at about 140°C, which was observed by Soldau[6] in his resistometric measurement on samples with composition range 31 to 35% Zn, could not be detected in the present measurements. It seems, however, to be reasonable to assume the existence of the phase boundary at about 140°C shown by the dotted horizontal line in Fig. 17 in order to account consistently for the results of the diffraction study. The phase diagram thus constructed is roughly similar to that proposed by Wilkens and Schubert[4], but a phase boundary between $Au_3Zn[R_1]$ and $Au_3Zn[R_2]$ is added, and the phase relation at about 20% Zn and at 300°C is changed from the eutectoid to the peritectoid in the present diagram.

By the present diffraction study on single crystals, the proposed structures of the ordered phases in the gold-zinc system were substantially confirmed, though the phase Au_5Zn_3 was not fully investigated, because bulk single crystals of this phase were not available.

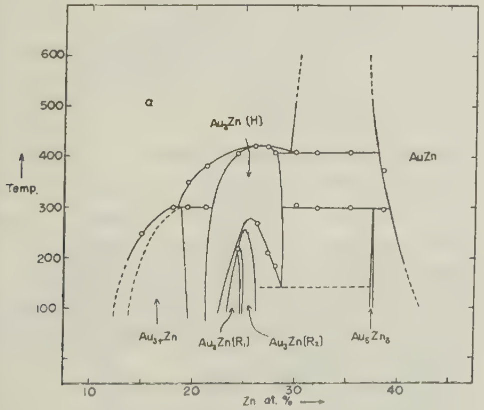

Fig. 17. The phase diagram of the Au-rich side of the Au-Zn alloy system concluded from the present work.

The asymmetry in intensity of the split superlattice spots and the appearance of satellite spots around the fundamental spots in the diffraction pattern of $Au_{3+}Zn$ cannot be derived from the simple model of the structure shown in Fig. 1. Presumably, the phenomena would be accounted for by assuming the presence of deviation in atomic arrangement from the simple model. Wilkens and Schubert[3] tried to explain the asymmetry of the spots by assuming the presence of the displacements of atoms at the anti-phase boundary. Another model is possible according to one of the present authors (H.I.), in which the non-stoichiometry in the alloy composition of $Au_{3+}Zn$ and the variation of lattice spacing with maximum spacing at the boundary are taken into account: in other words, the modulations of both the scattering factor and the lattice spacing in the structure are considered. By this model, it is possible to account for to some extent the intensity asymmetry of the split spots and the observed intensities of the satellite spots. The detailed discussion on this subject will be presented in the subsequent paper.

When the crystal is cooled down from the disordered state across the transition temperature of the order-disorder, one of the three axes of the disordered cubic cell may become the *c*-axis of the ordered cell, and this axis in the ordered state is generally expected to distribute equally along the directions of the three axes of the disordered cell. However, in some cases, as was shown in § **4**, the unequal orientation distribution of the ordered crystals can be observed. Examination of many of the diffraction patterns from the ordered phases in the present and other alloy systems revealed the following tendencies. In thin films, the manifoldly superposed diffraction patterns of single crystals of the ordered phase are very often observed, indicating that each single-crystalline region extends only over small volume. On the other hand, in bulk crystals, regions with single orientation of the ordered phase are so large that, in the case of $Au_3Zn[H]$, the diffraction pattern from the "true" single crystal can sometimes be obtained, as is shown in Photo. 8. In the nucleation of ordered phases such as Au_5Zn_3

and CuAu II, in which the c/a ratio of the fundamental cell deviates appreciably from unity, the preferential distribution of the c-axis is observed even in the case of thin films.

One of the peculiar phenomena in the ordered phase with long period in the present system is the occurrence of the phase transition between Au_3Zn[H] and Au_3Zn[R]. Au_3Zn[H] is thermally stable only in a definite temperature range and transforms by cooling into the room temperature modification Au_3Zn[R]. Though a few experimental facts have been reported on the stability of the phase Au_3Zn[H] by previous workers[8),2)], they could not elucidate thoroughly the nature of the transition. Since, as was shown in § **4**, there occurs only slight shift of atoms in the transition $Au_3Zn[H] \rightleftarrows [R]$, *i.e.*, the transition is martensitic, it is conceived that any rapid cooling cannot quench the high temperature phase Au_3Zn[H] into room temperature. In the present experiment, however, the quenching was not always impossible. A specimen, which was annealed for a short time at the temperature range of [H], *e.g.* for 6 hrs. at 290°C, was incomplete in atomic ordering, but yet enough to give fairly intense superlattice spots. If this specimen was rapidly cooled by water, it was possible to suppress practically the atomic movement on passing the transition point of $[H] \rightleftarrows [R]$. The transition $A_3uZn[H] \rightarrow [R]$ may thus be dependent on the degree of order, and this supposition seems to be consistent with the empirical fact that if the composition of the alloy deviates from the ideal value (3:1), or the third element is added to Au_3Zn, *i.e.*, if the development of the perfect order is disturbed by changing the alloy composition, the temperature range of the stable existence of Au_3Zn[H] becomes lower.

In Table III are compared the data of calorimetry obtained from the present alloy and other ordered alloys of the A_3B type with the theoretical predictions, where ΔE, $\Delta\Phi$ and Q represent the configurational energy, entropy just above the transition temperature and the latent heat, respectively. All of the ordered alloys cited in the Table, except Cu_3Au, have the ordered structure with long period.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 10, OCTOBER, 1960

On the Superconducting Ground State

By Ziro MIKURA
Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received May 7, 1960)

The energy difference ΔE between the superconducting and normal states is recalculated as a function of half an energy gap μ_0, manipulating the unrenormalized Hamiltonian of Fröhlich by the method of Bogoliubov. The result is in disagreement with experiment, in contrast to Bogoliubov's one. Extension to higher orders of perturbation calculation does not remove the discrepancy. It is then shown that the agreement with experiment is recovered if the theory is reformulated on the principle of minimum energy in place of the principle of compensation of dangerous diagrams. The screened Coulomb repulsions between electrons do not change the qualitative aspect of the result. No detailed discussion is offered on the electromagnetic properties, but it is suggested that a successful theory in predicting a correct ΔE-μ_0 relation would not necessarily lead to a full understanding of them.

§ 1. Introduction

Recently, Bardeen, Cooper and Schrieffer[1] developed a new theory of superconductivity and successfully explained many of the properties of superconductors. They started from the renormalized Hamiltonian of Fröhlich[2]. It is not evident, however, that this simplified Hamiltonian reflects all the essential features of the original, unrenormalized Hamiltonian. Bogoliubov[3], on the other hand, advanced another, ingenious method of attacking the same problem, and stated that he could arrive at the same result as Bardeen et al. His method can be applied to the unrenormalized Hamiltonian, and this is a great advantage over the BCS method. It is to be noted, however, that Bogoliubov based his theory, without giving legitimate justification, on an unfamiliar principle of compensation of dangerous diagrams. He chose a canonical transformation on this principle, merely for the reason that the subsequent mathematical treatments could be made easiest thereby. However, it should be noted that in the problem of superconductivity physically different solutions are expected for different canonical transformations adopted, and that, in consequence, mathematical convenience cannot be a guiding principle to find the best transformation from the physical point of view.

The object of the present work is to show:

(1) The principle of compensation leads to a relation in disagreement with experiment between an energy gap $2\mu_0$ and the difference in energy, ΔE, between the superconducting and normal states.

(ii) If the principle of minimum energy is adopted instead of the principle of compensation, then a satisfactory agreement is obtained between theory and experiment as regards the above-mentioned relation.

(iii) The screened Coulomb repulsion does not affect these results.

No attempt is made to account for the electromagnetic properties, but it is suggested that a successful theory in predicting an energy gap $2\mu_0$ and its relation to the energy difference ΔE would not necessarily lead to a full understanding of them.

§ 2. Second-Order Perturbation Calculation of the Energy on the Principle of Compensation

According to Fröhlich[2] the Hamiltonian of a system of electrons interacting with phonon fields, with the Coulomb interactions omitted, is written as

$$H=\sum_{k,\sigma}(\varepsilon_k-\lambda)a_{k\sigma}^+a_{k\sigma}+\sum_{w}\omega(w)\left(b_w^+b_w+\frac{1}{2}\right)+H_{\text{int}}\ , \tag{2.1}$$

$$H_{\text{int}}=(ig/\sqrt{2V})\sum_{\left(\substack{k,k',\sigma\\ k'-k=w}\right)}\sqrt{\omega(w)}\,a_{k\sigma}^+a_{k'\sigma}b_w^+ +\text{c.c.}\ , \tag{2.2}$$

where we employ a nomenclature of common use. The electron-phonon coupling constant g is assumed to be small in the sense that

$$g^2N(0)<1\ , \tag{2.3}$$

where $N(0)$ is the number of Bloch states of one spin per unit energy per unit volume a the Fermi surface. The parameter λ should be determined by requiring the expectatio value of $\sum_{k\sigma}a_{k\sigma}^+a_{k\sigma}$ for the state under examination to be equal to N, number of electron in the system.

Following Bogoliubov we introduce a set of new Fermion operators defined by a canonica transformation

$$a_{k\uparrow}=u_k\alpha_{k0}+v_k\alpha_{-k1}^+\ ,\qquad a_{k\downarrow}=u_k\alpha_{k1}-v_k\alpha_{-k0}^+\ , \tag{2.5}$$

$$u_k^2+v_k^2=1;\qquad u_k=u_{-k}\ ,\qquad v_k=v_{-k}\ . \tag{2.6}$$

In terms of these variables the Hamiltonian is expressed in the form

$$H=U+H_0+H'\ ,\qquad H'=H_1+H_2+H_3\ , \tag{2.7}$$

$$U=\sum_k 2(\varepsilon_k-\lambda)v_k^2\ , \tag{2.8}$$

$$H_0=\sum_k(\varepsilon_k-\lambda)(u_k^2-v_k^2)(\alpha_{k0}^+\alpha_{k0}+\alpha_{k1}^+\alpha_{k1})+\sum_w\omega(w)\left(b_w^+b_w+\frac{1}{2}\right)\ , \tag{2.9}$$

$$H_1=\sum_k(\varepsilon_k-\lambda)u_kv_k(\alpha_{k0}^+\alpha_{-k1}^+ +\alpha_{-k1}\alpha_{k0})\ , \tag{2.10}$$

$$\begin{aligned}H_2=(ig/2V)\sum_{\left(\substack{k,k'\\ k'-\ \ =w}\right)}\sqrt{\omega(w)}\{&u_kv_{k'}(\alpha_{k0}^+\alpha_{-k'1}^+ +\alpha_{-k'0}^+\alpha_{k1}^+)\\ &+u_{k'}v_k(\alpha_{-k1}\alpha_{k'0}+\alpha_{k'1}\alpha_{-k0})\}b_w^+ +\text{c.c.}\ ,\end{aligned} \tag{2.11}$$

$$\begin{aligned}H_3=(ig/2V)\sum_{\left(\substack{k,k'\\ k'-k=w}\right)}\sqrt{\omega(w)}\{&u_ku_{k'}(\alpha_{k0}^+\alpha_{k'0}+\alpha_{k1}^+\alpha_{k'1})\\ &-v_kv_{k'}(\alpha_{-k'1}^+\alpha_{-k1}+\alpha_{-k'0}^+\alpha_{-k0})\}b_w^+ +\text{c.c.}\ .\end{aligned} \tag{2.12}$$

When the energy of the lowest eigenstate of this Hamiltonian is formally calculated according to the Goldstone-Hugenholtz perturbation theory[4],[5] taking H' as a perturbation, the result is expected to depend on the choice of the transformation. The specific choice

$$\left.\begin{aligned}&u_k=0\ ,\qquad v_k=1\ ,\qquad &\varepsilon_k<\zeta\ ,\\ &u_k=1\ ,\qquad v_k=0\ ,\qquad &\varepsilon_k>\zeta\ ,\end{aligned}\right\} \tag{2.13}$$

(ζ: energy of an electron on the Fermi surface) is assumed to correspond to the normal state. Following Bogoliubov, perturbation calculation of the energy is carried out in the present section to terms in second order in g. No dangerous energy denominators arise in the perturbation expansion of the normal state energy. For an arbitrary choice of u_k, v_k [satisfying the condition (2.6)], however, there are in general some diagrams that give rise to dangerous denominators. The principle of compensation of dangerous diagrams states that the superconducting ground state corresponds to the special choice of u_k, v_k for which the contributions from such dangerous diagrams disappear by mutual compensation. In order to secure this compensation, it is necessary and sufficient to guarantee the mutual compensation of those processes in which a pair of quasi-particles with equal and opposite momenta is created from the vacuum without phonon creation. A diagram corresponding to such a process will be called a pair-creating diagram. Actually, it suffices, to second order in g, that the H_1-process illustrated in Fig. 1 is compensated by the sum of the H_2H_3-processes in Fig. 2. In these and all other figures, solid lines directed to the left or to the right represent respectively $\boldsymbol{k}0$ or $\boldsymbol{k}1$ particles and broken lines are phonons. There are many other diagrams which are of second order in g and lead to the same process, as some typical examples are illustrated in Fig. 3. However, they are found to have little effect on the determination of u_k, v_k provided that the condition (2.3) is satisfied. This may be realized if one examines the contribution of these diagrams to the compensation equation by making use of the approximate solution for u_k, v_k to be obtained on requiring the mutual compensation of diagrams in Figs. 1 and 2. The compensation of those processes illustrated in Figs. 1 and 2 requires

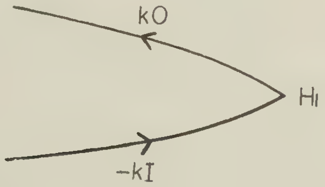

Fig. 1. Pair-creating diagram effected by H_1.

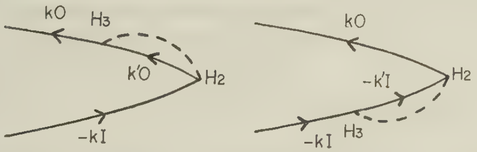

Fig. 2. Important pair-creating diagrams in second order in g.

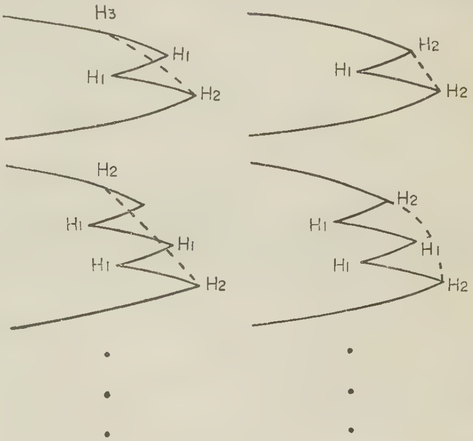

Fig. 3. Examples of unimportant pair-creating diagrams in second order in g. Particle lines may be directed either clockwise or counter-clockwise.

$$\alpha_{-k1}\alpha_{k0}H_1|0\rangle-\alpha_{-k1}\alpha_{k0}H_3H_0^{-1}H_2|0\rangle=0\ , \tag{2.14}$$

where $|0\rangle$ is the quasi-particle vacuum state. Making use of the explicit expressions (2.9)-(2.12) gives

$$\begin{aligned}2(\varepsilon_k-\lambda)u_kv_k-(u_k^2-v_k^2)\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}u_{k'}v_{k'}}{\omega_{kk'}+E_k+E_{k'}}\\-u_kv_k\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}(u_{k'}^2-v_{k'}^2)}{\omega_{kk'}+E_k+E_{k'}}=0\ ,\end{aligned} \tag{2.15}$$

where

$$E_k\equiv(\varepsilon_k-\lambda)(u_k^2-v_k^2);\qquad \omega_{kk'}\equiv\omega(\boldsymbol{k}-\boldsymbol{k}')\ . \tag{2.16}$$

E_k may be interpreted as the energy of a free quasi-particle. Setting

$$\overline{\varepsilon}_k=\varepsilon_k-\frac{1}{2}\sum_{k}\frac{g^2}{V}\frac{\omega_{\boldsymbol{kk}'}(u_{k'}^2-v_{k'}^2)}{\omega_{\boldsymbol{kk}'}+E_k+E_{k'}}\,, \tag{2.17}$$

$$\xi_k=\overline{\varepsilon}_k-\lambda\,, \tag{2.18}$$

$$c(k)=\sum_{k'}\frac{g^2}{V}\frac{\omega_{\boldsymbol{kk}'}u_{k'}v_{k'}}{\omega_{\boldsymbol{kk}'}+E_k+E_{k'}}\,, \tag{2.19}$$

we can transform (2.15) into the form

$$2\xi_k u_k v_k=(u_k^2-v_k^2)c(k)\ . \tag{2.20}$$

Besides the trivial solution (2.13), this has another solution:

$$u_k=\left[\frac{1}{2}\left(1+\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2},\quad v_k=\left[\frac{1}{2}\left(1-\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2}. \tag{2.21}$$

It follows easily that

$$u_k v_k=c(k)/2\sqrt{c^2(k)+\xi_k^2}\ ;\quad u_k^2-v_k^2=\xi_k/\sqrt{c^2(k)+\xi_k^2}\,. \tag{2.22}$$

Introducing (2.21) into (2.19) and solving the resulting equation

$$c(k)=\frac{1}{2}\sum_{k'}\frac{g^2}{V}\frac{\omega_{\boldsymbol{kk}'}}{\omega_{\boldsymbol{kk}'}+E_k+E_{k'}}\frac{c(k')}{\sqrt{c^2(k')+\xi_{k'}}}\,, \tag{2.23}$$

we can determine $c(k)$. Going over from summation to integration we have an integral equation for $c(k)$

$$c(k)=\frac{1}{2(2\pi)^3}\int g^2\frac{\omega_{\boldsymbol{kk}'}}{\omega_{\boldsymbol{kk}'}+E_k+E_{k'}}\frac{c(k')}{\sqrt{c^2(k')+\xi_{k'}^2}}d\boldsymbol{k}'\ . \tag{2.24}$$

We shall now attempt to solve this equation approximately. The following facts are taken into consideration: (i) $c(k)$ need not be exactly determined for large $|\xi_k|$ because the contribution of dangerous diagrams to the energy from this region is negligible, and (ii) the main contribution to the integral arises from the region $|\boldsymbol{k}'|\simeq k_0$ (k_0: wave number corresponding to $\xi_k=0$). It is to be noted that we may put, in a good approximation, for $g^2N(0)<1$

$$\lambda=\zeta;\quad k_0=k_F\ (k_F\text{: wave number corresponding to }\zeta)\ . \tag{2.25}$$

We shall first carry out the integration with respect to angle variables. We take approximately $|\boldsymbol{k}|$, $|\boldsymbol{k}'|\simeq k_0$, and, in consequence, assume

$$\omega_{\boldsymbol{kk}'}=\begin{cases}\hbar s_0 k_0\sqrt{2(1-t)}\,, & -t_0<t<1\,,\\ 0\,, & -1<t<-t_0\,,\end{cases} \tag{2.26}$$

s_0 being the velocity of sound and t the cosine of the angle between $\boldsymbol{k}$ and $\boldsymbol{k}'$. For $t=-t_0$ we have the maximum value of $\omega_{\boldsymbol{kk}'}$, which may be put equal to the phonon quantum at the Debye frequency, giving

$$\hbar s_0 k_0\sqrt{2(1+t_0)}=\omega_D=k\Theta_D\ . \tag{2.27}$$

Using (2.26) we can easily carry out the integrations with respect to angle variables in (2.24). The result is found to be represented by

$$c(k)=\frac{1}{(2\pi)^2}\int g^2\frac{\omega}{\omega+E_k+E_{k'}}\frac{c(k')}{\sqrt{c^2(k')+\xi_{k'}^2}}k'^2dk' \tag{2.28}$$

in a sufficient approximation, employing an average phonon energy

$$\omega=(3/5)k\Theta_D\ . \tag{2.29}$$

The maximum error arising from this averaging procedure is about one percent in the important region $E_k+E_{k'}<2\omega$. The procedure is equivalent to replacing, from the outset, $\omega_{kk'}$ by ω in (2.23). To solve the integral equation (2.28) one further approximation is made that E_k' in the denominator is replaced by $\bar{E}_{k'}$ defined by

$$\bar{E}_{k'}=(\bar{\varepsilon}_{k'}-\lambda)(u_{k'}^2-v_{k'}^2)=\xi_{k'}^2/\sqrt{c^2(k')+\xi_{k'}^2}\ . \tag{2.30}$$

Besides a normal state solution $c(k)=0$, we find a nontrivial solution expressed in the following approximate form*

$$c(k)=c_0/(1+E_k/\omega)\ , \tag{2.31}$$

where c_0 is the value of $c(k)$ at $E_k=0$ and can be found by solving

$$1=\frac{1}{2}\int g^2\frac{\omega}{\omega+\xi_{k'}^2/\sqrt{c^2(k')+\xi_{k'}^2}}\,\frac{N(\xi_{k'})}{\sqrt{c^2(k')+\xi_{k'}^2}}d\xi_{k'}\ , \tag{2.32}$$

$N(\xi_{k'})$ being a kind of density of states defined by $N(\xi_{k'})=k'^2(2\pi^2d\bar{\varepsilon}_{k'}/dk')^{-1}$. Since the important contribution to the above integral arises only from a region $|\xi_{k'}|\ll\lambda$, it is permissible to replace $N(\xi_{k'})$ by the value at $\xi_{k'}=0$, which may be approximately identified with the free electron value $N(0)$. Assuming that $c_0\ll\omega$, one is able to carry out the integration in (2.32) to get

$$1=Ax-A \tag{2.33}$$

with the abbreviations $A\equiv g^2N(0)$; $x\equiv\ln(2\omega/c_0)$. From (2.33)

$$c_0=2\omega\exp[-A^{-1}-1]\ . \tag{2.34}$$

The relation (2.33) is the same one as that obtained by Bardeen et al.[1] and Bogoliubov[2] except for a correction term of order A. The importance of the exact derivation to this order becomes apparent in § 5. Combination of (2.21), (2.31) and (2.34) fully determines the transformation fulfilling the principle of compensation to second order in g.

We are now able to proceed to the calculation of the energy of the "superconducting ground state", in Bogoliubov's sense, relative to the normal state energy. In second order perturbation theory it reads

$$\Delta E_c^{(2)}=D(U-\langle 0|H_2H_0^{-1}H_2|0\rangle)\ , \tag{2.35}$$

where D means the subtraction of the normal state value corresponding to (2.13). We have omitted not only the contributions from the dangerous ground state diagrams related to the pair-creating ones in Figs. 1 and 2, but also the contributions from those related to the diagrams in Fig. 3 and like ones, in the same spirit as stated before in discussing the compensation condition. As has been shown by Bogoliubov, Eq. (2.35) gives

$$\Delta E_c^{(2)}=D\sum_k 2\xi_k v_k^2-\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_kv_ku_{k'}v_{k'}}{\omega_{kk'}+E_k+E_k'}-D\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}\ ,$$

where $\varepsilon_k-\lambda$ has been replaced by ξ_k $(\equiv\bar{\varepsilon}_k-\lambda)$ in the first term without loss of accuracy. With (2.19) this yields

$$\Delta E_c^{(2)}=D\sum_k 2\xi_k v_k^2-\sum_k c(k)u_kv_k-D\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}\ . \tag{2.36}$$

With (2.21) the first two members on the right side gives

---

* In all applications of this equations E_k may be replaced by $\bar{E}_k$ defined by a similar equation as (2.30). Moreover, c_0 may be used in place of $c(k)$ in the expression of $\bar{E}_k$.

$$-(D\sum_{k}\xi_k^2/\sqrt{c^2(k)+\xi_k^2}+(1/2)\sum_{k}c^2(k)/\sqrt{c^2(k)+\xi_k^2})\,. \tag{2.37}$$

In going over to this we have neglected $D\sum_k(1/2)\xi_k$ which is clearly very small. To evaluate (2.37), we divide the k-space into two parts, the inner and outer regions of a spherical shell $|\xi_k|<P$ with P appropriately chosen so as to satisfy the condition $c_0 \ll P \ll \omega$. (Note that we are assuming that $c_0 \ll \omega$.) Putting $c(k)=c_0$ without loss of accuracy for $|\xi_k|<P$, we have

$$\begin{aligned}
&-(D\sum_{\substack{k\\(|\xi_k|<P)}}\xi_k^2/\sqrt{c^2(k)+\xi_k^2}+(1/2)\sum_{\substack{k\\(|\xi_k|<P)}}c^2(k)/\sqrt{c^2(k)+\xi_k^2})\\
&\quad=-N(0)V\{P\sqrt{c_0^2+P^2}-c_0^2\ln(2P/c_0)-P^2+c_0^2\ln(2P/c_0)\}\\
&\quad=-(1/2)N(0)c_0^2\,.
\end{aligned}\tag{2.38}$$

For the outer region we have

$$\begin{aligned}
&\lim_{\Lambda\to\infty}|D\sum_{\substack{k\\(P<|\xi_k|<\Lambda)}}\xi_k^2/\sqrt{c^2(k)+\xi_k^2}+(1/2)\sum_{\substack{k\\(P<|\xi_k|<\Lambda)}}c^2(k)/\sqrt{c^2(k)+\xi_k^2}|\\
&\quad<\lim_{\Lambda\to\infty}|\sum\xi_k^2/\sqrt{c_0^2+\xi_k^2}+(1/2)\sum c_0^2/\sqrt{c_0^2+\xi_k^2}-\sum|\xi_k||\\
&\quad=(1/8)N(0)c_0^4/P^2\,,
\end{aligned}\tag{2.39}$$

which is neglected compared with the contribution from the first region.

We shall next evaluate the last term in (2.36). Replacing E_k, $E_{k'}$ by $\bar{E}_k$, $\bar{E}_{k'}$ without loss of accuracy and making use of the same procedure of angle integrations used for (2.24), we have

$$-D\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}=-\lim_{\Lambda\to\infty}AN(0)VD\int_{-\lambda}^{\Lambda}\int_{-\lambda}^{\Lambda}\frac{(\omega/4)d\xi_{k'}d\xi_k}{\omega+\xi_k^2/\sqrt{c^2(k)+\xi_k^2}+\xi_{k'}^2/\sqrt{c^2(k')+\xi_{k'}^2}}\,.$$

Setting $\eta=\xi_k/c_0$, $\eta'=\xi_{k'}/c_0$, $\delta=\omega/c_0$, $L=\Lambda/c_0$, $K=\eta^2/\delta\sqrt{1+\eta^2}$ and $\delta_K=(1+K)\delta$ and extending the integration to $-\infty$, we get

$$-\lim_{L\to\infty}AN(0)VD\int_0^L\int_0^L\frac{c_0^2d\eta'd\eta}{1+\eta^2/\delta\sqrt{(1+K)^{-2}+\eta^2}+\eta'^2/\delta\sqrt{(1+K')^{-2}+\eta'^2}}\,. \tag{2.40}$$

Integrating first with respect to η' with due regard to the inequality $1\ll\delta\ll L$, we obtain from (2.40)*

$$-\lim_{L\to\infty}AN(0)VD\int_0^L c_0^2\left\{\delta\ln(L/\delta)+\frac{\ln(2\delta)}{2\delta(1+K)^2}-\delta\ln(1+K)+\delta\ln\left(1+\frac{\delta_K}{L}\right)\right\}d\eta\,. \tag{2.41}$$

No contribution arises from the first term in the brackets, because the quantity after the symbol D becomes independent of c_0 for this term. To evaluate the remaining terms use is made of

$$\int_0^L\frac{d\eta}{(1+K)^2}=\delta+\delta^{-1}\ln(2\delta)\,,$$

$$\int_0^L\ln(1+K)d\eta=(L+\delta)\ln(L/\delta)-L+\delta-(2\delta)^{-1}\ln(2\delta)\,,$$

$$\int_0^L\ln(1+\delta_k/L)d\eta=L\ln(1+\delta/L)+L\times[\text{func. of } L/(L+\delta)]-(L+\delta)^{-1}\ln(2L)\,,$$

which are valid for δ, $L\gg1$. The final result is then

---

* The η'-integration is carried out by dividing it into three parts, $(0,\delta)$, (δ,δ_k) and (δ_k, L) and expanding the integrand in powers of η'/δ and η'/δ_k in the first region, in powers of δ/η' and η'/δ_k and in powers of δ/η' and δ_k/η', respectively, in the second and third regions.

$$-\boldsymbol{D}\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}=-AN(0)Vc_0x\,. \tag{2.42}$$

This is exact in the approximation ignoring terms of relative order x^{-1}.

Combining (2.38) and (2.42) gives

$$\Delta E_c^{(2)}/V=-(1/2)N(0)c_0^2-AxN(0)c_0^2\,. \tag{2.43}$$

The right-hand side with the second term omitted is just that was found by Bogoliubov. It is felt that he thought the last term of (2.36) to be negligibly small. We find the contrary; if the relation (2.33) is substituted into (2.43), it becomes

$$\Delta E_c^{(2)}=-(3/2)N(0)c_0^2\,. \tag{2.44}$$

This is three times as large as the value obtained by Bogoliubov.

We shall next investigate the energy $\mu(\boldsymbol{k})$ for an elementary excitation of momentum $\boldsymbol{k}$. In second-order perturbation calculation

$$\mu(\boldsymbol{k})=E_k-\langle \boldsymbol{k}s|H'(H_0-E_k)^{-1}H'|\boldsymbol{k}s\rangle\,, \tag{2.45}$$

where $|\boldsymbol{k}s\rangle=\alpha_{ks}^+|0\rangle$, $s=0,\ 1$. Following Bogoliubov it is easily shown that the minimum excitation energy μ_0 occurs at $E_k=0$ and is given by

$$\mu_0=2u_kv_k\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}u_{k'}v_{k'}}{\omega_{kk'}+E_{k'}}=c_0\,. \tag{2.46}$$

Since a pair of quasi-particles should be excited in real excitation phenomena, μ_0 is to be compared with half an observed energy gap.

Summarizing this section, we can say that, if one calculates the difference in energy between the superconducting and normal states in second-order perturbation theory based on the principle of compensation, the result is expressed, in terms of half an energy gap μ_0, by

$$\Delta E_c^{(2)}=-(3/2)N(0)\mu_0^2\,. \tag{2.47}$$

The earlier result due to Bogoliubov

$$\Delta E_c^{(2)}=-(1/2)N(0)\mu_0^2 \tag{2.48}$$

seems to have been derived by incorrectly disregarding the contribution of the last term in (2.36).

§3. Comparison with Experimental Data

It is interesting to see what relation exists between the energy gap and the difference in energy between the superconducting and normal states for real superconductors. We know a relation $\Delta E/V=-H_0^2/8\pi$ (H_0: critical field at absolute zero) thermodynamically, and an expression $\gamma_n=(2/3)\pi^2k^2N(0)$ for the normal specific heat constant (per unit volume) of electrons in a metal according to the Sommerfeld theory. It is then easy to derive the following formula

$$\Delta E/V=-\kappa N(0)\mu_0^2 \tag{3.1}$$

with a dimensionaless quantity

$$\kappa=(\pi/3)(H_0^3/n^2\gamma_nT_c^2)\,, \tag{3·2}$$

where n is the energy gap measured in the unit of kT_c.

The theory in the preceding section predicts that the value of κ calculated from experimental data on H_0, T_c, γ_n and n should be the same constant for all superconductors and be equal to 3/2. In Table I the calculated values of κ are listed for some superconductors together with the observed data employed to derive them. Note that the semi-empirical value of κ is nearly equal to 1/2 for all these cases. This fact suggests that the relation (3.1) holds for all superconductors with $\kappa=1/2$, and that there must be something wrong in the theoretical treatments of the preceding section where κ is found to be 3/2. Despite the agreement with experiment, Bogoliubov's derivation of (2.48) cannot be acceptable for the very reason that it was only possible by missing an important contri-

bution to the energy.

§ 4. Fourth-Order Perturbation Calculation Based on the Principle of Compensation

First of all, we note that the principal contribution of the second order term in the perturbation expansion of ΔE in § 2 was exactly cancelled by the principal contribution of the zeroth order term. This is easily seen if one evaluates separately the two terms in the parentheses of (2.37) substituting (2.31) for $c(k)$. As a result of this cancellation the main part of ΔE consists of the next order contributions of the zeroth and second order terms in the perturbation expansion*. In view of these situations we are led to study the contribution to ΔE from the diagrams of fourth order in g, which may possibly be of the same order of magnitude as the next lowest order contribution from the second order diagrams. In this section we shall see that this really happens. The fact invalidates in principle the calculation of ΔE in second-order perturbation theory, but it will also be shown that the consideration of fourth order diagrams does not change the final relation between the difference in energy, ΔE, and half an energy gap μ_0 and, in consequence, cannot answer the purpose to avoid the discrepancy between theory and experiment discussed in the preceding section.

We have stated that the fourth order term in the perturbation expansion for ΔE is an order of magnitude smaller than the second order term, and, as expected, we find a similar situation for any two successive order terms except for the zeroth and second order terms. We are thus justified to restrict ourselves to the calculation of ΔE to fourth order in g.

Before proceeding to the calculation of the energy, it is necessary to extend the principle of compensation so as to eliminate the dangerous diagrams to fourth order in g. We need first of all to construct all important pair-creating diagrams of fourth order in g contributing to the compensation equation. They are conveniently constructed from the important, connected ground state diagrams of fourth order shown at the left end of Fig. 4. Note that there is a conjugate diagram with all arrows reversed to each of the ground state diagrams labelled as I–VII. To every ground state diagram belong four pair-creating diagrams, which are shown in the same figure and whose construction from the original ground state diagram will be explained immediately. Note that every ground state diagram has two or three points where particles are annihilated. If we modify a ground state diagram at one of these points in such a manner as illustrated in Fig. 5, then we have one pair-creating diagram for each case**. As easily observed, all important pair-creating diagrams of fourth order in g can be constructed in this way from the ground state diagrams in Fig. 4 without duplication. We disregard the unimportant pair-creating diagrams in fourth order in g which involve H_1-processes. This conforms to the earlier neglect of the second order diagrams such as shown in Fig. 3.

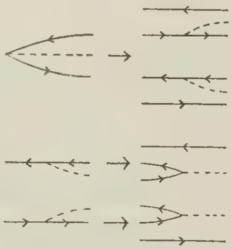

Fig. 5. Procedures in constructing pair-creating diagrams from a ground state diagram.

We have now to investigate the contribution of the pair-creating diagrams in Fig. 4 to the last term in the compensation equation

$$\alpha_{-k1}\alpha_{-k0}H_1|0\rangle-\alpha_{-k1}\alpha_{k0}H_3H_0^{-1}H_2|0\rangle-\alpha_{-k1}\alpha_{k0}H'H_0^{-1}H'H_0^{-1}H'H_0^{-1}H'|0\rangle_{\text{connected}}=0\,, \qquad (4.1)$$

which is the extension of (2.14). Making use of the explicit expressions for H_2 and H_3, we find that the contributions of all the diagrams belonging to one and the same group are always possible to be summed up into the form

$$-(u_k^2-v_k^2)\Phi_i(k)-u_kv_k\Psi_i(k)\,, \qquad i=\text{I}, \cdots, \text{XIII}, \quad (4.2)$$

---

* Note that we are assuming an inequality $c_0 \ll \omega \ll \lambda$.

** In Fig. 5 we illustrate only the cases where a phonon is annihilated, in order to save space.

where $\Phi_i(k)$ and $\Psi_i(k)$ are approximately constant for $E_k<\omega$ and approach zero with E_k increasing beyond ω. Since the expressions both for $\Phi_i(k)$ and $\Psi_i(k)$ are complicated and their evaluation is tedious, we omit details of them and give only a brief account of the evaluation of $\Phi_i(k)$ in the Appendix. An important remark should be made that all $\Phi_i(k)$'s vanish for the normal state solution (2.13). This is evident at first sight for the diagrams labelled as I-IV and VIII–XIII, and can be seen after some reduction for those labelled as V–VII. The compensation condition to fourth order in g reads now

$$2(\varepsilon_k-\lambda)u_kv_k-(u_k^2-v_k^2)\left\{\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}u_{k'}v_{k'}}{\omega_{kk'}+E_k+E_{k'}}+\sum_i\Phi_i(k)\right\}$$
$$-u_kv_k\left\{\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}(u_{k'}^2-v_{k'}^2)}{\omega_{kk'}+E_k+E_{k'}}+\sum_i\Psi_i(k)\right\}=0\,. \qquad (4.3)$$

If we put

$$\overline{\varepsilon_k}=\varepsilon_k-\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}(u_{k'}^2-v_{k'}^2)}{\omega_{kk'}+E_k+E_{k'}}-\sum_i\Psi_i(k);\qquad \xi_k=\overline{\varepsilon}_k-\lambda\,,$$
$$c(k)=\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}u_{k'}v_{k'}}{\omega_{kk'}+E_k+E_{k'}}+\sum_i\Phi_i(k)\,, \qquad (4.4)$$

then we have from (4.3)

$$2\xi_ku_kv_k=(u_k^2-u_k^2)c(k)\,, \qquad (4.5)$$

which is formally identical with (2.20). The nontrival solution is again

$$u_k=\left[\frac{1}{2}\left(1+\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2},\qquad v_k=\left[\frac{1}{2}\left(1-\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2}, \qquad (4.6)$$

which keeps both relations in (2.22). From the inspection of the expressions for $\Phi_i(k)$, we see that every $\Phi_i(k)$ can be assumed in the form $c_i/(1+E_k/\omega)$, c_i=const., taking account of the fact that the exact E_k-dependence is not essential for $E_k/\omega\lesssim 1$. (See the Appendix.) We can then solve Eq. (4.4) approximately by assuming $c(k)$ in the same form as in § 2, namely,

$$c(k)=c_0/(1+E_k/\omega)\,. \qquad (4.7)$$

Before proceeding to the determination of c_0, we shall study the energy of the "superconducting ground state" measured relative to that of the normal state, and the energy gap, both as a function of c_0. The former is given by

$$\varDelta E_c^{(4)}=\boldsymbol{D}(U-\langle 0|H_2H_0^{-1}H_2|0\rangle-\langle 0|H'H_0^{-1}H'H_0^{-1}H'H_0^{-1}H'|0\rangle_{\text{connected}})\,. \qquad (4.8)$$

The ground state diagrams of importance contributing to the last term in the parentheses are just those shown at the left end of Fig. 4. Careful examination of the contribution from each diagram reveals that it is expressed, to a reasonable approximation, in the form $-\sum_k u_kv_k\Phi_i(k)$, using the same $\Phi_i(k)$ as in (4.3) and (4.4). Application of (4.4) to the following expanded form of (4.8)

$$\varDelta E_c^{(4)}=\boldsymbol{D}\sum_k 2\xi_kv_k^2-\sum_{k,k}\frac{g^2}{V}\frac{\omega_{kk'}u_kv_ku_{k'}v_{k'}}{\omega_{kk'}+E_k+E_{k'}}$$
$$-\boldsymbol{D}\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}-\sum_k u_kv_k\sum_i\Phi_i(k) \qquad (4.9)$$

gives

$$\varDelta E_c^{(4)}=\boldsymbol{D}\sum_k 2\xi_kv_k^2-\sum_k c(k)u_kv_k-\boldsymbol{D}\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}\,. \qquad (4.10)$$

This is the same equation as that obtained earlier in the second order calculation [Eq. (2.36)].

If one replaces again the density of states $N(\xi_{k'})$ at $\xi_{k'}=0$ by the free electron value $N(0)$ and assumes $c(k)\ll\omega$, then the right-hand side of (4.10) can be manipulated in the same way as before with the result

$$\Delta E_0^{(4)}=-(1/2)N(0)c_0^2-AxN(0)c_0^2\,,\qquad [x\equiv\ln(2\omega/c_0)],\quad(4.11)$$

which is, of course, identical to (2.43) though a different value ought to be substituted for c_0. As described in the Appendix, the last term in (4.4) arising from the fourth order diagrams is of order $c(k)A^2x$ and, in consequence, is smaller than the second order contribution by factor A. This means that Eq. (4.4) must lead to the same relation (2.33), which was derived from (2.19), except for the correction term of order A. We have then $Ax=1+O(A)$. With this Eq. (4.11) gives

$$\Delta E_0^{(4)}=-(3/2)N(0)c_0^2\,,\qquad(4.12)$$

which is identical with the result of second order calculation, (2.44).

We shall now calculate half an energy gap μ_0. As before it is identified with the minimum energy required to excite a single quasi-particle from the vacuum. Considering, for example, an excitation of a $\boldsymbol{k}0$ particle, we have

$$\mu_0=\langle \boldsymbol{k}0|H'H_0^{-1}H'|\boldsymbol{k}0\rangle+\langle \boldsymbol{k}0|H'H_0^{-1}H'H_0^{-1}H'H_0^{-1}H'|'\boldsymbol{k}0\rangle_{\text{connected}}\,,\qquad(4.13)$$

where $|\quad|'$ means that no intermediate state should be taken equal to $|\boldsymbol{k}0\rangle$. The second order contribution has already been studied and found to equal c_0. To deal with the second term, we need to construct all the important diagrams contributing to it. It is easily seen that they have one-to-one correspondence to the pair-creating diagrams in Fig. 4 and are derived from the latter by merely exchanging the external $-\boldsymbol{k}1$-line for a new, external $\boldsymbol{k}0$-line running from the right and ending at the same point. Careful study of the contribution from each group of such diagrams reveals that it is given by $\Phi_i(k_0)$. As is shown in the Appendix, $\Phi_i(k_0)\sim c_0A$. Thus, we can neglect the fourth order contribution to the excitation energy and get $\mu_0=c_0$ as in second order calculation. Thus, from (4.12) we obtain

$$\Delta E_0^{(4)}=-(3/2)N(0)\mu_0^2\,.\qquad(4.14)$$

This means that the consideration of fourth order diagrams does not change the relation between the energy difference $\Delta E/V$ and half an energy gap μ_0 while it may possibly change both quantities. We are led then to conclude that the discrepancy between theory and experiment discussed in § 3 should be attributed not to lack of accuracy in mathematical manipulations but to some conceptional origin.

Both for the sake of completeness and later requirements we shall now express the constant c_0 in terms of the interaction parameter A. For this purpose it suffices to evaluate only the main part of $\Phi_i(k)$, linear in c_0, to the lowest order in A (assuming $x\sim A^{-1}$). A brief account of this evaluation is found in the Appendix. The result is

$$\sum_i\Phi_i(k)=-\gamma c_0A^2x/(1+E_k/\omega);\qquad\gamma\fallingdotseq0.1\,.\qquad(4.15)$$

On account of the difficulty in evaluating some of $\Phi_i(k)$'s accurately, we have confidence only in the order of magnitude of the above value for γ. However, we shall require no exact knowledge of γ to advance further arguments in subsequent sections.

Substituting (4.15) into (4.4) and solving it for c_0 give

$$1=Ax-(1+\gamma)A\quad\text{or}\quad c_0=\mu_0=2\omega\exp[-A^{-1}-(1+\gamma)]\,.\qquad(4.16$$

This means that the energy gap $2\mu_0$ is modified by a factor $\exp[-\gamma]$ and the difference in energy, $\Delta E/V$, by a factor $\exp[-2\gamma]$ if one takes into account the contribution of fourth order diagrams.

§ 5. Reformulation on the Basis of the Principle of Minimum Energy

In view of the results obtained in the preceding section as well as the considerations in Introduction, we are led to doubt the validity of the principle of compensation of dangerous diagrams due to Bogoliubov. Consequently, we attempt in this section to reformulate the theory on the basis of another, more legitimate principle, namely, the principle of minimum energy.

We shall start from the transformed Hamiltonian (2.7)-(2.12). Put

$$\xi_k=\varepsilon_k-\lambda\ , \qquad E_k=(\varepsilon_k-\lambda)(u_k^2-v_k^2) \tag{5.1}$$

and assume u_k and v_k in the form

$$u_k=\left[\frac{1}{2}\left(1+\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2}, \qquad v_k=\left[\frac{1}{2}\left(1-\frac{\xi_k}{\sqrt{c^2(k)+\xi_k^2}}\right)\right]^{1/2}, \tag{5.2}$$

where $c(k)$ is a function to be determined on a variational principle. The results obtained in preceding sections suggest that the electron-phonon interaction affects less effectively those electronic states which are at distances more than ω apart from the Fermi surface, and also that one may assume Eq. (4.7) for $c(k)$ in (5.2). Thus, we put

$$c(k)=c_0/(1+E_k/\omega) \tag{5.3}$$

with c_0 now considered as a variational parameter.

The parameter c_0 will now be determined by minimizing the energy of the lowest state calculated on perturbation theory taking H' as a perturbation. It is assumed that

$$c_0 \ll \omega\ , \tag{5.4}$$

$$g^2N(0)\ln(2\omega/c_0)\equiv Ax=1+O(A)\ . \tag{5.5}$$

We shall see later that both conditions are really fulfilled by c_0 in the vicinity of its best choice. A mathematical difficulty arises, of course, in connection with the dangerous diagrams, which are generally not compensated in the present treatment. We believe on physical grounds that the dangerous diagrams would provide us with a finite result if their contributions could be collected in an appropriate way. We expect further that the solution u_k, v_k satisfying the principle of minimum energy is not largely distinct from that satisfying the principle of compensation so that the contribution of dangerous diagrams is small enough to be dropped from the energy to be minimized. We assume it for a while, but some discussion on this point will be presented in the next section.

The energy of the lowest state corresponding to any set of u_k, v_k which is defined by (5.2) and (5.3) with c_0 satisfying (5.4) and (5.5), can be expressed in the same form as that obtained in the preceding section, namely, by Eq. (4.9), provided all dangerous diagrams are disregarded as assumed above. In applying this equation to the present case, however, ξ_k and E_k are, of course, differently defined, namely, by (5.1). Suggested by the inspection of this expression, we can reach the following general aspect of perturbation expansion of $\Delta E/V$. It is naturally a power series of A beginning with a constant term. The coefficient of any order term can be expressed by a double series expanded in powers of $(c_0/\omega)^2$ and x $[\equiv\ln(2\omega/c_0)]$. If one is interested only in terms linear in c_0^2, assuming $c_0\ll\omega$, then he does not meet with any higher powers of x than the second because x is always accompanied by factor c_0. This enables us to disregard diagrams contributing to the energy in sixth or higher order in g on assuming $Ax\sim1$. We have thus

$$\Delta E/V=N(0)c_0^2\{x-Ax^2+\alpha+\beta Ax+\gamma A^2x^2+O(A)\}\ , \tag{5.6}$$

where α, β and γ are numerical coefficients of order 1. The numerical coefficients in the first and second terms, 1 and -1 respectively, are easily found by evaluating the first two terms of (4.9) in a crude way. The values to be assigned to α, β and γ may be obtained by manipulating the right-hand side of the same equation accurately. We shall leave for a moment these three coefficients undetermined for a reason which becomes apparent later.

On minimizing $\varDelta E/V$ with respect to c_0 we find

$$Ax=1+(\alpha+\beta+\gamma+1/2)A\ , \tag{5.7}$$

which is reliable to the term of order A. It is easy to see that the value of c_0 corresponding to (5.7) really affords the minimum (not the maximum) energy. If it is denoted by $\bar{c}_0$, Eq. (5.7) gives

$$\bar{c}_0=2\omega\ln[-A^{-1}-(\alpha+\beta+\gamma+1/2)]\ . \tag{5.8}$$

It is to be noted that the final results, (5.7) and (5.8), are fully consistent with the initially made assumptions, (5.4) and (5.5), provided that A is fairly smaller than 1 and $\alpha+\beta+\gamma+1/2$ is not a large negative number. Actual evaluation of α, β and γ will show that the latter condition is really satisfied, as we see later.

Introduction of (5.7) in (5.6) gives the energy of the superconducting ground state measured relative to that of the normal state:

$$\begin{aligned}\varDelta E_m/V=N(0)\bar{c}_0^2\{&A^{-1}+(\alpha+\beta+\gamma+1/2)+\alpha-A^{-1}[1+(\alpha+\beta+\gamma+1/2)A]^2\\&+\beta[1+(\alpha+\beta+\gamma+1/2)A]+\gamma[1+(\alpha+\beta+\gamma+1/2)A]^2\}\\=-(1/2)&N(0)\bar{c}_0^2\ .\end{aligned} \tag{5.9}$$

Terms of relative order A should not be retained in the final result because it would be unreliable unless terms of order $N(0)c_0^2A$ were included in the initial equation (5.6). It is rather surprising that the final result does not explicitly depend on α, β and γ.

We shall next investigate half an energy gap μ_0. It is calculated in quite a similar way as in the theory based on the principle of compensation as long as all dangerous diagrams are disregarded, giving*

$$\bar{\mu}_0=2u_kv_k\sum_{k'}(g^2/V)u_{k'}v_{k'}/(1+E_{k'}/\omega)\ . \tag{5.10}$$

With (5.1), (5.2), (5.3) and (5.5) this yields $\bar{\mu}_0=\bar{c}_0A\bar{x}=\bar{c}_0$. Combining this with (5.9) we have

$$\varDelta E_m/V=-(1/2)N(0)\bar{\mu}_0^2\ , \tag{5.11}$$

which is a result in satisfactory agreement with experiment (c.f. § 3). We have thus confirmed that the discrepancy between theory and experiment, which was found in the theory based on the principle of compensation, can completely be removed by reformulating theory on the principle of minimum energy. Furthermore, it should be emphasized that the final result (5.11) can be obtained with any arbitrary values assigned to α, β and γ as long as an inequality $\alpha+\beta+\gamma+1/2>-1$ is fulfilled. We have left so far the above three numerical factors undetermined to find this situation most easily.

We shall now show that the superconducting ground state arrived at in the present section has really a lower energy than the " ground state " obtained earlier on the principle of compensation. To do so, we need the actual values for α, β and γ. They are obtained by evaluating the right-hand side of (4.9) employing (5.1), (5.2) and (5.3). Actual calculations are as follows.

$$\begin{aligned}\boldsymbol{D}\sum_k 2\xi_kv_k^2&=-N(0)V\lim_{\Lambda\to\infty}\left\{\int_{-\lambda}^{\Lambda}\xi_k^2/\sqrt{c^2(k)+\xi_k^2}\,d\xi_k-\int_{-\lambda}^{\Lambda}|\xi_k|d\xi_k\right\}\\&=2N(0)V\lim_{\Lambda\to\infty}\int_0^{\Lambda}\xi_k(1-\xi_k/\sqrt{c^2(k)+\xi_k^2})d\xi_k\end{aligned}$$

---

* Quantities fixed on the principle of minimum energy will be denoted by barred letters.

$$=N(0)V\lim_{\Lambda\to\infty}\left\{\Lambda^2-2\int_0^{\omega}\xi_k^2/\sqrt{c_0^2(1+\xi_k^2/\omega\sqrt{c_0^2+\xi_k^2})^{-2}+\xi_k^2}\,d\xi_k\right.$$
$$\left.-2\int_{\omega}^{\Lambda}\xi_k^2/\sqrt{c_0^2(1+\xi_k^2/\omega\sqrt{c_0^2+\xi_k^2})^{-2}+\xi_k^2}\,d\xi_k\right\}$$
$$=N(0)V\lim_{\Lambda\to\infty}\left\{\Lambda^2-\omega\sqrt{c_0^2+\omega^2}+c_0^2\ln(2\omega/c_0)-\left(\frac{1}{2}+\ln 2\right)c_0^2-\Lambda^2+\omega^2\right.$$
$$\left.+\left(\ln 2-\frac{1}{2}\right)c_0^2\right\}$$
$$=N(0)Vc_0^2(x-3/2)\,, \tag{5.12}$$

$$-\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_kv_ku_{k'}v_{k'}}{\omega_{kk'}+E_k+E_{k'}}$$
$$=-g^2N(0)Vc_0^2\lim_{\Lambda\to\infty}\lim_{\Lambda'\to\infty}\int_0^{\Lambda}\int_0^{\Lambda'}\left(1\Big/\left(1+\frac{\xi_k^2}{\omega\sqrt{c^2(k)+\xi_k^2}}+\frac{\xi_{k'}^2}{\omega\sqrt{c^2(k')+\xi_{k'}^2}}\right)\right)$$
$$\times\left(1+\frac{\xi_k^2}{\omega\sqrt{c^2(k)+\xi_k^2}}\right)^{-1}\left(1+\frac{\xi_{k'}^2}{\omega\sqrt{c^2(k')+\xi_{k'}^2}}\right)^{-1}$$
$$\times\frac{d\xi_{k'}d\xi_k}{\sqrt{c^2(k)+\xi_k^2}\sqrt{c^2(k')+\xi_{k'}^2}}$$
$$=-g^2N(0)Vc_0^2\lim_{\Lambda\to\infty}\int_0^{\Lambda}\frac{1}{\left(1+\dfrac{\xi_k^2}{\omega\sqrt{c_0^2+\xi_k^2}}\right)^2\sqrt{c_0^2+\xi_k^2}}$$
$$\times\left\{\ln(2\omega/c_0)-\frac{\omega\sqrt{c_0^2+\xi_k^2}}{\xi_k^2}\ln\left(1+\frac{\xi_k^2}{\sqrt{c_0^2+\xi_k^2}}\right)\right\}d\xi_k$$
$$=-g^2N(0)Vc_0^2\{\ln(2\omega/c_0)[\ln(2\omega/c_0)-1]-\ln(2\omega/c_0)\}$$
$$=-N(0)Vc_0^2(Ax^2-2Ax)\,. \tag{5.13}$$

Reduction of the last two terms in (4.9) is carried out in exactly the same way as described before (in § 2 and in the Appendix), giving

$$-D\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'}u_k^2v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}=-N(0)Vc_0^2Ax\,, \tag{5.14}$$

$$-\sum_k u_kv_k\sum_i \Phi_i(k)=\gamma N(0)Vc_0^2A^2x^2\,. \tag{5.15}$$

Substitution of the above results in (4.9) yields

$$\Delta E/V=N(0)c_0^2(x-3/2-Ax^2+Ax+\gamma A^2x^2)\,,$$

showing that the three numerical coefficients in (5.6) are as follows:

$$\alpha=-3/2\,,\qquad \beta=1\,, \tag{5.16}$$

and γ is identical with γ used in § 4 to express $\sum_i \Phi_i(k)$. Note that

$$\alpha+\beta+\gamma+1/2=\gamma;\qquad |\gamma|\ll 1 \text{ (c.f. Appendix)}, \tag{5.17}$$

which satisfies the earlier requirements that $\alpha+\beta+\gamma+1/2$ should not be a large negative number.

By use of these values Eqs. (5.7) and (5.8) are found to become

$$A\bar{x}=1+\gamma A\,, \tag{5.18}$$

$$\bar{c}_0=\bar{\mu}_0=2\omega\exp[-A^{-1}-\gamma]\,. \tag{5.19}$$

Comparing (5.19) with (4.16) we see that the energy gap derived here on the principle of minimum energy is e times larger than that obtained in the theory based on the principle of compensation. Comparison of the energy difference reads $\Delta E_m/\Delta E_c=e^2/3$. This means that the energy of the superconducting ground state defined here, measured relative to that of the normal state, is about 2.5 times lower than that of the earlier "superconducting ground state" defined on the principle of compensation.

§ 6. Discussion of the Contribution of Dangerous Diagrams

In the preceding section a very reasonable result has been obtained by reformulating the theory on the principle of minimum energy. However, the arguments advanced there can be justified only when the contributions from the dangerous diagrams can be collected by an appropriate mathematical device to give a finite and sufficiently small amount. Although we have not yet found any device to collect these contributions, some discussion will be given to suggest that they are really of little importance, at least, in the present procedure assuming $c(k)$ in the form (5.3).

In the first place it will be shown that we can find a state which lies very close to the "ground state" reached in the preceding section and whose energy can be calculated without suffering from the difficulty due to vanishing denominators to give the same energy and energy gap as those given by (5.11) and (5.19).

Consider a state which corresponds to assuming $c(k)$ slightly different from (5.3), namely, in the form

$$c(k)=\begin{cases}\bar{c}_0(1-A)/(1+E_k/\omega)\ , & |\xi_k|<\bar{c}_0\ ,\\ \bar{c}_0/(1+E_k/\omega)\ , & |\xi_k|>\bar{c}_0\ .\end{cases} \tag{6.1}$$

It is then easy to show that the principle of compensation of dangerous diagrams is fulfilled in the region $|\xi_k|<\bar{c}_0$. In fact, the right-hand side of the compensation equation (4.4) can be reduced, within the approximations keeping terms to relative order A, to the form

$$\frac{\bar{c}_0}{1+\xi_k^2/\omega\sqrt{c^2(k)+\xi_k^2}}(A\bar{x}-A-\gamma A^2\bar{x})=\frac{\bar{c}_0}{1+\xi_k^2/\omega\sqrt{c^2(k)+\xi_k^2}}(A\bar{x}-A-\gamma A) \tag{6.2}$$

in the present choice of $c(k)$. Applying Eq. (5.18) which holds as well with $c(k)$ given by (6.1), we have from (6.2)

$$\bar{c}_0(1-A)/(1+\xi_k^2/\omega\sqrt{c^2(k)+\xi_k^2})\ ,$$

which is just equal to the left-hand side of (4.3) when $|\xi_k|<\bar{c}_0$. Then, the so-called dangerous diagrams are no longer dangerous; they are compensated in the region $|\xi_k|<\bar{c}_0$ and do not bring forth difficulties in the region $|\xi_k|>\bar{c}_0$. Their contribution to the energy, ΔE, is finite and can be estimated to be negligible in the following way.

In Fig. 6 some lower order dangerous diagrams contributing to the energy are shown. The vertex represents either H_1 or the combined action H_2H_3 illustrated in Fig. 2 (or the reverse). The contribution from these diagrams may be expressed in the form

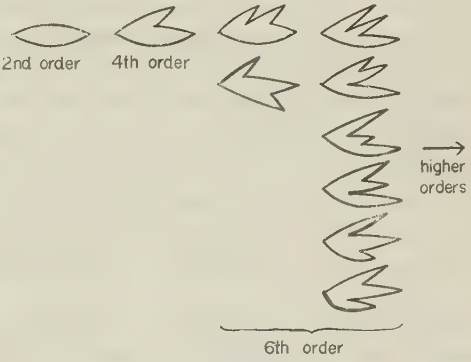

Fig. 6. Typical dangerous diagrams. Every vertex may represent either H_1 or the combined action of H_2 and H_3. Two alternative labellings are allowed for each diagram (except for the first one).

$$-\frac{1}{2}\sum_k{}'\frac{[c(k)-b_1(k)]^2}{\sqrt{\bar{c}_0^2+\xi_k^2}}+\frac{1}{2}\sum_k{}'\frac{[c(k)-b_1(k)]^2}{\sqrt{\bar{c}_0^2+\xi_k^2}}\frac{[c(k)-b_2(k)]^2}{4\xi_k^2}$$
$$-\frac{1}{2}\sum_k{}'\frac{[c(k)-b_1(k)]^2}{\sqrt{\bar{c}_0^2+\xi_k^2}}\frac{[c(k)-b_2(k)]^2}{4\xi_k^2}\left\{\frac{[c(k)-b_2(k)]^2}{4\xi_k^2}+\frac{[c(k)-b_3(k)]^2}{4\xi_k^2}\right\}+\cdots\ , \tag{6.3}$$

where the summation is limited to the region $|\xi_k|>\bar{c}_0$ and the successive terms correspond to the successive groups of diagrams in Fig. 6. The quantity denoted by $b_n(k)$ is introduced by the H_2H_3-process (or the reverse) and expressed in the form

$$b_n(k)=\sum_{k'}\frac{g^2}{V}\frac{\omega_{kk'}u_{k'}v_{k'}}{\omega_{kk'}+(2n-1)E_k+E_{k'}}+\sum_i \Phi_{in}(k)\ , \tag{6.4}$$

where $\Phi_{in}(k)$ is of the same form as $\Phi_i(k)$ introduced in §4 except that all energy denominators are increased by the same amount $2(n-1)E_k$. Note that

$$b_1(k)=\bar{c}_0(1-A)/(1+E_k/\omega)=c(k)(1-A)\ , \qquad |\xi_k|>\bar{c}_0\ . \tag{6.5}$$

Considering that the summation is carried out only in the region $|\xi_k|>\bar{c}_0$, we can expect the major contribution in (6.3) to arise from the first term. By use of (6.5) this is easily evaluated to give

$$-A^2N(0)\bar{c}_0{}^2\bar{x}\simeq -AN(0)\bar{c}_0{}^2\ . \tag{6.6}$$

There are many other complicated types of dangerous diagrams (which are of course not dangerous now) contributing to the energy, but it is possible to show that the sum of their contributions is small compared to that arising from the above-mentioned simplest diagrams.

The change in the originally non-dangerous part of energy, brought about by the modification of u_k, v_k under consideration, arises mainly from the first two terms on the right hand side of (4.9). In the approximations keeping only terms to relative order A, these terms give rise respectively to a change

$$-AN(0)\bar{c}_0{}^2\{2\ln(\sqrt{2}+1)-\sqrt{2}\} \qquad \text{and} \qquad -AN(0)\bar{c}_0{}^2\{-2\ln(\sqrt{2}+1)+\sqrt{2}\}\ ,$$

resulting in a vanishing sum. Thus, we have found that the non-dangerous part of energy of the new state introduced by the modification (6.1) differs from the value obtained for the original state in the preceding section [(5.9) with (5.19)] at most in terms of relative order A^2. In comparison with this part, the contribution of dangerous diagrams in (6.6) can be neglected. Since it is quite evident that half an energy gap μ_0 is again equal to $\bar{c}_0$ given in (5.19), we have reached all the final results in the preceding section without suffering from dangerous diagrams in the present case.

From these considerations it can be seen that the procedure advanced in the preceding section is practically equivalent to the following one. Let us asseme $c(k)$ in the form

$$c(k)=c_0(k)/(1+E_k/\omega)\ ,$$

$$c_0(k)=\begin{cases} c_0(1-pA)\ , & |\xi_k|<c_0\ , \\ c_0\ , & |\xi_k|>c_0\ , \end{cases} \tag{6.7}$$

instead of (5.3). Then, for any choice of c_0 ($\ll\omega$), the contribution to the energy from dangerous diagrams vanishes by mutual compensation for $\boldsymbol{k}$ such that $|\xi_k|<c_0$ and becomes negligibly small for $\boldsymbol{k}$ such that $|\xi_k|>c_0$ if p is chosen so as to satisfy

$$Ax=1+(1+\gamma-p)A\ ; \qquad x\equiv\ln(2\omega/c_0)\ . \tag{6.8}$$

This is easily verified in quite the same way as in the earlier case dealing with (6.1). To determine the best value of c_0, the variational procedure can be carried through in the same way as in the preceding section, neglecting dangerous diagrams with full justification in the present case as explained above. If we note that the perturbation series for the energy is the same as before in the approximation neglecting terms of order $AN(0)c_0{}^2$, it is easy to get the earlier result (5.18) and (5.19) [$c_0=\bar{c}_0$; $Ax=1+\gamma A$], and, hence, $p=1$ from (6.8) in agreement with (6.1). It may be said that we have chosen the best transformation among those which do not give rise to vanishing denominators in perturbation series.

In spite of the success of the present procedure in predicting the correct $\Delta E-\mu_0$ relation, it seems necessary to make the following remark: It is open to question that the transformation to give the true ground state needs to meet the above requirements of mathematical convenience.

§ 7. Effect of the Screened Coulomb Repulsion

So far, we have ignored entirely the effect of the Coulomb repulsion between electrons. A rigorous treatment of this repulsion is a difficult problem, and so we investigate here the effect of a model repulsion in the form such as considered by Abrikosov et al.[11]

A repulsive interaction may generally be written in the form

$$(2V)^{-1}\sum_{\left(\substack{\boldsymbol{k},\boldsymbol{l},\boldsymbol{k}',\boldsymbol{l}',\sigma,\rho\\ \boldsymbol{k}'-\boldsymbol{k}=\boldsymbol{l}-\boldsymbol{l}'}\right)} h(\boldsymbol{k},\,\boldsymbol{l},\,\boldsymbol{l}',\,\boldsymbol{k}')a_{\boldsymbol{k}\sigma}{}^+a_{\boldsymbol{l}\rho}{}^+a_{\boldsymbol{l}'\rho}a_{\boldsymbol{k}'\sigma}\,;\qquad h(\boldsymbol{k},\,\boldsymbol{l},\,\boldsymbol{l}',\,\boldsymbol{k})\geqq 0\,. \tag{7.1}$$

Adding this term to the earlier Hamiltonian (2.1) and applying the Bogoliubov transformation, we have*

$$H=U+H_0+H'\,,\qquad H'=H_1+H_2+H_3+H_4\,, \tag{7.2}$$

where

$$U=\sum_{\boldsymbol{k}}(2\xi_k v_k{}^2-V^{-1}v_k{}^2\sum_{\boldsymbol{k}'}\bar{h}_{\boldsymbol{k}\boldsymbol{k}'}v_{k'}{}^2+V^{-1}u_kv_k\sum_{\boldsymbol{k}'}h_{\boldsymbol{k}\boldsymbol{k}'}u_{k'}v_{k'})\,, \tag{7.3}$$

$$\begin{aligned}H_0=\sum_{\boldsymbol{k}}\{\xi_k(u_k{}^2-v_k{}^2)-V^{-1}u_kv_k\sum_{\boldsymbol{k}'}2h_{\boldsymbol{k}\boldsymbol{k}'}u_{k'}v_{k'}\}(\alpha_{\boldsymbol{k}0}{}^+\alpha_{\boldsymbol{k}0}+\alpha_{-\boldsymbol{k}1}{}^+\alpha_{-\boldsymbol{k}1})&\\ +\sum_{\boldsymbol{w}}\omega(\boldsymbol{w})\left(b_w{}^+b_w+\frac{1}{2}\right),&\end{aligned} \tag{7.4}$$

$$H_1=\sum_{\boldsymbol{k}}\{2\xi_ku_kv_k+V^{-1}(u_k{}^2-v_k{}^2)\sum_{\boldsymbol{k}'}h_{\boldsymbol{k}\boldsymbol{k}'}u_{k'}v_{k'}\}(\alpha_{\boldsymbol{k}0}{}^+\alpha_{-\boldsymbol{k}1}{}^++\alpha_{-\boldsymbol{k}1}\alpha_{\boldsymbol{k}0}) \tag{7.5}$$

with the abbreviations

$$\left.\begin{aligned}&\xi_k\equiv\varepsilon_k-\lambda+V^{-1}\sum_{\boldsymbol{k}'}\bar{h}_{\boldsymbol{k}\boldsymbol{k}'}v_{k'}{}^2\,,\\ &\bar{h}_{\boldsymbol{k}\boldsymbol{k}'}\equiv h(\boldsymbol{k},\,-\boldsymbol{k}',\,-\boldsymbol{k}',\,\boldsymbol{k})+h(\boldsymbol{k},\,\boldsymbol{k}',\,\boldsymbol{k}',\,\boldsymbol{k})-h(\boldsymbol{k},\,\boldsymbol{k}',\,\boldsymbol{k},\,\boldsymbol{k}')\,,\\ &h_{\boldsymbol{k}\boldsymbol{k}'}\equiv h(\boldsymbol{k},\,-\boldsymbol{k},\,-\boldsymbol{k}',\,\boldsymbol{k}')\,.\end{aligned}\right\} \tag{7.6}$$

H_2 and H_3 stand for the same expressions as given in (2.11) and (2.12), and H_4 is a sum of terms expressed in products of four creation and destruction operators, arising from the repulsive interaction term. It is to be noted that H_4 is non-diagonal and can be disregarded in the calculation of the ground state and singly excited state energies to the present approximation. As a model of the screened Coulomb repulsion, Abrikosov et al. considered the following case

$$\bar{h}_{\boldsymbol{k}\boldsymbol{k}'}=h_{\ \ \boldsymbol{k}'}=\begin{cases}h\ \text{(a positive constant)}, & |\xi_k|,\ |\xi_{k'}|<\omega_c,\\ 0\,, & \text{otherwise},\end{cases} \tag{7.7}$$

where ω_c is assumed to be much larger than ω (average phonon energy) taking account of the fact that the Coulomb repulsion in metals is screened at very short distances comparable to the lattice spacing. Furthermore, we assume a weak repulsion, that is,

$$hN(0)\equiv B<1\,. \tag{7.8}$$

Taking account of the difference in force range of the two kinds of interactions, we put

$$u_k=\left[\frac{1}{2}\left(1+\frac{\xi_k}{\sqrt{c^2(k)+\xi_k{}^2}}\right)\right]^{1/2},\quad v_k=\left[\frac{1}{2}\left(1-\frac{\xi_k}{\sqrt{c^2(k)+\xi_k{}^2}}\right)\right]^{1/2}, \tag{7.9}$$

---

* See Beliaev's article in reference[12].

assuming

$$c(k)=\begin{cases} c_0/(1+\xi_k^2/\omega\sqrt{c_0^2+\xi_k^2})+c_1\ , & |\xi_k|<\omega_c\ , \\ c_0/(1+\xi_k^2/\omega\sqrt{c_0^2+\xi_k^2})\ , & |\xi_k|>\omega_c\ , \end{cases} \tag{7.10}$$

where c_0 and c_1 are independent parameters which are to be determined variationally on the principle of minimum energy.

Proceeding in exactly the same way as in § 4, we have the energy difference in the following form

$$\begin{aligned} \Delta E=D\Big\{&\sum_k 2\xi_k v_k^2-V^{-1}\sum_{k,k'} h v_k^2 v_{k'}^2+V^{-1}\sum_{k,k'} h u_k v_k u_{k'} v_{k'} \\ &-\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'} u_k v_k u_{k'} v_{k'}}{\omega_{kk'}+E_k+E_{k'}}-\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'} u_k^2 v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}-\sum_k u_k v_k\sum_i \Phi_i(k)\Big\}\ , \end{aligned} \tag{7.11}$$

where $E_k=\xi_k(u_k^2-v_k^2)-2V^{-1}u_k v_k \sum_{k'} h u_{k'} v_{k'}$. The last term in the brackets which arises from the diagrams in fourth order in g has the same expression as the corresponding one in (4.9). Substitution of (7.9) with (7.10) for u_k and v_k shows that the second term in the brackets has a negligible contribution and the other contributions are as follows:

$$D\sum_k 2\xi_k v_k^2=N(0)V\Big\{(c_0+c_1)^2x+c_1^2D-(c_0+c_1)^2\Big[\frac{1}{2}+\frac{c_0^2}{(c_0+c_1)^2}\Big]\Big\}\ , \tag{7.12}$$

$$V^{-1}\sum_{k,k'} h u_k v_k u_{k'} v_{k'}=N(0)VB(c_0x+c_1y)^2\ , \tag{7.13}$$

$$\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'} u_k v_k u_{k'} v_{k'}}{\omega_{kk'}+E_k+E_{k'}}=N(0)VA\{(c_0+c_1)^2x^2-2c_0(c_0+c_1)x\}\ , \tag{7.14}$$

$$D\sum_{k,k'}\frac{g^2}{V}\frac{\omega_{kk'} u_k^2 v_{k'}^2}{\omega_{kk'}+E_k+E_{k'}}=N(0)VA(c_0+c_1)^2x\ , \tag{7.15}$$

$$\sum_k u_k v_k\sum_i \Phi_i(k)=-N(0)V\gamma A^2(c_0+c_1)^2x^2\ , \tag{7.16}$$

where

$$x\equiv\ln[2\omega/(c_0+c_1)],\quad y\equiv\ln[2\omega_c/(c_0+c_1)],\quad D\equiv y-x=\ln(\omega_c/\omega)$$

and γ in (7.16) is the same numerical factor as in (4.15). By use of these results we have from (7.11)

$$\begin{aligned} \Delta E/V=N(0)(c_0+c_1)^2\Big\{x+\alpha\Big(\frac{c_0}{c_0+c_1}\Big)-Ax^2+\beta\Big(\frac{c_0}{c_0+c_1}\Big)Ax+\gamma A^2x^2\Big\}& \\ +N(0)c_1^2D+N(0)B(c_0x+c_0y)^2\ ,& \end{aligned} \tag{7.17}$$

where

$$\alpha(r)=-(1/2+r^2);\qquad \beta(r)=2r-1\ . \tag{7.18}$$

Comparison of this equation with the earlier one (5.6) shows that we have two additional terms other than all corresponding to those in the latter equation.

We shall now minimize $\Delta E/V$ by taking independent variations with respect to c_0 and c_1. From $\delta\Delta E/\delta c_0=\delta\Delta E/\delta c_1=0$ it follows, neglecting small quantities,

$$\begin{aligned} &(c_0+c_1)x-(1/2)(c_0+c_1)+(c_0+c_1)\alpha+(1/2)c_1\alpha'-(c_0+c_1)Ax^2+(c_0+c_1)Ax \\ &\qquad+(c_0+c_1)\beta Ax+(1/2)\beta' c_1 Ax+\gamma(c_0+c_1)A^2x^2+B(x-1)(c_0x+c_1y)=0\ , \end{aligned} \tag{7.19}$$

$$\begin{aligned} &(c_0+c_1)x-(1/2)(c_0+c_1)+(c_0+c_1)\alpha-(1/2)c_0\alpha'-(c_0+c_1)Ax^2+(c_0+c_1)Ax \\ &\qquad+(c_0+c_1)\beta Ax-(1/2)\beta' c_0 Ax+\gamma(c_0+c_1)A^2x^2+B(y-1)(c_0x+c_1y)=0\ , \end{aligned} \tag{7.20}$$

The difference gives

$$c_1+B(c_0x+c_1y)=(c_0+c_1)S/D\,, \tag{7.21}$$

where

$$S=(1/2)(\alpha'+Ax\beta') \tag{7.22}$$

which is a quantity of order 1. Introducing (7.21) into (7.19) gives

$$Ax=1-c_1/(c_0+c_1)+S/D\,, \tag{7.23}$$

where we have neglected terms of order A. The energy difference corresponding to the minimum condition, $\varDelta E_m/V$, can be obtained, by combining (7.16) and (7.19), in the form

$$\begin{aligned}\varDelta E_m/V=N(0)(c_0+c_1)^2\Big\{\frac{1}{2}-Ax-\frac{1}{2}\,\frac{c_1}{c_0+c_1}(\alpha'+\beta' Ax)+\frac{c_1{}^2}{(c_0+c_1)^2}D\\ -B(x-1)\frac{c_0x+c_1y}{c_0+c_1}+Bx\frac{(c_0x+c_1y)^2}{(c_0+c_1)^2}\Big\}\,.\end{aligned} \tag{7.24}$$

By use of (7.21), (7.22) and (7.23) this equation can be reduced to

$$\varDelta E_m/V=-(1/2)N(0)(\bar{c}_0+\bar{c}_1)^2\,, \tag{7.25}$$

where the letters $\bar{c}_0$ and $\bar{c}_1$ are used to show that they are now fixed values corresponding to the minimum energy.

The excitation energy for a particle $\boldsymbol{k}s$ is given (neglecting higher order effects) by

$$\mu(\boldsymbol{k})=E_k-2u_kv_k\sum hu_{k'}v_{k'}-\langle \boldsymbol{k}s|H'(H_0-E_k)^{-1}H'|\boldsymbol{k}s\rangle\,.$$

Putting $E_k=0$ gives half an energy gap

$$\begin{aligned}\bar{\mu}_0&=-B(\bar{c}_0\bar{x}+\bar{c}_1\bar{y})+A(\bar{c}_0+\bar{c}_1)\bar{x}\\ &=(\bar{c}_0+\bar{c}_1)\{\bar{c}_1/(\bar{c}_0+\bar{c}_1)-\bar{S}/D+A\bar{x}\}=\bar{c}_0+\bar{c}_1\end{aligned} \tag{7.26}$$

Combining this result with (7.25) yields

$$\varDelta E_m/V=-(1/2)N(0)\bar{\mu}_0{}^2\,, \tag{7.27}$$

which is exactly the same equation that has been obtained earlier and found to agree with experiment.

In order to study the effect of the repulsion on the energy gap, we need to find the actual value of $\bar{c}_0+\bar{c}_1$ as a function of interaction parameters A and B. For this purpose, we first transform Eq. (7.19), using (7.22), into the following form

$$A\bar{x}=1+B\frac{\bar{c}_0\bar{x}+\bar{c}_1\bar{y}}{\bar{c}_0+\bar{c}_1}-\frac{1}{\bar{x}}\Big(\frac{1}{2}-A\bar{x}-\bar{\alpha}-\bar{\beta}A\bar{x}-\frac{\bar{c}_1}{\bar{c}_0+\bar{c}_1}\bar{S}-\gamma A^2\bar{x}+B\frac{\bar{c}_0\bar{x}+\bar{c}_1\bar{y}}{\bar{c}_0+\bar{c}_1}\Big)\,. \tag{7.28}$$

Making use of (7.21) and the following relation to be derived therefrom

$$\bar{c}_1/(\bar{c}_0+\bar{c}_1)=-B\bar{x}/(1+BD)+\bar{S}/D(1+BD)\,,$$

we can reduce Eq. (7.28) further to the form

$$A\bar{x}=1+\frac{B\bar{x}}{1+BD}-\frac{1}{\bar{x}}\Big\{\frac{1}{2}-A\bar{x}-\bar{\alpha}-\bar{\beta}A\bar{x}-\frac{\bar{S}^2}{D(1+BD)}-\gamma A^2\bar{x}^2+\frac{B\bar{x}}{1+BD}\Big\}\,. \tag{7.29}$$

In the first approximation, we have $A\bar{x}=1+B\bar{x}/(1+BD)$, which, introducing an effective interaction parameter

$$A'\equiv A-B/(1+BD)\,, \tag{7.30}$$

can be written as

$$A'\bar{x}=1\,. \tag{7.31}$$

Employing the approximate relation (7.31) to estimate the last term and assuming that $D\equiv\ln(\omega_c/\omega)\gg 1$, we have finally from (7.29)

$$A'\bar{x}=1+\left\{\alpha\left(\frac{A}{A'}\right)+\beta\left(\frac{A}{A'}\right)\frac{A}{A'}+\gamma\frac{A^2}{A'^2}+\frac{1}{2}\right\}A'\,, \tag{7.32}$$

where an approximate relation $\bar{c}_0/(\bar{c}_0+\bar{c}_1)=1+B\bar{x}/(1+BD)=A\bar{x}=A/A'$ has been used to transform the last term. From (7.32) we get

$$\begin{aligned}\bar{c}_0+\bar{c}_1=\bar{\mu}_0&=2\omega\exp\left[-\frac{1}{A'}-\left\{\alpha\left(\frac{A}{A'}\right)+\beta\left(\frac{A}{A'}\right)\frac{A}{A'}+\gamma\frac{A^2}{A'^2}+\frac{1}{2}\right]\right.\\&=2\omega\exp\left[-\frac{1}{A'}+\frac{A}{A'}-(1+\gamma)\frac{A^2}{A'^2}\right],\end{aligned} \tag{7.33}$$

where the last equality is effected by the definition (7.18). The last expression in (7.33) coincides with the right-hand side of the earlier equation (5.19) when $A'=A$, and in general cases such that $A'<A<1$ the former is always smaller, indicating that the repulsive interaction diminishes the energy gap. Comparison of the above result with (5.19) shows further that the major effect of the repulsive interaction on the energy gap and the energy difference between the superconducting and normal states can be taken into account by changing the interaction parameter in the old equation into A' given by (7.30). This was the conclusion reached by Abrikosov et al. dealing with the renormalized Fröhlich Hamiltonian in a rough way by Bogoliubov's method. As was pointed out by these authors and can be seen from (7.30), the repulsive interaction is less effective on account of a large difference in force ranges $[D\gg 1]$.

Finally, we shall give, for comparison, some results to be obtained when the same problem is treated on the principle of compensation. We need again to introduce two constants, c_0 and c_1, to express $\Delta E/V$ and μ_0. They are found to be given by

$$\Delta E_c/V=-(1/2+A/A')N(0)(c_0+c_1)^2; \qquad \mu_0=c_0+c_1\,, \tag{7.34}$$

thus yielding

$$\Delta E_c/V=-(1/2+A/A')N(0)\mu_0^2\,, \tag{7.35}$$

where A' is the same quantity as that used in the preceding case and defined by (7.30). We can find for the minimum excitation energy

$$\mu_0=c_0+c_1=2\omega\exp\left[-\frac{1}{A'}-(1+\gamma)\frac{A^2}{A'^2}\right]. \tag{7.36}$$

Note that the ratio of $\Delta E_c/V$ to $N(0)\mu_0^2$ is no longer independent of the interaction parameters. The fact that $1/2+A/A'>3/2$ indicates that the deviation from the semi-empirical law is even larger in the presence of a repulsive interaction.

To compare the energy difference between the superconducting and normal states calculated on different principles, we consider the ratio $\Delta E_m/\Delta E_c=\exp[2(A/A')]/[1+2(A/A')]$, which is always larger than $e^2/3$ when $A/A'>1$, indicating that the ground state reached on the principle of minimum energy has really a much lower energy than the one presumed on the principle of compensation.

§ 8. Concluding Remarks

We have been suspiscious of Bogoliubov's idea that the perturbation treatment based on the principle of compensation of dangerous diagrams provides the superconducting ground state of the electron-phonon system. Recalculation of the ground state energy, $\Delta E/V$, and the energy gap, $2\mu_0$, shows indeed the invalidity of this principle in predicting a well-established semi-empirical relation. A satisfactory agreement between theory and experiment is obtained if the theory is reformulated on the principle of minimum energy.

It is found that the difference in energy between the superconducting and normal states is always given correctly as a function of an energy gap if we have lowest order terms of the form $N(0)c_0{}^2x$ and $-N(0)c_0{}^2Ax^2$ in the energy expansion such as (5.6) and if the parameter c_0 is determined on the principle of minimum energy. Note that the next order terms of order $N(0)c_0{}^2$ have no importance to the derivation of the final result [Eq. (5.9)], in spite of the fact that $\varDelta E_m/V$ is just of this order of magnitude. We believe that this is the reason for the success of the BCS theory in which both the model and the mathematical treatment were much simplified but nevertheless both quoted terms were found in the expression of the energy.

In connection to this fact, an important remark should be made. First of all note that the lowest order terms just mentioned are quite insensitive to change in the form of $c(k)$ within a very narrow region for $\boldsymbol{k}$ surrounding the Fermi surface (e.g., in $|\xi_k|<c_0$). Note further that in the present theory we have assumed $c(k)$ to be nearly constant for $\boldsymbol{k}$ such that $|\xi_k|<c_0$ in order to circumvent the mathematical difficulty due to vanishing denominators. From these facts, we see that, although we have reached a correct relation between $\varDelta E$ and μ_0, this does not necessarily mean the validity of the obtained distribution function u_k, v_k in the immediate vicinity of the Fermi surface. On the other hand, it is evident that some of the electromagnetic properties (e.g., a non-vanishing Knight shift or low frequency Fourier components of current) may be closely connected to the behaviour of quasi-particles in this narrow region*. Thus, it may be concluded that a successful theory in predicting a correct $\varDelta E-\mu_0$ relation would not necessarily lead to a full understanding of the electromagnetic properties of superconductors.

Appendix

The contributions to the equation of compensation (4.1) from the pair-creating diagrams in fourth order in g (shown in Fig. 4) are found to be collected for each group into the form

$$-(u_k{}^2-v_k{}^2)\varPhi_i(k)-u_kv_k\varPsi_i(k)\ , \tag{A.1}$$

where the index i discriminates the group (i=I–XIII) and both $\varPhi_i(k)$ and $\varPsi_i(k)$ are functions of k^2 expressed in a complicated form. Careful examination of the expressions for $\varPhi_i(k)$'s shows that all $\varPhi_i(k)$'s vanish for the normal state solution, resulting in the vanishing total expression (A.1). Since we have no space to write down all the explicit expressions for $\varPhi_i(k)$'s and $\varPsi_i(k)$'s and to describe the procedures of their evaluation, we shall only present approximate expressions and evaluations of $\varPhi_i(k)$ in some typical cases.

First of all we have approximately**

$$\varPhi_{\mathrm{I}}(k)=-\left(\frac{g^2}{2V}\right)^2\sum_{k',k''}\left\{\omega_{kk'}u'v'\left[\frac{\omega_{kk''}}{(D_{kk''}+2E)(D_{kk'}+D_{kk''})D_{kk''}}+\frac{\omega_{k'k''}}{(D_{k'k''}+2E)(D_{kk'}+D_{k'k''})D_{k'k''}}\right]\right.$$
$$\left.+\frac{\omega_{kk''}u''v''}{D_{kk''}{}^2}\left[\frac{\omega_{kk'}}{D_{kk'}+D_{kk''}}+\frac{\omega_{k'k''}}{D_{kk'}+D_{k'k''}}\right]\right\}, \tag{A.2}$$

---

* Note that if one modifies the distribution function in this region in such a way that it tends to the normal one ($u_kv_k=0$) when the Fermi surface is approached, then the excitation energy vanishes for a quasi-particle on the Fermi surface although the value of $\sum_{k'}(g^2/V)u_{k'}v_{k'}/(1+E_{k'}/\omega)$ remains almost unchanged. [c.f. (5.10).]

** Eqs. (A.2) and (A.3), and (A.7) below are obtained from the exact expressions after some reduction taking the best advantage of the fact that $c(k)\ll\omega\ll\lambda$. We need only to retain the main part of the term linear in c_0. We can further omit all terms linear in $u_{k'}{}^2-v_{k'}{}^2$ provided that they have either a product $u_{k'}v_{k'}$ as a factor or a denominator involving $E_{k'}$, because in this case the important region for the summation over $\boldsymbol{k}'$ is limited to $\boldsymbol{k}'$ in a close vicinity of the Fermi surface, where the density of states $k'^2/(2\pi^2d\xi_{k'}/dk')$ is approximately constant (according to the condition c_0, $\omega\ll\lambda$), and the quantity $u_{k'}{}^2-v_{k'}{}^2$ is an odd function of $\xi_{k'}$.

$$\Phi_{\rm II}(k)=-\left(\frac{g^2}{2V}\right)^2\sum_{k',k''}\left\{\omega\ u'v'\left[\frac{\omega_{kk''}}{(D_{kk''}+2E)(D_{kk'}+D_{kk''})D_{kk''}}\right.\right.$$

$$\left.+\frac{\omega_{k'k''}}{D_{k'k''}+2E)(D_{kk'}+D_{k'k''}-2E')D_{k'k''}}\right]$$

$$\left.-\frac{\omega_{kk''}u''v''}{D_{kk''}{}^2}\left[\frac{\omega_{kk'}}{D_{kk'}+D_{kk''}-2E}+\frac{\omega_{k'k''}}{D_{kk''}+D_{k'k''}-2E''}\right]\right\}, \qquad \text{(A.3)}$$

where the suffix k, k', $\cdots$ are suppressed for clarity (except for $\omega_{kk'}$, $D_{kk'}$, $\cdots$) and $D_{kk'}\equiv\omega_{kk'}+E_k+E_{k'}$, etc. It is convenient to evaluate $\Phi_{\rm I}(k)+\Phi_{\rm II}(k)$ instead of evaluating $\Phi_{\rm I}(k)$ and $\Phi_{\rm II}(k$ separately. The evaluation is rather straightforward if one goes over from summation to integration and replaces all phonon energies by the average value ω $[=(3/5)k\Theta_D]$ introduced in § 2, giving

$$\Phi_{\rm I}(k)+\Phi_{\rm II}(k)=-2(1-\ln 2)c_0A^2x/(1+E/\omega)\ . \qquad \text{(A.4)}$$

Evaluation of $\Phi_{\rm III}(k)$ and $\Phi_{\rm IV}(k)$ can be carried out similarly with the result

$$\Phi_{\rm III}(k)=-(2\ln 2)c_0A^2x/(1+E/\omega)\ , \qquad \text{(A.5)}$$

$$\Phi_{\rm IV}(k)=(1/2)c_0A^2x/(1+E/\omega)\ . \qquad \text{(A.6)}$$

These results are not very accurate for $E>\omega$, but this fact does not affect any final result obtained in the text.

Straightfoward evaluation of $\Phi_{\rm V}(k)-\Phi_{\rm XIII}(k)$ is a difficult problem, since in these cases we encounter summations over three momenta which are not independent but are connected by the momentum conservation law. We devise a shortcut means of evaluating them at the sacrifice of accuracy. The actual procedure will be described taking $\Phi_{\rm VIII}(k)$ as a typical example. We have to evaluate

$$\Phi_{\rm VIII}(k)=\left(\frac{g^2}{2V}\right)^2\sum_{k',k'',k'''}{}'\frac{\omega_{kk'}{}^2u'v'}{E+E'+E''+E'''}\left\{\frac{1}{(D_{kk'}+2E)D_{kk'}}+\frac{1}{(D_{k''k'''}+2E)D_{k''k'''}}\right\}, \qquad \text{(A.7)}$$

where the prime over the summation symbol indicates that the momentum conservation $\boldsymbol{k}'-\boldsymbol{k}=\boldsymbol{k}'''-\boldsymbol{k}''$ should be satisfied. Since we need not an accurate result for $E>\omega$, we can drop $2E$ from the second denominators. We can also omit E' from the first denominator because we have a factor $u'v'$ in the numerator. Furthermore, E', E'' and E''' can be replaced by $|\xi'|$, $|\xi''|$ and $|\xi'''|$, respectively, in all denominators without loss of accuracy. We introduce polar coordinates k', θ', φ' and k'', θ'', φ'', taking the z-axis coinciding with the vector $\boldsymbol{k}$. We have then

$$k'''^2=k_0{}^2\{2+(k''/k_0)^2-2\cos\theta'-2(k''/k_0)\cos\theta''$$
$$+2(k''/k_0)[\cos\theta'\cos\theta''+\sin\theta'\sin\theta''\cos(\varphi'+\varphi'')]\}\ , \qquad \text{(A.8)}$$

where both $|\boldsymbol{k}|$ and $|\boldsymbol{k}'|$ are replaced approximately by the momentum such that $\lambda=\hbar^2k_0{}^2/2m$. If we introduce new variables such as $\eta'=\xi'/c_0$, $\eta''=\xi''/c_0$, $\eta'''=\xi'''/c_0$, $t'=\cos\theta'$, $t''=\cos\theta''$, $\varphi=\varphi'+\varphi''$ together with the dimensionless quantities $L=\lambda/c_0$, $\delta=\omega/c_0$, then we have, after integrating with respect to ϕ',

$$\Phi_{\rm VIII}(k)=\frac{A^2c_0\delta}{32\pi^2}\int_{-L}^{\infty}d\eta'\int_{-L}^{\infty}d\eta''\int_{-t_0}^{1}dt'\int_{-1}^{1}dt''\int_{0}^{2\pi}d\varphi$$

$$\times\frac{1}{(E/c_0+|\eta''|+|\eta'''|)\sqrt{1+\eta'^2}}\left\{\frac{1}{(\delta+E/c_0+|\eta'|)^2}+\frac{1}{(\delta+|\eta''|+|\eta'''|)^2}\right\}, \qquad \text{(A.9)}$$

where

$$\eta'''=2L+\eta''-2Lt'-2L\sqrt{L(L+\eta'')}\,t''$$
$$+2\sqrt{L(L+\eta'')}(t't''+\sqrt{1-t'^2}\sqrt{1-t''^2}\cos\varphi)\ . \qquad \text{(A.10)}$$

The last relation has been derived from (A.8) by putting approximately $k''^2=k_0^2+2mc_0\eta''/\hbar^2$ and $k'''^2=k_0^2+2mc_0\eta'''/\hbar^2$. The lower limit of the t'-integration is chosen as $-t_0$, which was introduced in (2.26) and related to the maximum phonon energy by Eq. (2.27). The approximations made so far have little effect on the accuracy of the final result as long as we are interested in the main term of $\Phi_{\text{VIII}}(k)$.

To proceed further, we put, first of all, $-t_0=-1$. We believe that this approximation does not bring forth any large error, because the largest possible value of θ' is not largely apart from π and, moreover, $dt'/d\theta'$ is very small for θ' close to π.

Before taking a next step, we shall attempt to find a conventional method of evaluating the following integral

$$I(\eta'')=(8\pi)^{-1}\int_{-1}^{1}dt'\int_{-1}^{1}dt''\int_{0}^{2\pi}d\varphi f(\eta'''), \tag{A.11}$$

where $f(\eta''')$ may be any arbitrary function of η''' and is assumed to be expressed as a function of t', t'' and φ according to (A.10). We try to replace this triple integral approximately by a single integral

$$I'(\eta'')=\int_{-L}^{\infty}P(\eta'',\eta''')f(\eta''')d\eta''', \tag{A.12}$$

introducting an appropriately chosen probability density $P(\eta'',\eta''')$. Graphical consideration suggests that one may put, with a fairly good approximation,

$$P(\eta'',\eta''')=\begin{cases} P(\eta''), & -L<\eta'''<Y(\eta''), \\ 0, & \text{otherwise.}\end{cases}$$

In the actual procedure we determine $P(\eta'')$ and $Y(\eta'')$ so that we get an exact result for a simple case, $f(\eta''')\equiv\eta'''$. It follows then

$$P(\eta'')=(6L+2\eta'')^{-1}, \qquad Y(\eta'')=5L+2\eta'', \tag{A.13}$$

as easily verified by directly integrating both integrals and comparing the results. To check up to what extent this procedure is useful, we apply it to the evaluation of some directly integrable functions and compare the result, $I'(\eta'')$, with that of direct integration, $I(\eta'')$, in the following table.

	η''	$f(\eta''')\equiv\eta'''$	η'''^2	η'''^4	η'''^6	$[(5L-2\eta'')^2-\eta'''^2]^3$
$\left(\frac{I'-I}{I}\right)\times 100$ (errors in %)	$-L$	0	0	0	0	0
	0	0	+14	+84	+227	+6
	L	0	+9	+62	+86	+5

Note that the method is fairly reliable when aplied to the function $[(5L-2\eta'')^2-\eta'''^2]^3$, to which the actual integrand in (A.7) bears the best resemblance. Both functions have a maximum at $\eta'''=0$ and descreasing on both sides. We may thus expect errors of the same order of magnitude as those listed in the last columm when the present method is applied to the evaluation of $\Phi_{\text{VIII}}(k)$. Applying (A.12) with (A.13), we can transform (A.9) into the form

$$\Phi_{\text{VIII}}(k)=\frac{A^2c_0\delta}{4}\int_{-L}^{L}\frac{d\eta'}{\sqrt{1+\eta'^2}}\int_{-L}^{L}\frac{d\eta''}{6L-2\eta''}\int_{-L}^{5L-2\eta''}\left\{\frac{1}{(\delta+E/c_0+|\eta'|)^2}+\frac{1}{(\delta+|\eta''|+|\eta'''|)^2}\right\} \times\frac{d\eta'''}{E/c_0+|\eta''|+|\eta'''|}. \tag{A.14}$$

The approximate evaluation of the right-hand side is now possible. The first term in the brackets gives

$$-(1.38/4)c_0A^2x/(1+E/\omega)^2 \tag{A.15}$$

and the second term is found to be

$$-c_0 A^2 x(\omega/\lambda) \ln(\lambda/\omega) \tag{A.16}$$

except for numerical factor of order 1. Assuming $\omega/\lambda \ll 1$ we neglect (A.16) and get

$$\Phi_{\mathrm{VIII}}(k) = -(1.38/4) c_0 A^2 x/(1+E/\omega)^2 \,. \tag{A.17}$$

Evaluating all remaining $\Phi_i(k)$'s in similar ways, we find that $\Phi_{\mathrm{IX}}(k)$, $\Phi_{\mathrm{XII}}(k)$ and $\Phi_{\mathrm{XIII}}(k$ have the same contribution as $\Phi_{\mathrm{VIII}}(k)$ except for unimportant difference in E-dependent factor and all other $\Phi_i(k)$'s can be neglected. Thus, we have

$$\Phi_{\mathrm{IX}}(k) = \Phi_{\mathrm{XII}}(k) = \Phi_{\mathrm{XIII}}(k) = -(1.38/4) c_0 A^2 x/(1+E/\omega)^2 \,, \tag{A.18}$$

where we have assumed the same E-dependence as in $\Phi_{\mathrm{VIII}}(k)$.

By use of (A.4), (A.5), (A.6), (A.17) and (A.18), we get finally

$$\sum_i \Phi_i(k) = -\gamma c_0 A^2 x/(1+E/\omega) \tag{A.19}$$

with

$$\gamma = 2(1-\ln 2) + 2\ln 2 - 1/2 - 4(1.38/4) \doteqdot 0.1 \,, \tag{A.20}$$

where a common factor $(1+E/\omega)^{-1}$ is applied to all $\Phi_i(k)$'s. Since the positive and negative contributions to γ nearly cancels each other, there might be a large error in the value of γ arising from the rough estimate (A.17) and (A.18). We believe, however, that this does not exceed two hundred percents.

Impurity Trapped Interstitials and the Low Temperature Annealing Stages of Irradiated Copper

By Ryukiti R. HASIGUTI

Department of Metallurgy, University of Tokyo

(Received May 7, 1960)

A semi-empirical method was developed to evaluate interaction energies of close impurity-atom-interstitial pairs. It was found that an undersize impurity atom provides with a deep trap for an interstitial, while an oversize impurity atom furnishes to an interstitial several shallow traps with different interaction energies. These results were applied to the annealing temperature problem of irradiated copper. Stage II was interpreted as due to the liberations and annihilations of several kinds of shallow trapped interstitials, and stage III was explained as due to the liberations and annihilations of deep trapped interstitials.

1. Introduction

The behaviors of lattice defects introduced into noble metals such as copper, gold and silver by electron, deuteron or neutron irradiations have been extensively investigated by many workers1). Copper is especially well investigated among these metals from both experimental and theoretical standpoints1). Nevertheless several most important problems are not yet solved. One of these important unsolved problems is the low temperature annealing stage problem of irradiated copper.

Annealing of lattice defects in copper takes place in five successive temperature stages1),2),3). The stage I ranges from about 14°K to about 65°K. The stage II has so wide a range that it is often called a garbage annealing stage. It extends from the end of stage I to the advent of stage III. The stage III has a fairly sharp range, which extends from about 240°K to about 300°K. The temperature range of stage IV is considerably different according to different authors, but it extends usually from about 100°C to about 200°C. The stage V is usually found in the range from about 300°C to about 400°C.

As far as the stage V is concerned, the interpretations by different authors agree with each other. We shall omit, therefore, to consider the stage V. The interpretations of lower four stages are quite confusing today, as will be shown in the next section.

The present author will propose in this paper a new interpretation which explains the lower four stages consistently. Interstitial atoms trapped by impurity atoms will play important roles in the interpretation of stages II and III. We shall investigate the behaviors of these impurity trapped interstitials from various points of view.

§ 2. Previous Interpretations of Annealing Stages

Earlier interpretations appeared in literatures up to 1955 were reviewed and tabulated by Glen4). Interpretations appeared since 1956 will be summerized in Table I. The last row shows the interpretation proposed by the present author in this paper.

Now we shall consider the five views shown in Table I. Earlier views up to 1955 will be

considered, when it will be necessary to do so. The ways of allocations of various lattice defects to four annealing stages in Table I are roughly divided into two categories. The views expressed by the first three groups of investigators belong to the first category, and those shown by the second two research groups make the second category.

The chracteristics of the first category are in that stage IV is considered to be due to the migration of free vacancies and that the stage III is considered to be due to the migration of free interstitials except the case of van Bueren[3]. In the second category, it is considered that the free interstitials migrate in the stage I and the free vacancies migrate in the stage III. All the research groups agree with each other in two points; i.e. in the first place close vacancy-interstitial (V–I) pairs annihilate at least partly in stage I, and in the second place free interstitials migrate always at lower temperatures than free vacancies.

It must be emphasized here that G. E. group[6),7),8] and Illinois group[10] have performed most beautiful experimental works concerning the stage I. More detailed works have never been done concerning the other stages. The results published by these two groups will be shown in Table II.

Table II. Interpretations of annealing sub-stages.

Sub-stages	I_A	I_B	I_C	I_D	I_E
Corbett et al.	c.p. (1)	c.p. (2)	c.p. (3)	I (corr.)	I (uncorr.)
Ill, group	c.p.	c.p.	c.p.	I	

c.p. (1), etc.: first closest pair, etc., (corr.): correlated recombination, (uncorr.): uncorrelated recombination.

G. E. group found five sub-stages in the stage I. After careful analyses of their results, they conclude that the first three substages are due to recombinations of close V–I pairs with different interaction energies, and that the last two sub-stages are due to migrations of free interstitials to recombine with correlated vacancies (sub-stage I_D) or with uncorrelated vacancies (sub-stage I_E). Illinois group also found a fine structure of the stage I.

It may be considered that the mechanisms of annealing in stage I were clarified as the results of investigations of G. E. group and Illinois group to such an extent as we can believe that free migrating interstitials, besides close V–I pairs, do contribute to the annealing processes in stage I. This means that the interpretations which include the allocations of free interstitials to stage II or III must be revised. On the other hand, it is highly probable from the experimental results on cold-worked copper[11] and quenched copper[12] that the stage IV is due to the migration of free vacancies. It seems that the confusion of interpretations by various schools comes mainly from the unclearness of stages II and III. It is the main objective of this paper to make these two stages clear.

§ 3. Evidences for trapping of Interstitials by Impurity Atoms

Impurity trapping of interstitials is by no means a new concept. It was first discussed by Lomer and Cottrell[13] in 1955. It was not, however, on the firm foundation of knowledges that they considered the impurity trapping of interstitialcies*, because important informations concerning the behaviors of interstitials in stage I annealing processes were lacking at that time. Many authors, who treated the annealing stage problems since 1956, rather disregarded the important roles of impurity trapped interstitials, although they considered, so to say, the auxiliary functions of these trapped interstitials, as some examples are seen in Table I.

There are many experimental evidences for impurity trapping of interstitials. We shall show here an evidence which is important from the point of view of the present paper.

According to Blewitt and others[14], the stage I annealing process is partially or completely suppressed in properly impurity doped copper as shown in Fig. 1. In this figure the lower curve shows the isochronal annealing behavior of 99.999+% copper neutron-irradiated at 14.5°K. The stage I is suppressed about 60% in 0.1% Be-doped specimen as shown by the middle curve. The complete suppression is seen in the upper curve, where the specimen is doped with 1% Be. The suppression of stage I annealing process can be understood, if it is considered that the defects, which migrate in the stage I, are trapped by beryllium atoms. If the migrating defects are interstitials, it is natural that they are trapped by undersize impurity atoms like beryllium. It is also possible for an oversize impurity atom to trap an interstitial by Eshelby's elastic interaction[15)]. This point will be discussed in detail later.

---

* As far as the static nature is concerned, an interstitialcy is considered to be the same as an interstitial.

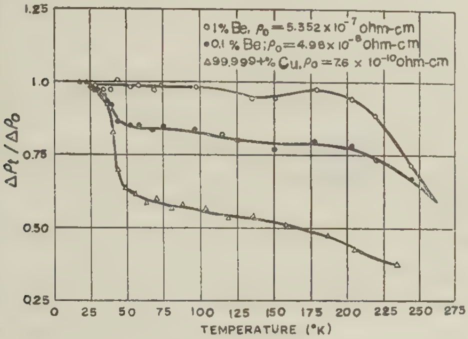

Fig. 1. The isochronal annealing curve of beryllium-doped copper following a reactor irradiation at 14.5°K. $\Delta\rho_t/\Delta\rho_0$ is the fraction of the radiation-induced resistivity remaining after each annealing pulse. (After Blewitt et al.[14)])

§ 4. Elastic Interaction between an Interstitial Atom and an Impurity Atom

Now we shall consider the interactions between an interstitial atom and an impurity atom. First of all let us consider the interaction calculated by the elasticity theory. According to Eshelby[15)], the interaction energy E_{int} between two defects with dilatations Δv_1 and Δv_2 is expressed by

$$E_{\text{int}}=-\frac{15d}{8\pi\gamma^2}\Delta v_1\Delta v_2\frac{\Gamma}{r^3}\,, \tag{1}$$

$$\gamma=3(1-\sigma)/(1+\sigma)\,, \tag{2}$$

$$\Gamma=\frac{2}{5}-2(l^2m^2+m^2n^2+n^2l^2)\,, \tag{3}$$

where d is a constant with negative value in the case of metals which is derived from elastic constants, σ is Poisson's ratio, r is the distance between two point defects, and l, m and n are direction cosines. The dilation Δv should be taken here as that in a body with a free surface. If $\Delta v_1\Delta v_2$ is negative and Γ is positive, the interaction will be attractive, because d is always negative in the case of metals.

The interaction can, however, be either attractive or repulsive for a given pair of defects, if the configuration of two defects changes, because the value of Γ can either be positive or negative according to the values of direction cosines. In other words an attractive interaction is expected from both negative and positive values of $\Delta v_1\Delta v_2$, which means that an interstitial is trapped by an oversize impurity atom as well as by an undersize impurity atom. This was pointed out in section 3.

An interstitial atom in a face-centered cubic lattice can take various forms in the crystal lattice, i.e. (1) an ordinary interstitial form, in which the interstitial atom occupies the the body center of cubic unit cell, (2) Huntington's C configuration[16)], and (3) a crowdion form. An atom in the ordinary interstitial form will be called simply an interstitial atom or an interstitial in this paper.

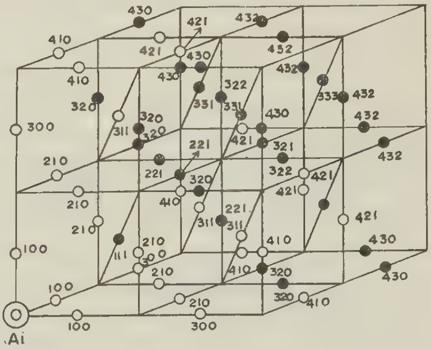

Fig. 2. Various configurations of impurity-atom-interstitial pairs in face-centered cubic lattice. ◎: substitutional impurity atom, ○: interstitial for $\Gamma>0$, ●: interstitial for $\Gamma<0$. No distinction is made between (100), (010), (001), etc. The unit of the coordinates is $a/2$.

Various possible configurations of impurity-atom-interstitial (A_i–I) complexes or associations are shown in Fig. 2. A double circle at the left *h* and lower corner shows a substitutional impurity atom (A_i) and open and solid circles indicate the possible positions of interstitial atoms. The figures at these circles show the coordinates of interstitials, of which the unit is in $a/2$, where a is the lattice constant. No distinction is made between (100), (010), (001), etc. in the figure. Open circles show the interstitial positions for $\Gamma>0$, and solid ones show those for $\Gamma<0$. The values of Γ for various configurations are given in

Table III. The distance r is expressed in unit of $a/2$ in the table.

The dilatations of interstitial (I), vacancy (V) and various impurity atoms are shown in Table IV. Impurity atoms in the middle columns of the table are those used in the experiments by Blewitt et al.[14], as some of them are shown in Figs. 1, 5 and 6. The right hand columns of the table contain impurity atoms usually found in high purity copper. They are shown in the order of decreasing amount in copper except phosphorus. Phosphorus is found in considerable amount in copper in some cases, and is not found at all in other cases.

Ω: atomic volume of copper.
* From Tucker and Sampson (Acta Met. **2** (1954) 433).
** From Tewordt (Phys. Rev. **109** (1958) 61).

Fig. 3 shows interaction energy vs. A_i–I distance curves calculated from the equation (1) with $\Delta v_1 \Delta v_2 = 0.9\Omega^2$, where Ω is the atomic volume of copper. Energies are expressed in their absolute values. Curves 1 and 2 are for $\Gamma = +0.400$ and $\Gamma = -0.267$, respectively. Interaction energies of various A_i–I configurations with these two values of Γ are shown as open circles on the curves, and those with other values of Γ than these two are shown as triangles without accompanying curves.

As the Eshelby's equation is based on the elasticity theory, it cannot be applied to very close A_i–I pairs. Corbett et al.[6] hesitatingly use the elasticity equation to calculate the interaction energy of vacancy-interstitial pair as close as (300) configuration. Magnuson et al.[10] apply the same equation to estimate the interaction energy of interstitial pair in (222) configuration, although they point out that a careful atomic calculation should be made to obtain more reliable value. It seems after

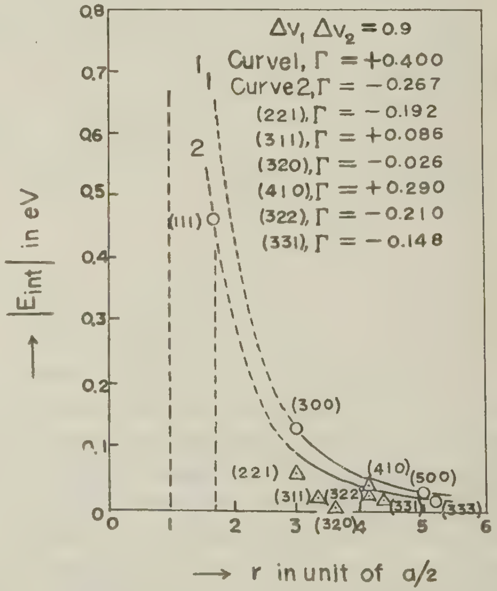

Fig. 3. Interaction energies calculated by elasticity theory. Dotted portions of the curves are rather meaningless, because elasticity theory fails there. Interaction energies are expressed in their absolute values.

all that the elasticity equation is not applicable inside $r=3\sim4$. The dotted portions of the curves in Fig. 3 are rather meaningless, because they are in the region where the equation (1) fails.

However, the interaction energies of close A_i–I pairs, where the elasticity theory fails, are what we want to know the most to elucidate the trapping behaviors of interstitials by impurity atoms. We shall consider this problem from a different point of view in the next section.

§ 5. Interaction Energies of Close Impurity-Atom-Interstitial Pairs

As mentioned above, the interaction energies of close A_i–I pairs with separations less than $r=3\sim4$ cannot be calculated by the elasticity equation. We shall use some experimental data to estimate the interaction energies at moment to avoid rather complicated straightforward atomic calculations.

In section 3, we referred to the experiments by Blewitt et al.[14] on the suppression of stage I annealing processes by impurity doping. Fig. 1 shows of examples of beryllium doped copper. These results can be interpreted as follows. In 1% beryllium doped copper (the upper curve in Fig. 1) all the interstitials produced by neutron irradiation are trapped by beryllium atoms, resulting in a disappearance of annealing stage I. These trapped interstitials are released from impurity atoms above about 200°K as is seen from the upper curve in Fig. 1. If the annealing kinetics for the temperature range above 200°K, which is evidently the annealing stage III, are known, we can calculate the activation energy, E, of this annealing process. If this annealing process is considered to be due to the release of impurity trapped interstitials, and if E is known, we are able to obtain the interaction energy from the equation

$$E=E_{\text{int}}+E_{\text{mig}}\ , \tag{4}$$

where E_{mig} is the migration energy of an interstitial. As the released interstitials will migrate very quickly to appropriate sinks and will disappear there, the dissociation of A_i–I pairs will form the rate determining process. Hence the above equation (4) is justified.

It would be possible to assume appropriate kinetics for the annealing process to obtain the activation energy, E, from the data of Blewitt et al., if necessary. However, the accurate estimation of activation energy from insufficient data is not necessarily important for the objective of this paper. We shall choose, therefore, the simplest possible way to estimate the activation energy.

It is recognized that the average absolute temperature, T_a, at which the annealing process is observed in usual measurements, is proportional to the activation energy, when the annealing processes in question are similar in nature to each other. This may be expressed as

$$T_a=cE\ , \tag{5}$$

where c is a proportionality constant. This equation is easily derived from the rate equations of annealing processes, if the same entropy of activation is assumed for different annealing processes. And this relation can be well checked experimentally, if well-defined suitable experimental data are chosen.

Now it may be assumed that the constants c's obtained from different experiments give the same values, if the annealing temperature stages concerned are the same with each other, because it is considered that the annealing modes are the same in the same annealing temperature stages. This assumption may be especially well applied in the case of such a well-defined stage as the stage III, with which we are concerned now. We shall use, therefore, the data of T_a and E of annealing stage III by several workers including those of deuteron irradiated copper by Overhauser[17] to obtain the value of c. Then c is calculated as

$$c=380°\text{K/eV}\ . \tag{6}$$

Taking the average annealing temperature as 230°K in the case of beryllium doped copper (Fig. 1), we obtain 0.49 eV for $A_{i(\text{Be})}$–I interaction energy from the equations (4) and (5) and the value (6). E_{mig} was put as 0.12 eV according to Corbett et al.[6] Now we shall put as

$$E_{\text{int(Be)}}=0.5\text{ eV}\ , \tag{7}$$

instead of 0.49 eV, considering the low accuracy of the method to obtained the interaction energy.

This energy, $E_{\text{int(Be)}}$, is considered to be for the closest $A_{i(\text{Be})}$–I pair with (100) configuration, because beryllium is an undersize atom. This point will be discussed later in detail.

The next problem is to combine the above obtained E_{int} with elasticity curve (Fig. 3). This was done in Fig. 4. An open circle at the left end of curve (2) indicates the $E_{\mathrm{int(Be)}}$ value for (100) configuration. The curve (1), which is the same as the curve (1) in Fig. 3, represents the elasticity equation (1).

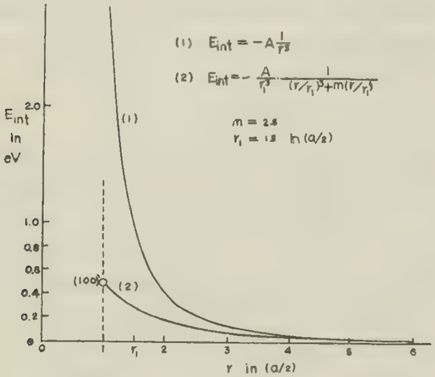

Fig. 4. Interaction energies between a beryllium atom and an interstitial in copper. Curve (2) is calculated from the equation (8). Curve (1) is calculated from the elasticity equation for comparison.

Now we assume a relation between E_{int} and r as

$$E_{\mathrm{int}}=-\frac{A}{r_1^3}\cdot\frac{1}{(r/r_1)^3+m(r/r_1)}\,, \qquad (8)$$

to obtain the values of interaction energy at various separations. The equation (8) is just a conventional expression which reduces to the elasticity equation at large separations as is seen from the curve (2) in Fig. 4. The curve (2) is obtained, putting $m=2.5$ and $r_1=1.5$ (in $a/2$).

Now the interaction energies of various A_i–I configurations are calculated by means of the equation (8). The results are shown in Tables V and VI. These values are only to obtain a knowledge of the order of magnitudes.

§ 6. Stable and Unstable Configurations

Various A_i–I configurations were shown in Fig. 1 in section 3. We have to distinguish, however, between stable and unstable configurations as follows. Let us first examine an undersize impurity atom, which attracts an interstitial, if Γ is positive. (100) configuration is of course stable, because it is the closest pair with attractive force.

Table V. Various configuration of impurity-atom-interstitial pairs in the case of undersize beryllium atoms in copper crystal. The (300) configuration and others are unstable and will change to the (100) configuration as indicated by the arrow.

$\Gamma>0$, undersize atom (attraction)			
(100)	stable	$E_{\mathrm{int}}\approx0.5$,	$E\approx0.62$
(300)	⟶ (100)		
(210)	⟶ (100)		
(311)	stable	$E_{\mathrm{int}}\approx0.01$,	$E\approx0.13$
(410)	⟶ (210)	⟶ (100)	
(421)	⟶ (410)	⟶ (210)	⟶ (100)

Table VI. Various configurations of impurity-atom-interstitial pairs in the case of oversize gold atoms in copper crystal. The arrows indicate the change to the stable configuration.

$\Gamma<0$, oversize atom (attraction)			
(111)	stable	$E_{\mathrm{int}}\approx0.17$,	$E\approx0.29$
(221)	stable	$E_{\mathrm{int}}\approx0.03$,	$E\approx0.15$
(320)	stable	$E_{\mathrm{int}}\approx0.003$,	$E\approx0.12$
(322)	⟶ (221)		
(331)	stable	$E_{\mathrm{int}}\approx0.01$,	$E\approx0.13$
(430)	⟶ (320)		
(333)	⟶ (331)		
(432)	⟶ (322)	⟶ (221)	

It is usually considered that an interstitial moves always in ⟨100⟩ direction[10]. This means that an interstitial makes interstitialcy movements, when it migrates through the crystal lattice. In other words it has the "C configuration" of Huntington[16] as the saddle point, when it makes migration through the lattice. This restriction of the migrating direction is a condition for considering stable configurations.

Now the (300) configuration will be considered. An interstitial at (300) position will move towards the impurity atom by the attractive force, resulting in an (100) configuration. Thus the (300) is an unstable configuration. The results of this kind of considerations are shown in Table 5 for an undersize impurity atom with $\Gamma>0$. It is seen that (300), (210), (410), (421), etc. are all unstable, all reducing to (100) configuration. The only one stable position other than (100) is (311), which has $E_{\text{int}} \approx 0.01$ eV. (311) is stable, because (111) is a repulsive position.

It should be emphasized here, however, that the occurence of (311) is rather seldom, because it cannot be reached from any other position in the eight unit cells in Fig. 2, while all the open circled positions other than (311) reduce to (100) positions as shown in Table V. (311) cannot be reached from (331), because (331) is a repulsive position. It is possible of course to reach (311) from (511), but (511) configuration has an almost negligible interaction. It may be concluded after all that (100) is almost the unique stable configuration for an undersize impurity atom, although it may be an over-simplification to neglect completely the (311) positions.

The activation energy of annealing process due to the dissociation of $A_{i(\text{Be})}$–I pairs is 0.62 eV as shown in Table V. This is for the stage III annealing process. Dissociated interstitials disappear very quickly recombining with vacancies, resulting in second order kinetics.

§ 7. Oversize Impurity Atoms

The situation for an oversize impurity atom is quite different. The results of considerations along the same line as before are given in Table 6 for an impurity gold atom, which is an oversize atom. An oversize atom attracts an interstitial, when Γ is negative. As are shown in the table, there are four stable configurations in the eight unit cells of Fig. 1. The occurrences of these configurations are comparatively evenly distributed. The values of activation energies range from 0.12 eV to 0.29 eV as shown in Table VI. The interaction energies for $A_{i(\text{Au})}$–I pairs were calculated using the equation (8) with constants obtained through $A_{i(\text{Be})}$–I interaction.

The results in Table VI should be compared with Fig. 5, which is a reproduction of the experimental results on gold-doped copper by Blewitt et al.[14] As are expected from the results in Table VI, the annealing stages of irradiated gold-doped copper should extend rather continuously from the end of stage I to some higher temperatures as a result of overlapping of several annealing processes with different activation energies. This type of annealing is found in Fig. 5. In other words Blewitt's results on gold-doped copper are explained at least qualitatively by our model. Incidentally Blewitt et al. explain their results in a different way[14].

Blewitt et al. performed further experiments on nickel-, silicon-, and zinc-doped copper. These results are all explained at least qualitatively by our model.

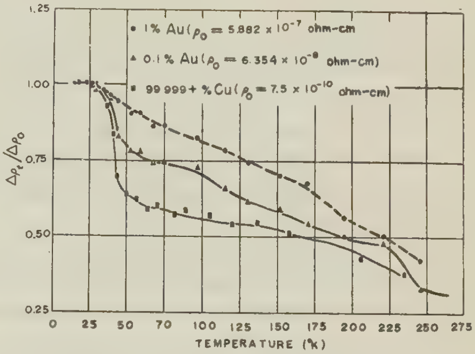

Fig. 5. The isochronal annealing curve of gold-doped copper following a reactor irradiation at 14.5°K. $\Delta\rho_t/\Delta\rho_0$ is the fraction of the radiation induced resistivity remaining after each annealing pulse. (After Blewitt et al.[14])

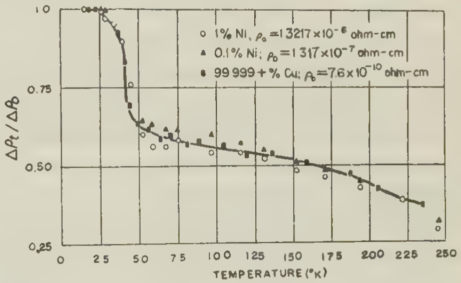

Fig. 6. The isochronal annealing curve of nickel-doped copper following a reactor irradiation at 14.5°K. $\Delta\rho_t/\Delta\rho_0$ is the fraction of the radiation-induced resistivity remaining after each annealing pulse. (After Blewitt et al.[14])

The addition of 1% nickel shows almost no influence on the annealing behaviors of copper, as is seen from Fig. 6. This is understandable from the small dilatation of nickel (see Table IV). But if the interaction energy of $A_{i(\text{Ni})}$–I is calculated from the equation (8) with constants obtained through beryllium-atom-interstitial interaction, there should be a small interaction, which is not found in Fig. 6. This discrepancy may be due to some effects other than atomic radius effect.

Although the behaviors of silicon (undersize) and zinc (oversize) are understood qualitatively on the basis of atomic radius concept, it seems there are some additional effects again in these cases. These effects may presumably be valence effects. To inquire further, however, into this problem is not the aim of this paper.

§ 8. Conclusions

(1) Both undersize impurity atoms and oversize impurity atoms trap interstitials.

(2) Various configurations of impurity-atom-interstitial pairs were considered.

(3) An undersize impurity atom provides with a deep trap, if the dilatation is large. An undersize atom with a small dilatation gives rise of course to a shallow trap.

(4) An oversize impurity atom furnishes several shallow traps with different interaction energies.

(5) Annealing temperature stages of irradiated copper are interpreted as follows.

(5a) Stage I is considered after G. E. group and Illinois group to be due to the annihilations of close V–I pairs and free migrating interstitials.

(5b) Stage II is interpreted as due to the liberations and annihilations of several kinds of shallow trapped interstitials (I*) with different interaction energies. The annihilations of divacancies and the dissociations and annihilations of multi-interstitials will take place in this stage, if they exist.

(5c) Stages III is considered to be due to the liberations and annihilations of deep trapped interstitials (I**) with almost unique interaction energy. The annihilation of liberated interstitials is achieved by the recombination with vacancies, which results in second order kinetics.

(5d) Stages IV is considered to be due to the annihilation of vacancies.

(5e) These interpretations are summarized in the last row of Table I.

Note added in proof. We have recently received a preprint of an article entitled "Thermally Activated Point Defect Migration in Copper" by C. J. Meechan, A. Sosin and J. A. Brinkman, in which A. I. group have modified their annealing model from the one presented in the present paper as the A. I. model.

The Structure Analysis of $AuCu_3$ by Means of a Fourier Transformation of X-ray Diffuse Scatterings

By Kenji DOI

Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, Japan

(Received December 10, 1959)

The method of analysing the two-dimensional disordered structure using the function;

$$\varphi_H(x_1, x_2)=\iint A(s_1,s_2)\frac{\sin \pi a_1(s_1-s_1{}^H)}{\pi(s_1-s_1{}^H)}\cdot\frac{\sin \pi a_2(s_2-s_2{}^H)}{\pi(s_2-s_2{}^H)}\exp 2\pi i\{(s_1-s_1{}^H\cdot x_1)+s_2-s_2{}^H\cdot x_2)\}ds_1ds_2$$

is described, where $s_1{}^H$ and $s_2{}^H$ mean the coordinates of a relpoint $H(=hk0)$, and $A(s_1, s_2)$ the *amplitude* of the diffuse scattering at the point (s_1, s_2) in reciprocal space.

The method is applied to the disordered structure of Cu_3Au projected upon (001), giving the statistical parameters describing the atomic composition of each atomic site. The unit cell compositions, which are readily derived from the atomic site compositions, are found appreciably deviated from those corresponding to the bulk composition of Cu_3Au, the Au-rich cell being surrounded by the Cu-rich ones. This suggests that the ordering of this alloy progresses rather by the inter- changes of neighbouring atoms than by the growth of domains in which Au atoms are supposed not to come in contact with each other.

In Appendices remarks are given in relation to the short-range order parameters, and the significances of phase assignments for diffuse scatterings are discussed.

§ 1. Introduction

The diffuse scatterings produced by the disordered alloy crystals have been usually interpreted in terms of the short-range order parameters which specify the statistical characters of atom *pairs* of given separation and orientation. For instance Cowley[1] has developed a method of deriving the short-range order parameters from the diffuse scattering of X-rays by the Fourier transformation of *intensity* distribution in reciprocal space. It is noted, however, that the short-range order parameters alone cannot be considered as a full description of the disordered structure, in the sence that in usual structure analyses Patterson maps cannot be regarded as to give full informations on crystal structures.

Just as in the case of the usual perfect crystal analysis, it was shown[2] that certain plausible assumptions as to the structure examined made it possible to assign phase angles to the diffuse scatterings, and thus to derive more direct informations on the statistical structure of the disordered crystal, than those derived from intensity distribution. In other words, the statistical parameters describing the disordered structure can be deduced not only for the atom *pairs* but also for the configurations of atoms present in the structure examined. An application was given for the structure analysis of Guinier-Preston zone[3] which gives rise to diffuse scatterings in the neighbourhoods of the relpoints of matrix crystal.

In this paper the method is applied to the diffuse scatterings distributed in the neighbourhoods of the superlattice points of the $AuCu_3$ crystal above the critical point; giving as results the statistical parameters specifying more directly the disordered state of alloy structure than the usual short-rang order parameters.

§ 2. The principle of analysis

Let us consider a crystal in which the electron density distribution is represented by a function $\rho(\boldsymbol{x})$ which is not necessarily periodic with respect to the coordinate $\boldsymbol{x}$. The intensity of X-rays diffracted by this is given by

$$I(\boldsymbol{s})=|A(\boldsymbol{s})|^2 \qquad (1)$$

with

$$A(\boldsymbol{s})=\int \rho(\boldsymbol{x}) \exp -2\pi i \boldsymbol{s}\cdot \boldsymbol{x} dv_x \, . \qquad (2)$$

With inversion of (2), we have

$$\rho(\boldsymbol{x})=\int A(\boldsymbol{s}) \exp 2\pi i \boldsymbol{s}\cdot \boldsymbol{x} dv_s \, . \qquad (3)$$

It is noted here that the Fourier reciprocity (2) and (3) need not be restricted to the cases where $\rho(x)$ is strictly periodic, that is to say, structure analyses using the Fourier relations (2), (3) are feasible for disordered structures as well as for the perfectly ordered structures, *provided that the phase angles can be defined without ambiguity and that they can be assigned correctly in reciprocal space*[2),3)].

The principle of analysis here developed consists of taking into account of the intensity distributions only in the limited region of reciprocal space, which permits us to assign phase angles of scattered X-rays with less arbitrary and more plausible assumptions as will be seen at the end of this section.

For example, let us take a two-dimensional structure $\rho(x_1, x_2)$ and consider a function related to it:

$$\varphi_H(x_1, x_2)=\iint A(s_1, s_2) K_{a_1}(s_1-s_1^H) \cdot K_{a_2}(s_2-s_2^H) \exp 2\pi i\{(s_1-s_1^H\cdot x_1)+(s_2-s_2^H\cdot x_2)\} ds_1 ds_2 \qquad (4)$$

with

$$K_{a_1}(s_1)=\frac{\sin \pi a_1 s_1}{\pi s_1} \quad \text{and} \quad K_{a_2}(s_2)=\frac{\sin \pi a_2 s_2}{\pi s_2} \, , \qquad (5)$$

where a_1 and a_2 represent the unit translations in the directions of two crystallographic axes, and s_1^H and s_2^H mean the coordinates of a relpoint $H(=hk0)$. The kernel $K_{a_1}(s_1-s_1^H)\cdot K_{a_2}(s_2-s_2^H)$ permits us to calculate the right-hand side of (4) only with the knowledge of $A(s_1, s_2)$ in the neighbourhood of H, as the kernel decreases with the deviation of (s_1, s_2) from H, and in particular, it vanishes at all the relpoints other than H, where $s_1=s_1^H$ and $s_2=s_2^H$. After rearrangements using the convolution theorem[2),4)], the right-hand side of (4) is written;

$$\varphi_H(x_1, x_2)=\iint \rho(x_1', x_2') \Delta(x_1-x_1', x_2-x_2') \exp -2\pi i(s_1^H x_1'+s_2^H x_2') dx_1' dx_2' \, , \qquad (6)$$

where

$$\Delta(x_1, x_2)=\iint \frac{\sin \pi a_1 s_1}{\pi s_1} \cdot \frac{\sin \pi a_2 s_2}{\pi s_2} \exp 2\pi i(s_1 x_1+s_2 x_2) ds_1 ds_2 \, . \qquad (7)$$

As it is seen that

$$\Delta(x_1, x_2)=\begin{cases} 1 & \text{for} \quad |x_1|<a_1/2 \quad \text{and} \quad |x_2|<a_2/2 \, , \\ 0 & \text{otherwise} \end{cases} \qquad (8)$$

the right-hand side of (6) is interpreted as *the structure factor of index* (H) *for the electrons contained in the rectangular region which is defined by*

$$|x_1-x_1'|<a_1/2 \quad \text{and} \quad |x_2-x_2'|<a_2/2 \qquad (9)$$

Practically, the integration of (4) is replaced by a discrete summation to give the function $\Phi_H(x_1, x_2)$ defined as

$$\Phi_H(x_1, x_2)=\sum_{(n)}\sum A(s_1^n, s_2^n) K_{a_1}(s_1^n-s_1^H) K_{a_2}(s_2^n-s_2^H) \cdot \exp 2\pi i\{(s_1^n-s_1^H\cdot x_1)+(s_2^n-s_2^H\cdot x_2)\} \, , \qquad (10)$$

in place of the function $\varphi_H(x_1, x_2)$ of (4), s_1^n and s_2^n being the coordinates of the discrete points in reciprocal space. When we sample the points *regularly* in reciprocal space, i. e.

$$\left.\begin{aligned} s_1{}^n - s_1{}^H &= \frac{n_1}{a_1 L_1} \qquad (n_1=0,\ \pm 1,\ \pm 2,\ \cdots,\ \pm M_1) \\ s_1{}^n - s_2{}^H &= \frac{n_1}{a_2 L_2} \qquad (n_2=0,\ \pm 1,\ \pm 2,\ \cdots,\ \pm M_2) \end{aligned}\right\} \tag{11}$$

L_1 and L_2 being integers greater than 1, then it is proved that[2)]

$$\Phi_H(x_1, x_2) \propto \overline{\varphi_H(\overline{x_1, x_2})}^{L_1 L_2} \tag{12}$$

provided that M_1 and M_2 in (11) are both sufficiently large, where $\varphi_H(x_1, \overline{x_2})^{L_1 L_2}$ means the values of $\varphi_H(x_1, x_2)$ averaged over the points $(x_1 \pm m_1 a_1 L, x_2 \pm m_2 a_2 L_2)$ with $m_1, m_2 = 0, 1, 2, 3, \cdots$, etc. When we write the values of $\rho(x_1, x_2)$ averaged over the points $(x_1 \pm m_1 a_1 L_1, x_2 \pm m_2 a_2 L_2)$ as $\overline{\rho(x_1, x_2)}^{L_1 L_2}$, we have

$$\overline{\varphi_H(x_1, x_2)}^{L_1 L_2} = \iint \overline{\rho(x_1', x_2')}^{L_1 L_2} \Delta(x_1 - x_1', x_2 - x_2') \exp -2\pi i(x_1' s_1{}^H + x_2' s_2{}^H) dx_1' dx_2' \ . \tag{13}$$

Now we come to the point where the problem of phase assignment for $A(s_1, s_2)$ may be answered correctly, when phase angle can be *defined* at the point (s_1, s_2). In Appendix II we shall consider the case where the phase angles are not to be defined and therefore the substantial phase assignment seems impossible.

Since $A(s_1{}^n, s_2{}^n)$'s for regularly sampled $(s_1{}^n, s_2{}^n)$'s (see Eq. (8)), are the Fourier transforms of $\overline{\rho(x_1, x_2)}^{L_1 L_2}$, they are real if

$$\overline{\rho(x_1, x_2)}^{L_1 L_2} = \overline{\rho(-x_1, -x_2)}^{L_1 L_2} \ . \tag{14}$$

The structure satisfying the condition (14) shall be called *statistically centrosymmetric*. As $A(s_1, s_2)$ is a continuous function of s_1 and s_2, the real function $A(s_1{}^n, s_2{}^n)$ should pass a nodal line $|A(s_1, s_2)| = 0$, when $A(s_1, s_2)$ canges its sign[5)]. Under the statistical centrosymmetry (14) we can thus assign the same sign to all points in a limited region of reciprocal space surrounded by a nodal line.

§ 3. The structure of AuCu₃ above the critical temperature

The intensity distribution of diffuse scatterings of AuCu₃ annealed at 405°C were measured by Cowley[1)]. The observed intensity $I_{\mathrm{dif}}(s_1, s_2, 0)$ in the plane passing through the origin and perpendicular to [001] was sampled according to (11) with $L_1 = L_2 = 15$*. The observed values were normalized to the electronic unit using the following relation[1),6)]

$$\underset{\binom{\text{reciprocal}}{\text{unit cell}}}{\iint} \frac{I_{\mathrm{dif}}(s_1, s_2, 0)}{C_{\mathrm{Au}} C_{\mathrm{Cu}} (f_{\mathrm{Au}} - f_{\mathrm{Cu}})^2} ds_1 ds_2 = \sum_n \alpha(00n) \tag{15}$$

where f_{Au} and f_{Cu} mean the atomic form factors of Au and Cu at the point $(s_1, s_2, 0)$ of the reciprocal space, C_{Au} and C_{Cu}, the atomic composition of Au and Cu, viz. $C_{\mathrm{Au}} = 1/4$ and $C_{\mathrm{Cu}} = 3/4$ for this case. $\alpha(lmn)$'s in the right-hand side are the short-range order parameters which were determined by Cowley by means of the Fourier transformation of intensity distribution.

The phase angles of the structure amplitudes at relpoints (100), (010) and (110) were assumed to be zero**, implying that the origin of direct space was set at an atomic site where Au atoms are of the highest concentration. One can then assign the same phases to all the points sampled after (11), assuming the statistical centrosymmetry (14) for $L_1 = L_2 = 15$. With the normalized values of $I_{\mathrm{dif}}(s_1, s_2, 0)$ (Eq. (15)) and the phase assignment described above, the function

---

* The detailed discussion on the point-samplings in reciprocal space, which is related to the resolving power of intensity observation, is found in the previous paper of the author[2)].

** One may adopt an alternative assumption that they have the values π. It was found, however, that the assumption led to the negative values of $c(ij)$, which are contradictory to the definition of this quantity (see Eq. (20)).

$$A(s_1, s_2, 0)=+\left\{\frac{I_{\mathrm{dif}}(s_1, s_2, 0)}{(f_{\mathrm{Au}}-f_{\mathrm{Cu}})^2}\right\}^{1/2}(Z_{\mathrm{Au}}-Z_{\mathrm{Cu}}) \tag{16}$$

was calculated, where Z_{Au} and Z_{Cu} mean the number of electrons contained in Au and Cu atoms respectively. By the substitution of (16) into (10) the Fourier transforms of amplitude distribution were made, the relpoint H in (10) was set at three superlattice points (100), (010) and (110), so that equation (10) may give us three φ-functions, viz. $\overline{\varphi_{(100)}(x_1, x_2)}^{L_1L_2}$, $\overline{\varphi_{(010)}(x_1, x_2)}^{L_1L_2}$ and $\overline{\varphi_{(110)}(x_1, x_2)}^{L_1L_2}$ as shown in Figs. 1 (a) and (b). The φ-function for (100) was derived from the one for (010) by permuting the axes a_1 and a_2 because of the tetragonal symmetry of $A(s_1, s_2)$. All the φ-functions are found real, the summand of (10) being centro-symmetrical.

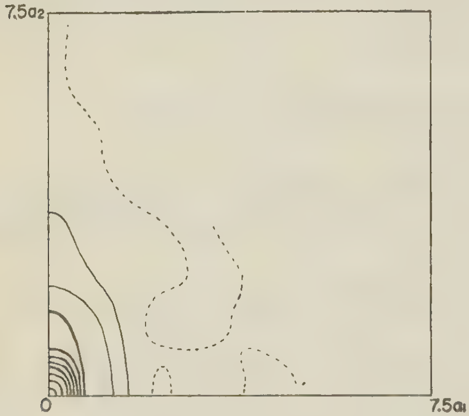

Fig. 1 (a). The function $\overline{\varphi_{(010)}(x_1, x_2)}^{L_1L_2}$. Thick contours represent the levels of 24, 21, 18, 15, 12, 9, 6 and 3 electron units, and thin ones the levels of 1.5 and 0.75 electron units respectively. Zero levels are broken.

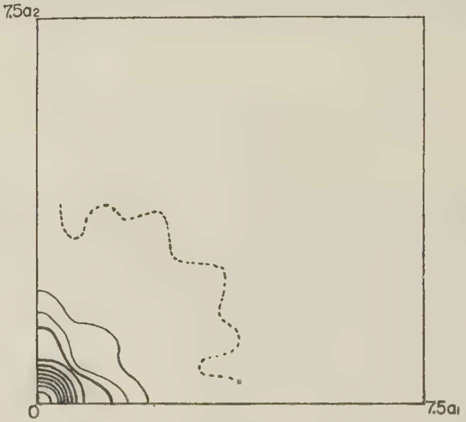

Fig. 1 (b). The function $\overline{\varphi_{(110)}(x_1, x_2)}^{L_1L_2}$. The contours represent the same levels as in (a).

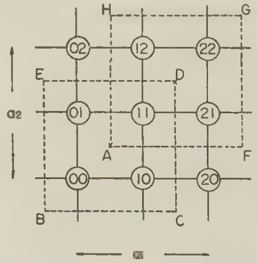

Fig. 2. The structure of Cu$_3$Au projected upon (001). Small circles represent the atomic sites which constitute the projection of face-centred cubic lattice. Points A and D are two sampling points of φ-functions.

The structure of AuCu$_3$ projected upon (001), which is denoted by $\overline{\rho(x_1, x_2)}^{L_1L_2}$ is represented in Fig. 2, where the atomic site at the position $(ia/2, ja/2)$ is denoted by (ij). Now let us consider the φ-functions at point $A(a/4, a/4)$, for which the dotted rectangle $BCDE$ gives the region defined by equation (9). As the Δ-function has a constant value of 1 inside the rectangle, we have, when we assume each atomic site occupied by a point-like atom of electronic content $r(ij)$,

$$\left.\begin{aligned}
\overline{\varphi_{(100)}\left(\frac{a}{4}, \frac{a}{4}\right)}^{L_1L_2} &= r(00)+r(01)-r(10)-r(11)\\
\overline{\varphi_{(010)}\left(\frac{a}{4}, \frac{a}{4}\right)}^{L_1L_2} &= r(00)-r(01)+r(10)-r(11)\\
\overline{\varphi_{(110)}\left(\frac{a}{4}, \frac{a}{4}\right)}^{L_1L_2} &= r(00)-r(01)-r(10)+r(11)
\end{aligned}\right\} \tag{17}$$

As these are three independent linear equations for 4 unknowns, we can solve them for $r(00)$

$-r(10)$, $r(00)-r(01)$ and $r(00)-r(11)$. Next, let us sample the values of φ-functions at point $D(3a/4, 3a/4)$, the region characterized by the non-zero constant value of Δ-function is now given by the rectangle *AFGH*, which holds one atomic site (11) in common with the rectangle *BCDE*. We have three linear equations analogous to (17) for the atomic sites contained in the rectangle *AFGH*, which, combined with (17), permit us to calculate the values of $r(00)-r(12)$, $r(00)-r(21)$ and $r(00)-r(22)$. By sampling the φ-function in such a way that two rectangles defined by (9) for every adjacent sampling points may possess always one atomic site in common, we can derive the values of $r(00)-r(ij)$'s for all (ij)'s.

As a matter of fact, it was found that, for the sites (IJ)'s such that

$$I^2+J^2>X^2\sim 60 \tag{18}$$

the values of $r(00)-r(IJ)$'s were almost constant. We can then assume that

$$c(IJ)\sim C_{\mathrm{Au}}=\frac{1}{4}\,, \tag{19}$$

where $c(ij)$ means the atomic compositon of Au at the site (ij), because we can write $r(ij)$ as

$$r(ij)=Z_{\mathrm{Au}}c(ij)+Z_{\mathrm{Cu}}[1-c(ij)]\ . \tag{20}$$

The we have for the site (IJ)'s

$$r(00)-r(IJ)=r(00)-\frac{1}{4}Z_{\mathrm{Au}}-\frac{3}{4}Z_{\mathrm{Cu}}\ . \tag{21}$$

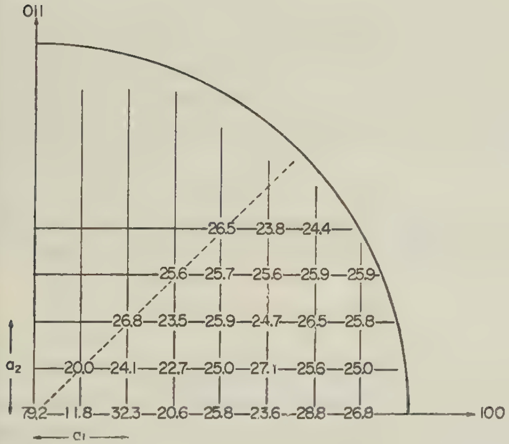

Fig. 3. The percent values of $c(ij)$'s, the Au-concentration at the site (ij)'s. The values for the upper half of the figure are derived from those for the lower half by the reflection with respect to the dotted line. The great circle represents the region outside of which the values of $c(ij)$'s are approximately constant (Eq. (16)).

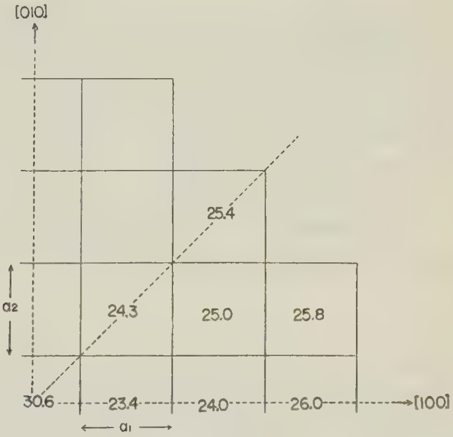

Fig. 4. The percent values of $\kappa(ij)$'s, the Au-concentration of unit cell centred at the site (ij). The values for the upper half of the figure are derived from those for the lower half by the reflaction with respect to the dotted line.

As the left-hand side of (21) is obtained in the electronic scale (Eq. (15)), it is possible to determine the value of $r(00)$ and hence all the values of $r(ij)$'s. The values of $c(ij)$'s are then calculated using Eq. (20) giving the results as shown in Fig. 3. In this figure a large circle represents the region outside of which the condition (19) is approximately satisfied. At the neighbourhood of the origin the Au-rich and Cu-rich sites are arranged almost alternatively.

Whereas the short-range order parameter $\alpha(lmn)$ concerns only to the statistics of atom pairs, the values of $c(ij)$'s here obtained give the information on the statistics of the *squares constituted from* 15×15 *atomic sites* in terms of which the averaged structure $\rho(x_1, x_2)^{L_1L_2}$ ($L_1=L_2=15$) is described.

It is interesting to calculate *the atomic composition of the unit cell centred at the site* (ij), as defined

$$\kappa(ij)=\frac{1}{4}\Big[c(ij)+\frac{1}{2}\{i+1, j)+c(i-1, j)+c(i, j+1)+c(i, j-1)\}$$
$$+\frac{1}{4}\{c(i+1, j+1)+c(i+1, j-1)+c(i-1, j+1)+c(i-1, j-1)\}\Big]. \tag{22}$$

The values of $\kappa(ij)$'s are shown in Fig. 4, where one can see clearly the deviations from $C_{\mathrm{Au}}=25\%$, which may possibly be attributed to the termination errors in the summation of (10). It must be noted, however, that the values in question are those averaged over 9 adjacent sites forming a unit cell, and if we make estimations for those effects[7] it is found that the period of diffraction ripples due to the termination is of the order of $a_1/2$, i. e. the distance between twe adjacent sites. Therefore it is concluded that the finite termination in (10) can be regarded as almost ineffective as far as the values of $\kappa(ij)$'s are concerned. Then it is seen that the unit cell centred at the origin shows the substantial excess in Au-concentration, while in the region surrounding the origin cell there found the unit cells which are in defects of the Au-concentration. The avaraged value of $\kappa(ij)$'s within the circle of Fig. 3 is found to be 25.0%, that is, the value of C_{Au}.

These deviations in the unit cell atomic compositions from those of perfectly ordered structure mean that the diffuse scattering may not be explained by the models as adopted by Wilson[8], where Au atoms are supposed not to come in contact leaving the unit cell compositions unchanged. It is therefore concluded that the ordering of this alloy progresses rather by the interchanges of the neighbouring atoms, than by the growth of the domains in which the perfect order is maintained by keeping all the Au atoms from being in contact with each other. The conclusion is in agreement with that of Edmunds and Hinde[9] arrived at from quite a different point of view. On the other hand Steeple and Edmunds[10] have given a similar result for the ordering of $\mathrm{CdMg_3}$.

Appendix I. The Relation of $c(ij)$ to the Short-range Order Parameters

When we write the short-range order parameter $\alpha(lmn)$ as

$$\alpha(lmn)=1-\frac{1}{C_{\mathrm{Au}}}n_{\mathrm{CuAu}}(lmn) \tag{A. 1}$$

where $n_{\mathrm{CuAu}}(lmn)$ means the proportion of the pairs Cu–Au whose separation and orientation are specified by the triplet of integers (lmn), our result as represented in Fig. 3 should be related to the values of of $\alpha(lmn)$'s projected upon l–m plane, say,

$$\alpha(lm)\equiv\sum_n \alpha(lmn)=1-\frac{1}{C_{\mathrm{Au}}}\sum_n n_{\mathrm{CuAu}}(lmn)\,, \tag{A. 2}$$

because the proportion of pairs $n_{\mathrm{CuAu}}(lmn)$ can be expressed as

$$\sum_{ijk}[1-c(ijk)]c(i+l, j+m, k+n)\,,$$

and

$$n_{\mathrm{CuAn}}(lm)\equiv\sum_n n_{\mathrm{CuAu}}(lmn)=\sum_{ij}[1-c(ij)]c(i+l, j+m)\,. \tag{A. 3}$$

Then (A. 2) runs;

$$\alpha(lm)=1-\frac{1}{C_{\mathrm{Au}}}\sum_{ij}[1-c(ij)]c(i+l, j+m)\,. \tag{A. 4}$$

It is to be noted, however, that the values of $c(ij)$'s in Fig. 3 are the averaged ones in the sence that they are related to the averaged structure $\overline{\rho(x_1, x_2)}^{L_1L_2}$ and not to $\rho(x_1, x_2)$, so that they should be rather denoted by $\overline{c(ij)}^{L_1L_2}$ in order to make clear the differences from the quantities appearing in (A. 4). That is, what we obtain as short-range order parameters using the values given in Fig. 3 is not $\alpha(lm)$ as defined by (A. 2) but $\overline{\alpha(lm)}^{L_1L_2}$ as defined:

$$\overline{\alpha(lm)}^{L_1L_2}=1-\frac{1}{C_{\text{Au}}}\sum_{ij}[1-\overline{c(ij)}^{L_1L_2}]\overline{c(i+l, j+m)}^{L_1L_2} . \tag{A. 5}$$

On the other hand, the short range order parameters obtained by means of the Fourier transformation of intensity distribution, too, cannot be identical as those defined by (A. 1) or (A. 4), because an averaging is inevitably introduced through the replacement of integration by discrete summation which is necessitated by the finite resolving power of intensity observation[2]. In this case the parameter $\alpha(lmn)$ is not related to $P(x_1, x_2)$ but to $\overline{P(x_1, x_2)}^{L_1'L_2'}$, where $P(x_1, x_2)$ is the self-convolution of $\rho(x_1, x_2)$ and L_1', L_2' are the integers greater than 1 which are in general different from L_1 and L_2.

Thus what we obtain is $\overline{\overline{\alpha(lm)}}^{L_1'L_2'}$ defined as

$$\overline{\overline{\alpha(lm)}}^{L_1'L_2'}=1-\frac{1}{C_{\text{Au}}}\overline{\sum_{ij}[1-c(ij)]c(i+l, j+m)}^{L_1'L_2'} . \tag{A. 6}$$

It is seen that the values of $\overline{\alpha(lm)}^{L_1L_2}$ and $\overline{\overline{\alpha(lm)}}^{L_1'L_2'}$ may be different, and in general the one is not derivable from the other unless L_1, L_2, L_1' and L_2' are so large that a_1L_1, a_2L_2, a_1L_1' and a_2L_2' become comparable to the size of the crystal under examination and the values of $\overline{c(ij)}^{L_1L_2}$'s become identical with those of $c(ij)$'s.

Appendix II. A Remark on the Phase Assignment of Diffuse Scattering

In the preceding sections it was supposed implicitely that the disordered structure in question could be represented uniquely by a continuous function $\rho(\boldsymbol{x})$, thus the phase angles could be *defined* without any ambiguity at every point in reciprocal space. In general it cannot be the case because it is known that single crystals are composed of coherent domains (mosaics) which diffract X-rays independently with each other. Let the electron distribution of each coherent domain be represented by $\rho_n(\boldsymbol{x})$ and its Fourier transform by $A_n(\boldsymbol{s})$ $(n=1, 2, 3, \cdots, N)$, the observed diffraction pattern is then expressed as;

$$I(\boldsymbol{s})=\sum_{n=1}^{N}|A_n(\boldsymbol{s})|^2\equiv N|A_0(\boldsymbol{s})|^2 . \tag{A. 7}$$

In this case the phase assignment to the square root of $I(\boldsymbol{s})$ seems quite impossible and even deprived of any substantial significance. The Fourier transformation of *amplitude* distribution, which is nevertheless feasible at least in quite a formal way, leads to the structure $\rho_0(\boldsymbol{x})$ defined as;

$$\rho_0(\boldsymbol{x})\bigstar\rho_0(\boldsymbol{x})=\frac{1}{N}\sum_{n=1}^{N}\{\rho_n(\boldsymbol{x})\bigstar\rho_n(\boldsymbol{x})\} , \tag{A. 8}$$

$\rho_0(\boldsymbol{x})$ being the Fourier transform of $A_0(\boldsymbol{s})$ which is proportional to the square root of $I(\boldsymbol{s})$.

As we have seen in § 2, what we obtain practically is not $\rho_0(\boldsymbol{x})$ itself but the averaged one $\overline{\rho_0(\boldsymbol{x})}^{\boldsymbol{L}}$ defined as;

$$\overline{\rho_0(\boldsymbol{x})}^{\boldsymbol{L}}\bigstar\overline{\rho_0(\boldsymbol{x})}^{\boldsymbol{L}}=\frac{1}{N}\sum_{n=1}^{N}\{\overline{\rho_n(\boldsymbol{x})}^{\boldsymbol{L}}\bigstar\overline{\rho_n(\boldsymbol{x})}^{\boldsymbol{L}}\} , \tag{A. 9}$$

where $\boldsymbol{L}$ stands for the triplet of integers (L_1, L_2, L_3). Although $\rho_n(\boldsymbol{x})$'s at the right-hand side of (A. 8) may vary from domain to domain, and $\rho_0(\boldsymbol{x})$ cannot represent any real structure present in the crystal under examination, one may expect that the averaged structures $\overline{\rho_n(\boldsymbol{x})}^{\boldsymbol{L}}$'s are at little variance among themselves, unless (L_1, L_2, L_3) is so large that L_1a_1, L_2a_2 and L_3a_3 become comparable to the sizes of coherent domains, and therefore that

$$\overline{\rho_0(x)}^L \sim \overline{\rho(x)}^L \,. \qquad \text{(A. 10)}$$

Here $\overline{\rho(x)}^L$ means as a representative structure of the assembly of coherent domains from which the crystal examined is constituted.

The condition (A. 10) may hold for the case of Cu_3Au treated in § 3, and the conclusion of that section need not suffer from possible lack of reality due to the phase assignment given by (16).

Visible Light Emission and Microplasma Phenomena in Silicon p-n Junction

II. Classification of weak spots in diffused p-n junctions

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received June 6, 1960)

In the course of study on the visible light emission and microplasma phenomena in diffused silicon p-n junctions, it has been discovered that there exist several types of weak spots in the junction. They can be roughly classified into two groups, one of them includes tiny weak spots which reveal microplasma current pulses at certain characteristic bias voltages, and the other includes tiny spots which contribute "soft" component to the reverse current without being accompanied with microplasma pulses. The latter type of spots could be produced by scratching the surface of the junction with a tungsten needle, whereas the former could not be produced by the same operation.

In real diffused junctions there are distributed above mentioned types of point defects. Typical experimental results are given, and the correlation between those weak spots and the current-voltage characteristics is discussed.

§ 1. Introduction

Strictly speaking, no definite model is established for the explanation of the microplasma pulses and the visible light emission. The possibility of the visible light emission by the thermal vibration of lattice has already been ruled out because of unbelievable high temperature gradient in the crystal. From the experimental results on the spectral distribution of the emitted light, intra-band transition of energetic carriers has been postulated[1].

However, the switching action of the microplasma spot and the correlation between the light emission and the current pulses are now still in question. Therefore, in the course of investigation on the occurrence of microplasma pulses in reverse-biased diffused silicon p-n junctions, it has been intended to check the carrier multiplication at the microplasma spot. The experimental result was negative, that is, no multiplication could be found in the voltage range where microplasma current pulses were clearly observed on a synchroscope. High value of "apparent" carrier multiplication has already been discussed in the previous paper[2].

During the measurement of multiplication, it has been found out that there exists light emitting spot in the junction which reveals no microplasma pulses at all. Some of them show high value of multiplication but some of them do not. The color of the emitted light from this type of spots is much more brilliant and whitish than that from microplasma spots. In the previous paper[3], only the appearance of the bright spots is mentioned, but it has been found that this kind of spots contribute considerable amount of leakage current component to the reverse characteristic of the junction.

The purpose of this paper is to present the experimental results on the above mentioned weak spots in the junction, as well as to give additional results on the microplasma spots. In the last section, brief discussion and speculation are given.

§ 2. Experimental Procedures

2.1 *Specimens*

The specimens used in this experiment are summarized in Table I with the condition of boron diffusion for making p-n junction on the surface. As shown in the table, resistivity of the samples ranges from 0.1 to 6 ohm-cm. After making a p-type layer on the surface, small area of 1–3 mm in diameter is protected and the remainder of the surface p-type layer is etched off. Four specimens are fixed on a copper plate with silver paste. The copper plate is mounted on a large metal block of the micromanipulator which serves as a heat sink.

2.2 *Experimental apparata and procedures*

Most of the experimental apparata are the same as that described in the previous paper[2].

Table I.

No. of speci-men	resistivity (chm-cm)	diffusion temperature (°C)	diffusion time (min)
B 25	2—6	1050	30
B 26	2—6	1050	40
B 27	2—6	1050	50
B 28	0.02	1050	40
B 29	0.1	1050	40
B 30	1.6	1050	40
B 32	0.15	1050	40
B 33	1.7	1050	40

Essentially, the apparatus for measuring multiplication and for locating weak spots in the junction consists of a chopped light source and micromanipulator with a high sensitivity synchroscope. Micromanipulator is so operated that the maximum performance of certain characteristic can be observed on the synchroscope to find the position of the spot in the junction. Usign an X-Y recorder simultaneously, appearance and disappearance of microplasma pulses can be marked on the reverse current-voltage characteristic of the junction.

§ 3. Experimental Results

3.1 *Microplasma pulses and the current-voltage characteristic*

As has already been described in the previous paper, microplasma pulses appear as reverse bias is increased up to certain voltage. As the voltage is further increased, pluse length and pulse rate is increased and finally the pulses completely disappear. Observing microplasma pulses on a synchroscope, their appearance and disappearance can be indicated on the reverse current-voltage characteristic as shown in Fig. 1. As is shown in the figure, about ten microplasma spots reveal their existence successively as the total current is increased up to 1 mA. The trace of the characteristic as shown in Fig. 1 is quite reproducible.

Fig. 2 shows a part of the characteristic near the appearance of the first microplasma spot. As is shown, the characteristic is rather complex microscopically, i.e., the second derivative is oscillatory. However, the segments (1A), (2B), and (3C) of the curve are meaningless in a sense, since the values of junction current in these regions is only a time average of pulsing current weighted by measuring circuit conditions. It must be noted here that the parts (A2), (B3)··· are quite linear, which has been confirmed on most of the specimens. The above mentioned results, i.e., (1A), (2B), ··· are only the curves of weighted average of "probability", and (A2), (B3)··· are the segments of straight line, must be carefully taken into account for theoretical interpretation of the reverse characteristic of those diffused p-n junctions.

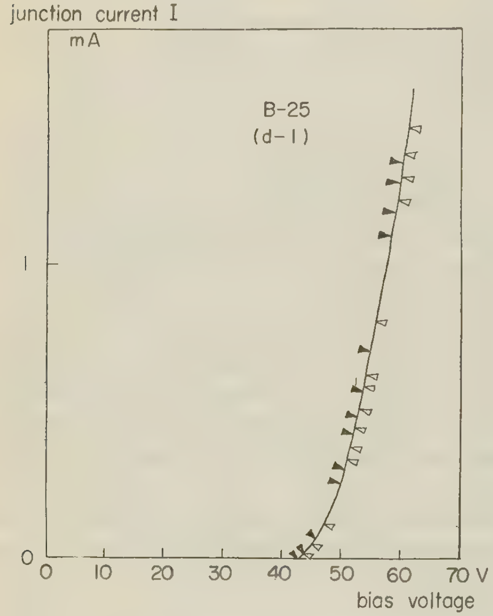

Fig. 1. Typical reverse characteristic of a diffused p-n junction on which appearance and disappearance of microplasma pulses are marked. ▶ and ▷ shows the appearance and disappearance, respectively.

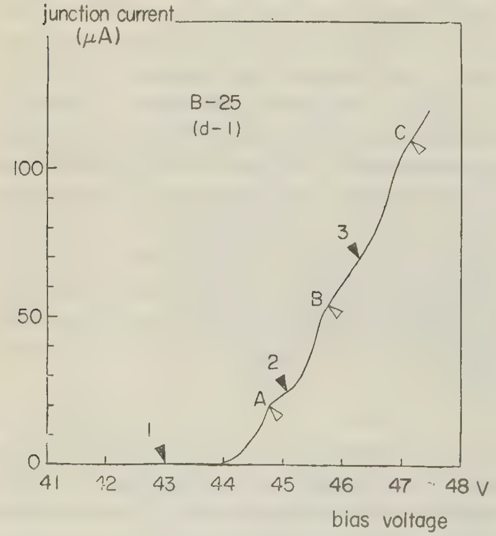

Fig. 2. Part of the current-voltage characteristic curve with the marks of appearance and disappearance of microplasma pulses.

As previously reported, we have succeeded in locating the positions of individual microplasma spots using small chopped light spot. By this technique, it is observed on a synchroscope that the microplasma pulses are most strongly modulated at the chopping frequency when the chopped light just coincides with a microplasma spot. Fig. 3. shows the change in characteristic curve when one of the microplasma spot is illuminated.

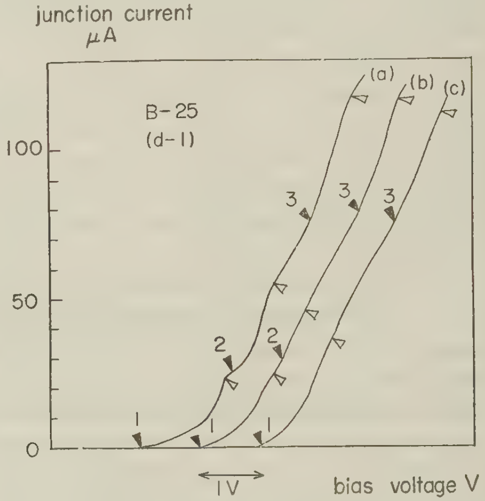

Fig. 3. Change of characteristic curve when certain microplasma spot is selectively illuminated. (The voltage axis is shifted 1 volt for each svccessive measurement) (a) dark, (b) (c) stronger illumination on the spot No. 2.

The voltage axis in the figure is shifted 1 volt for each measurement. As the illumination on the spot No. 2 is made stronger, the variation in the second derivative of the curve is reduced, and finally, appearance of the microplasma pulses from spot No. 2 is shifted to lower voltage. Therefore, it becomes that pulses from spot No. 1 and spot No. 2 can no longer be separated, as shown in the curve (c).

3.2 *Characteristics of microplasma pulses*

In Fig. 4, the grow-up of microplasma pulses is shown. This semi-schematic figure shows the increase of pulse height with increasing bias voltage. The dot circle indicates the time average of the pulsing current.

As is seen in the figure, the pulse height is very small and gradually increases after its appearance, but it is reduced abruptly to zero upon its disappearance. This lack of symmetry must be noted.

The other important feature of the microplasma phenomena is the lack of carrier multiplication, which has already been reported in the previous paper. In our present work, this has been confirmed again. With careless measuring conditions, the apparent multiplication will be confused with the true carrier multiplication but these must be distinguished.

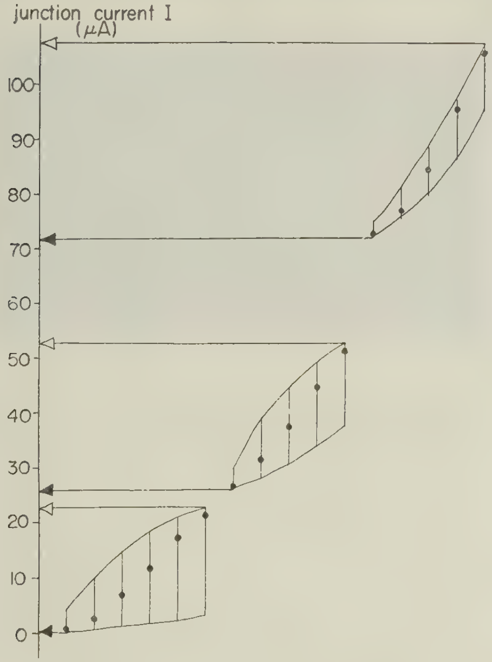

Fig. 4. Grow-up microplasma pulses with increasing bias voltage. The abscissa is reverse bias voltage, but quantitatively meaningless.

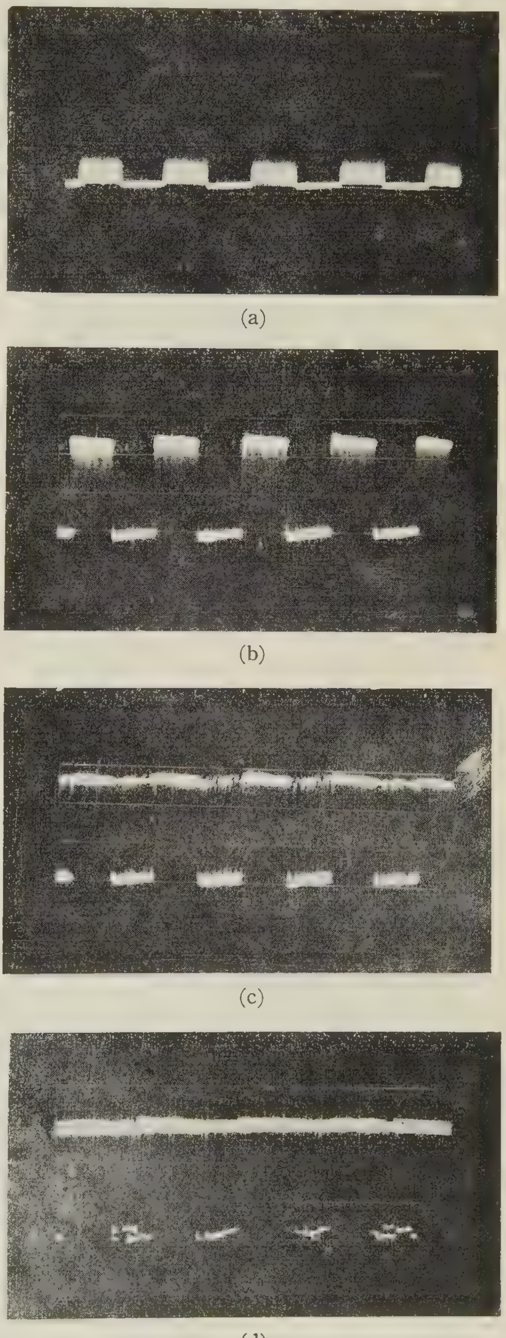
Fig. 5 shows the appearance of microplasma pulses with chopped light illumination. The bias voltage is increased from (a) to (d), successively. As is shown, pulse rate of the microplasma current pulses is modulated by the illumination, but the multiplication cannot be found in the case of (d), i.e., the spot is mostly in " ON " state both in the dark and illuminated condition.

3.3 *Weak point in the junction without microplasma pulses*

In the course of study on the above mentioned phenomena, it has been found that there exists light emitting spot in the junction which is not accompanied with the occurrence of microplasma current pulses.

At first, a bright spot was found in the junction through microscope, where the chop-



(a)

(b)

(c)

(d)

Fig. 5. Patterns of the microplasma pulses when the junction is illuminated by chopped light. The light is focused on the microplasma spot and the bias voltage is increased from (a) to (d).

ped light was carefully focused. Bias voltage was slowly decreased watching the pattern on the synchroscope. In the case of microplasma spot, the clear pattern like that shown in Fig. 5 should be observed. However, no pattern could be seen even the voltage was decreased as low as 10 volts. It was astonishing that the light emission could be still observed from the spot at this bias. This type of weak spot was found out in this way.

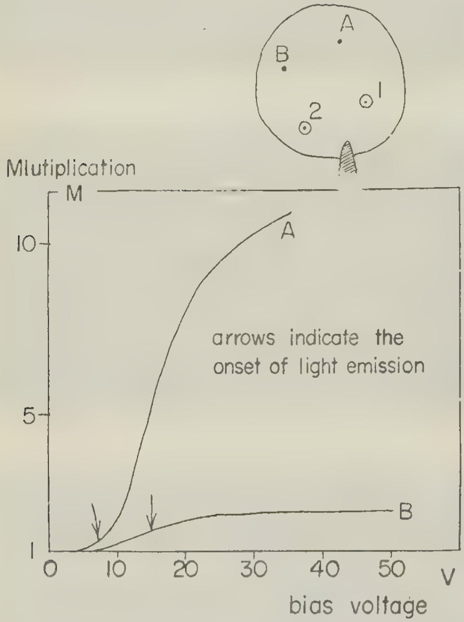


Fig. 6. Examples of weak spots in the junction with multiplication and without microplasma pulses.

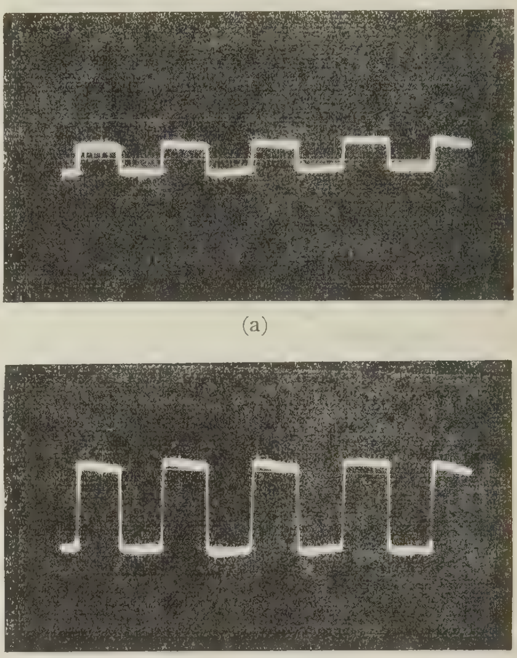
By careful observation on many specimens, it has been found that some of those spots reveal high multiplication. In Fig. 6 typical examples are given. In this diffused junction, four weak spots are revealed when the bias voltage is increased up to 65 volts. Two of them are the previously mentioned microplasma spots (1 and 2 in the figure), and the other two are the spots without microplasma pulses which are accompanied with carrier multiplication (A and B). As is shown, multiplication occurs in these spots from the bias valtages as low as 5 and 7 volts, respectively. Moreover, it must be noticed that light emission occurs also at low voltages. In Fig. 7, an example of photoresponse of these kind of spots is shown. It is clearly seen that the nature is essentially different from microplasma spot as shown in Fig. 5.



(a)

(b)

Fig. 7. Pattern of photoresponse of the weak spot which reveals no microplasma pulses. Multiplication is clearly observed.

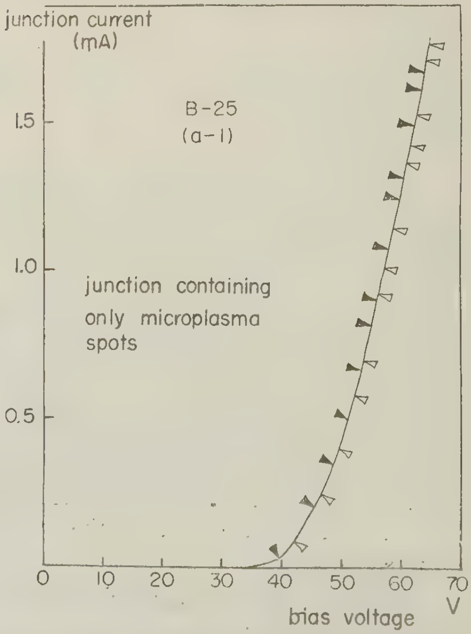


Fig. 8. Current-voltage characteristic of a junction which contains microplasma spots only. (#B-25(a-1)). ▶ and ▷ indicates the appearance and disappearance of microplasma pulses.

It has been found that the existence of this new kind of spot has remarkable influence on the current-voltage characteristic of the junction. Fig. 8 shows the characteristic of the diffused junction which contains only microplasma spots. Although relatively large number of microplasma spots can be found in this junction, the characteristic is pretty hard, i.e., it has sharp breakdown at the voltage where the first microplasma pulses appear.

If the junction contains at least one weak spot without microplasma pulses, however, the characteristic becomes remarkably soft, as shown in Fig. 9. This softness results from the existence of this kind of spots either with or without multiplication. From these experimental results it may well be concluded that the so-called leakage current in the backward characteristic is caused by those kind of weak spots in the junction.

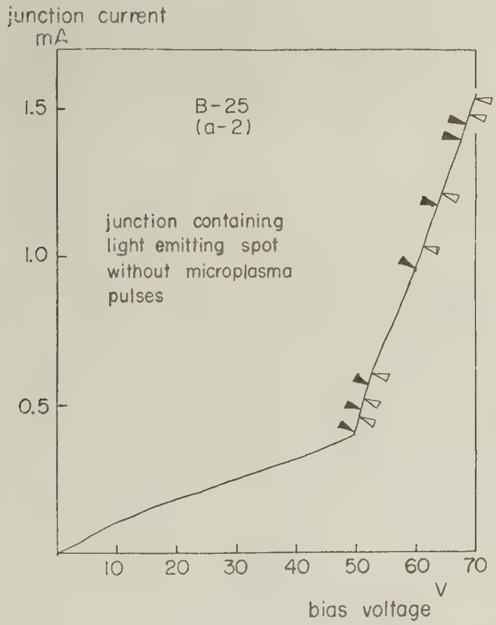

Fig. 9. Current-voltage characteristic of a junction which contains at least one weak spot without microplasma pulses.

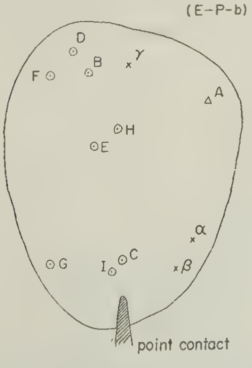

Fig. 10. Map of the light emiting spots in the diffused junction. (#-E-P-b)

In Fig. 10, a result of mapping light emitting weak spots in a diffused junction is given. The sign ⊙ indicates the microplasma spot, △ and × indicates the spot without microplasma pulses, with and without multiplication, respectively. The detailed description of these weak spots are summarized in Table II.

Table II. Detailed description of the weak spots mapped in Fig. 10.

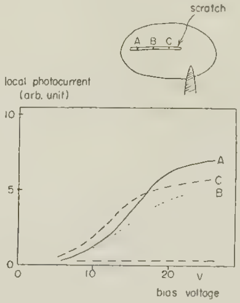

Fig. 11. Multiplication characteristic of the light emitting spots produced by scratching.

3.4 *Effect of scratch on the surface of diffused junction*

On the course of experiment it was sometimes observed that the current-voltage characteristic changed permanently. Recently, it has been found that this change in characteristic can be attributed to the scratch on the surface of the junction made by drawing the metal point electrode by micromanipulator.

It may be very interesting to note that light emitting spot can be produced by the scratch intentionally. The light emitting spots produced by the scratching reveal multiplication as shown in Fig. 11. As is shown, the light emitting spots appear along on the scratch line and the multiplication appears in these spots from the bias voltage as low as 6–10 volts.

It must be noted that none of the spots produced in this way revealed microplasma pulses.

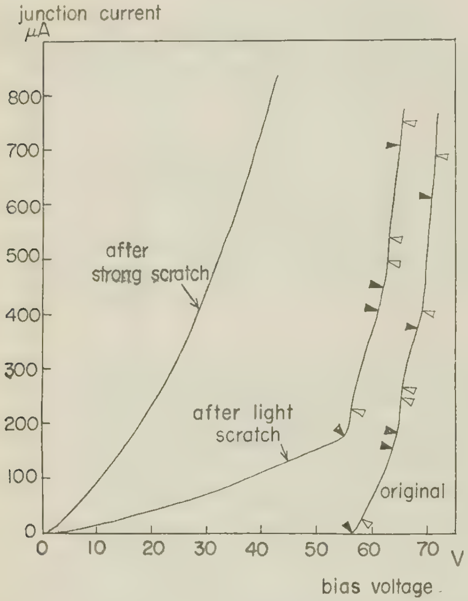

Fig. 12. Effect of scratching on the current-voltage characteristic of a junction.

Fig. 12 shows the effect of scratching on the current-voltage characteristic. From the experimental results mentioned in the previous section, it may be quite natural to expect that the scratching results in the increase of leakage current. It is noted that during the scratching treatment, the ocurrence of microplasma pulses is not influenced.

It must be noticed here that relatively slow response to chopped light has often been observed in the spots produced by scratching. The slow effect appears also in the current, i.e., the increased leakage current by scratching reveals considerable drift (or creep).

3.5 *Summary of the experimental results*

The observed weak spots in the diffused junction can be classified by their characteristics as shown in Table III. Type I is the usual microplasma spot, which is characterized by the occurrence of microplasma pulses and also by the lack of multiplication. Type II is also the microplasma spots, but this seems to be lacking of light emission. In some specimens, no light emitting spots could be observed through microscope after ten or more microplasma breakdown had been observed on the synchroscope. Strictly speaking, however, the existence of type II spot may be still in question.

Table III. Classification of weak spots in the junction.

Type	Microplasma pulses	Light emission	multiplication
I	yes	yes	no
II	yes	no	no
III	no	yes	yes
IV	no	yes	no

Type III and IV are the spots without microplasma pulses. In general, the emitted light from III and IV spots is much brighter than that from I and II spots. The colour is more reddy for I and II, while it is whitish for III and IV. The existence of multiplication is the main feature to distinguish III from IV.

Type III can be produced by scratching on the surface of the junction. III and IV contribute considerable amount of leakage current to the backward characteristic. Therefore, the current-voltage characteristic of the junction containing only I or II spots is hard, while the junction containing at least one of III or IV spots reveals soft characteristic.

It is also noted that visible light emission from III or IV occurs at very low voltages as low as 5–15 volts.

§ 4. Discussions

4.1 *Microplasma spots and current-voltage characteristics*

As has been already mentioned in connection with the experimental result shown in Fig. 2, current-voltage characteristic of a junction containing microplasma spots does not obey the existing simple theories. One of the important features of the characteristic is its linearity between the disappearance and appearance of microplasma as schematically shown in Fig. 13. As is shown in the figure, the parts (BC) and (DE) are linear. As previously noticed, the current is the sum of continuous current and pulses in the regions of (AB) and (CD).

From the above mentioned features of the characteristic curve, it seems natural to have the physical picture as follows. There exist considerable number of weak spots in the junction, and they reveal breakdown successively as the bias voltage is increased. When the bias voltage passes through the breakdown voltage of certain spot, that spot contributes local current which is limited by spreading resistance only. This picture can be represented by the equivalent circuit as shown in Fig. 14. Relay switches are in parallel and each switch has its resistance in series.

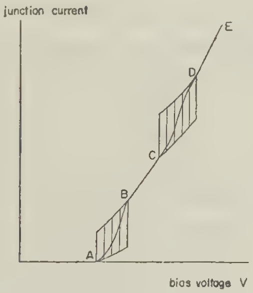

Fig. 13. Schematic representation of the current-voltage relation of a junction containing microplasma spots.

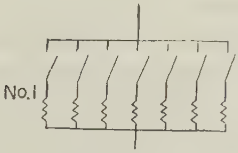

Fig. 14. Equivalent circuit of the junction containing microplasma spots.

When the bias voltage is increased up to the breakdown voltage of the spot No. 1, the relay No. 1 begins to oscillate. The probability of the relay to be in "ON" state is increased as the bias is further increased, and finally the relay is completely switched on.

There are, however, some doubts in the validity of this equivalent circuit. From the experimental results it has been found that the microplasma pulse height grows up at most to 150μA. On the other hand, the resistance of the individual spot (resistance in series to the relay in Fig. 14) has been determined from the derivative of the linear part of the characteristic to be of the order of 20–50 kΩ. From the value of 50 kΩ and equivalent circuit in Fig. 14, the height of the microplasma pulses should be 1 mA, since the first pulses appear nearly 50 volts. Moreover, it should be expected from the equivalent circuit that the extrapolation of the linear part of the characteristic will intersect the origin as shown in Fig. 15 (a). It is observed, however, that the characteristic of real junction is schematically shown as Fig. 15 (b).

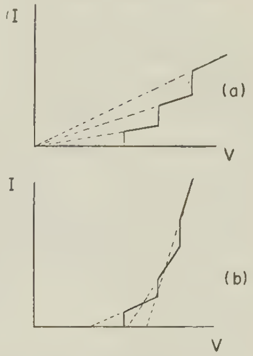

Fig. 15. Schematic representation of the characteristic of (a) equivalent circuit, (b) real junction.

From the resistance determined above and the usual relation

$$R=\frac{\rho}{2d} \qquad (1)$$

for the spreading resistance, where ρ is the bulk resistivity, the diameter d of the spot can be given to be about 0.5 micron. This value is at least one order of magnitude larger than usually believed for the microplasma spot.

Although the detailed mechanism underlying microplasma phenomena is still in question, above mentioned discrepancies seem to show that we must take into account the modulation of spreading resistance in the analysis.

4.2 *Soft characteristic*

It can be concluded that the existence of type III or IV spot give rise to soft reverse characteristic. This may be seen in Table IV where some of the experimental results are summarized.

Characteristic features of type III and IV

Table IV. Summary of the experimental results on the correlation between softness of the current-voltage characteristic and the existence of type III or IV spots.

No. of specimen	Type I or II	Type III or IV	Characteristic
(B-26)			
a-1	yes	no	hard
a-2	yes	yes	soft
a-3	yes	no	hard
a-4	yes	yes	soft
b-1	yes	no	hard

spots are visible light emission and lack of microplasma pulses. Moreover, light emission begins from bias voltages as low as 5 volts. From the results mentioned in 3.4, local damage or highly dislocated region is imagined as the origin of these types of spots. For instance, high density of energy states in the band gap will be responsible for high rate of generation and also for high rate of recombination. On the other hand, high density of energy states will help the Zener mechanism.

At any rate, there must exist high energy carriers since the light emission occurs. However, we are puzzled from the fact that there is clear differecce between type III and IV spots in carrier multiplication characteristic. One possible way to solve this question is to consider the threshold energy $E_s=2.3\,\text{eV}$ for pair creation. Visible light emission may be observed without multiplication if the carriers have energy sufficiently high but less than 2.3 eV. However, this model seems to be too much sophisticated.

4.3 *Microplasma spots*

The most difficult question on the mechanism of microplasma phenomena may be the lack of multiplication after the breakdown where visible light emission can be observed. Light emission occurs after the current pulses appear. Following considerations lead us to believe that the microplasma phenomena is only partly related with avalanche breakdown.

(a) Individual current pulse is not the avalanche induced by a chance carrier, since the pulse width ($10^{-6}-10^{-5}$ sec) it too long compared with the transit time of electrons in the barrier, i.e., 10^{-8} sec..

(b) Above model is not valid also because no carrier multiplication is found after the breakdown.

(c) If it is assumed that the long pulse width is maintained by high density of chance carriers to cause avalanche multiplication, it becomes then difficult to explain long intervals between the pulses.

We have proposed a model taking analogy with the p-n-p-m switch in the previous paper. We have really succeeded to observe similar current pulses in the vicinity of the " turn-on " point of a p-n-p-n four layer diode. However, in the case of this simulation, it is very difficult to keep the " randomness " of the current pulses. The current pulses are apt to fall into relaxation oscillation, and the condition to keep randomness is quite critical.

Therefore, it may be concluded that the first rise of a microplasma pulse is induced by a high energy chance carrier, while its fall is governed by some internal feedback mechanism, which is still in question at present.

The effect of oxygen impurity on the visible light emission has been reported in the previous paper[4]. Recently, it has been found that very few light emiting spots can be observed in the junction formed on a crystal grown by floating-zone method, while the light spots are increased by heating these specimens in oxygen or oxygen-rich atmosphere. Since, however, our equipments to perform heat-treatment are not perfectly free from other chemical impurities, it may not be concluded that only the oxygen impurity is responsible for above mentioned change.

4.4 *Other remarks*

Magnetic field of 6000 Gauss has been applied either in parallel or perpendicular to the surface of the junction, but no effect could be detected on the microplasma pulses.

When the junction is put into vacuum of 10^{-4} mm Hg, leakage current is considerably changed but no change can be detected on the appearance of the microplasma pulses. This result shows that the microplasma spot is rather isolated from the surface condition.

§ 5. **Conclusions**

It has been found that there are four types of weak spots in diffused silicon junctions. They can be classified on light emission, multiplication and microplasma current pulses.

In real junction, these spots are distributed mixed and randomly in the junction, and the current-voltage characteristic is closely correlated with the existence of the spots.

Type III spots have been found to be produced by scratching on the surface by sharp needle.

Experiments are still now being undertaken to clarify the mechanisms underlying microplasma pulses.

The author wishes to express his appreciation to Mr. K. Tachikawa for preparing silicon diffused junctions.

Optical and Structural Anomalies in Potassium Ferrocyanide Trihydrate Crystals

Hiroo TOYODA, Nobukazu NIIZEKI and Shigeru WAKU

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation

(Received April 16, 1960)

Potassium ferrocyanide trihydrate crystals grown from aqueous solution have been studied with polarizing microscope, X-ray diffraction methods, etching technique, and dielectric measurements at temperature region between 20° and −140°C. Various types of optical anomalies were observed, and the crystals were classified into five types by optical and X-ray investigations. Crystallographic data of monoclinic and tetragonal single crystals were measured. The various optic anomalies were clarified by twinning and parallel growth characteristic to the layer structure of the two modifications. Dislocation pits were observed by etching with a mixture of water and alcohol. Ferroelectric monoclinic phase, and the behaviors of tetragonal phase at low temperatures were studied by low temperature polarizing microscope, dielectric measurements and low temperature precession X-ray photographs. Teteragonal phase was shown to undergo a monotropic phase transition at about −55°C, and transform into a twinned monoclinic phase.

§ 1. Introduction

The authors reported previously the ferroelectricity of potassium ferrocyanide trihydrate ($K_4Fe(CN)_6 \cdot 3H_2O$, hereafter abbreviated as KFCT crystals[1], and pointed out that there appear several peaks in the dielectric constant vs temperature curve, and that the crystal exhibits some peculiar optical behaviors. In a resent study of Waku *et al*[2], it has been revealed for a monoclinic single crystal that the dielectric constant vs temperature curve shows only a single peak, and the polarization axis is along the [10$\bar{1}$] direction.

The authors have found several type of KFCT crystals grown from the aqueous solution with behaviors significantly different from monoclinic single crystals in optical, dielectric, and other properties. The authors have investigated these crystals with X-ray diffraction method, polarizing microscope, dielectric measurement, and etching technique.

1. *Optical classification and X-ray study of crystals*

KFCT is known to crystallize in two types of modifications, one monoclinic and the other tetragonal. Hawever, because of the pseudo-tetragonality of the former structure and also of the layer structure of both of them, samples of single crystals grown from solution show complicated varieties due to twinning and oriented overgrowth. By optical observation and X-ray analysis, the samples can be classified into several types as follows.

I. Monoclinic single crystal: Monoclinic crystal of KFCT is discriminated by its large optic axial angle, $2V=78°10'(-)$, X: ∠[10$\bar{1}$]$=31°50'$, as well as by Laue symmetry 2 (Fig. 1 (a)). By the use of rotation, Weisenberg, and precession methods, the unit cell dimensions were determined as $a=9.380$ A, $b=16.84$ A, $c=9.397$ A and $\beta=90°\pm3'$, where the b axis of the crystal is taken normal to its cleavage face. The space group was assigned to be C2/c. These results are in agreement with those of Posperov and Zdanov[3].

II. Tetragonal single crystal: Tetragonal crystal of KFCT is identified by its uniaxial positive interference figure, and by Laue pattern showing the Laue symmetry 4 (Fig. 1 (b)). The unit cell dimensions were determined as $a=9.410$ A, $c=33.67$ A, where the c axis is chosen normal to the cleavage face. A space group I $4_1/a$ was assigned.

III. Crystal without extinction: In the observation under an orthoscope, the rotation of this type of crystals around the normal to the cleavage face brings out merely a slight change in interference color, and no extinction

(c) Schematic representation of the relation between optic planes of two individuals.

positions. The Laue pattern and a schematic representation of the reciprocal lattice level hll are shown in Fig. 2 (a) and 2 (b) respectively. From the analysis, the crystal is interpreted as a macroscopic twin of monoclinic individuals with the twinning axis along [100]. In this type of twinning, the optic axial planes of two individuals make an angle of 26° so that any extinction position cannot exist (Fig. 2 (c)).

IV. Optically biaxial crystal without isogyers: Though the extinction positions exist through an orthoscope for this type of crystals, main isogyers do not appear through a conoscope and two dark points correponding to the apparent optic axes are observed (this unusual feature is explained in Appendix). The Laue pattern and the reciprocal lattice level hll are illustrated in Fig. 3 (a) and 3 (b) respectively. The analysis showed that the crystal is composed of two monoclinic individuals, whose orientations are mutally rotated around their common b axis so that two optic axial plane should be perpendicular to each other, in accordance with the observed optic

(a) Laue pattern of type IV crystal.
(b) Reciprocal lattice level hll of the above crystal.
(c) Relations between two optic planes.

anomalies (Fig. 3(c)).

V. Optically biaxial crystals with small optic angle: Though main isogyers are observed through a conoscope for this type of crystals, the optic axila angle 2V is not only smaller than that of monoclinic single crystal but indefinite. These crystals do not show any evidence of macroscopic twinning in their Laue pattern. They are either tetragonal pattern containing some diffuse spots and streaks when 2V angle is much smaller or monoclinic pattern with some diffuse spots and streaks when 2V angle is relatively larger. This type of crystals is supposed to be composed of monoclinic and tetragonal crystals which are stacked together with their cleavage planes parallel to each other in a microscopic scale, since, if this is the case, the crystal may be observed as optically homogeneous unit and its 2V angle may decrease according to the proportion of each modification.

Some of the crystal samples actually obtained are found to be composed of combinations of the above five types. It takes place frequently the case in which an individual crystal in the macroscpoic twins or parallel growth is not always a true monoclinic crystal but is a crystal classified under Type V for which 2V angle is smaller than 78°. The crystals divided into biaxial quadrants by a crossed uniaxial band, such as shown in Fig. 5, are also frequently found. It is usual that the neighboring quadrants across an uniaxial part have optic axial planes perpendicular to each other. The angle 2V decreases continuously near the uniaxial band.

§2. X-ray Study at Low Temperatures

Low temperature precession photographs of KFCT crystal were taken with the cooling equipment described elsewhere[4]. It has been established that the monoclinic phase (Type I) transforms to ferroelectric phase at −24°C. The unit cell dimensions −90°C were determined as $a=9.332$ A, $b=16.6$ A and $\beta=90°3' \pm 3'$. The space group was assigned as Cc from the observed systematic absences of spectra and the observation that the polarization axis lies in (010) plane.

With the tetragonal crystal, Laue patterns were taken at various temperatures, and it

was revealed the fact that an irreversible transition to monoclinic phase occurs between −35°C and −60°C (Figs. 4 (a) and 4 (b)). The study by precession method revealved that thus produced monoclinic phase gives the similar pattern as that of Type IV, indicating that the crystal contains two groups of monoclinic components which are related to each other by 90 degrees rotation around the common *b* axis.

§ 3. Optical Observations at Low Temperatures

By the use of an optical stage specifically designed for microscopic observations at low temperature, the observation down to −140°C could be carried out without disturbances due to icings. Dielectric measurement was also carried out in parallel. Conoscopic observation, however, was not successful at low temperatures and was performed only at room temperature.

When a tetragonal crystal (Type II) is cooled down, the interference color does not show any appreciable change down to about −55°C, where a fairly rapid change occurs with the increase of retardation. The color change starts from localized nuclei and spreads over the whole area. The temperature at which the change begins depends more or less on specimen and cooling rate, and it ranges from −55°C to −60°C. The intereference color does not show any rapid change neither by further cooling down to −140°C nor by heating up to room temperature, except a minute change just above −24°C, namely the ferroelectric transition point.

The crystal sample whose optic character is illustrated in Fig. 5 exhibits an interesting change. A typical case is shown in Fig. 6, in which the dark areas are uniaxial and the bright areas contain some biaxial components. As shown by Fig. 6 (b), the boundary movement occurs around a fixed position and the patterns always remain radial. By the conoscopic observation, it is revealed that the apparent optic axial angle has increased over the whole area after the cooling cycle.

§ 4. Etch Figures

When crystals of KFCT are etched in the mixture of water and alcohol, pyramidal etch pits appear on the clevage surface. The pits have some characteristic features such as follows.

(a) Side faces of pyramids are composed of small steps.

(b) The pits appear at definite positions for each sample. When a crystal is cleaved away into two parts and then etched, the pits of two matching faces perfectly fit to each other, as shown in Fig. 7.

(c) The number of etch pits is scanty (a few per millimeter square) for slowly grown crystals, while this number is great many for rapidly grown ones.

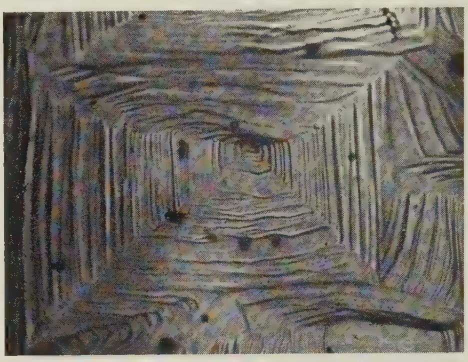

Fig. 8. Inclined etch pits. (×300)

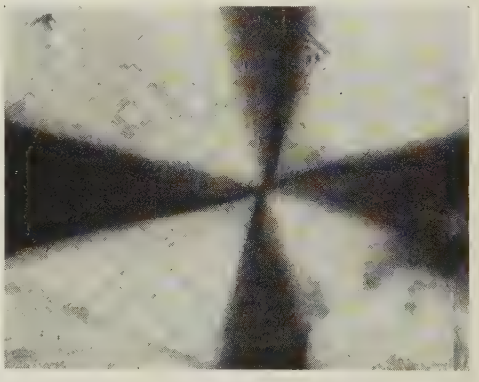

Fig. 9. Etch pit observed through a polarized microscope. ×75

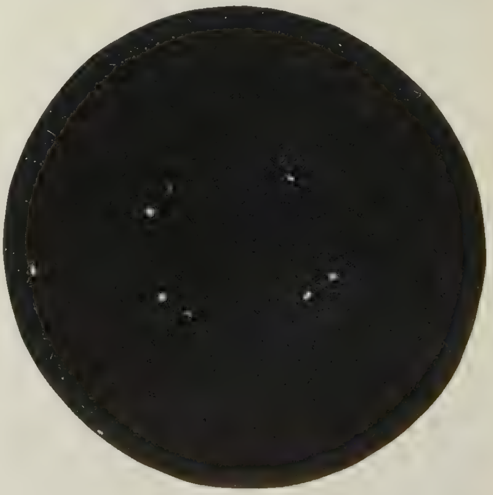

Fig. 15. Laue pattern of type IV crystal taken with monochromatic radiation (Mo Kα, 45 kv 20 ma, 1 hr).

(d) The pyramids are not always perpendicular to the cleavage face as shown in Fig. 8. When etching proceeds, the tip goes ahead along the inclined lines.

(e) Etch pits have a close relation to the optical anomaly. In a crystal with a crossed uniaxial area, the pit density increases near this area and a markedly sharp pit appears at the intersection of the cross (Fig. 9). In the crystals of Type IV, a wedge shaped area distinguishable by difference in birefringence is often observed. In such cases the pit has an octagonal base as schematically shown in Fig. 10.

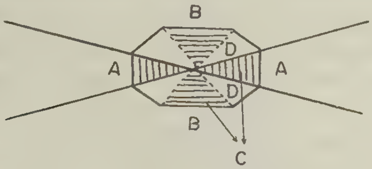

Fig. 10. Etch pit with octagonal base.
Birefringence of area A is smaller than that of B. Side face C of pyramid is composed of steps, while on the face D steps are not so marked.

The observed results are similar to those found in GASH crystals by Nakamura[5], and suggest that the pits are closely related to dislocations in the crystal, and that the various optical anomalies may be caused at least partly by dislocations.

§ 5. Dielectric Measurement

By a dielectric measurement, it has been shown for the Type I crystal that the polarization axis lies in the direction [10$\bar{1}$] which makes an angle of 32° with optic plane, while for an optically abnormal crystal, ferroelectric hysteresis loops are observed in two directions perpendicular to each other. Dielectric measurements so far reported[1),2)] were performed only for heating processes up to room temperature. The results obtained in cooling and heating runs together with optical observation are described below.

When an teragonal crystal (Type II) is cooled down, the dielectric constant shows no appreciable change down to -55°C, where a small peak appears, and the dielectric hysteresis loop appears suddenly, though unsaturated because of a high coercive field. At this temperature the structural transition to the twinned monoclinic phase takes place as mentioned before. In the heating process, the anomaly at about -55°C disappears and the dielectric property shows the features characteristic to Currie point Tc=24°C, where the dielectric constant marks a sharp peak and, at the same time, the dielectric hysteresis loop disappears.

A second cooling cycle differs considerably from the first one, but only slightly from the heating cycle. The Curie point is slightly lower than that for heating. The dielectric peak and the saturated polarization compared at the same (Tc-T) value are also smaller than those in the heating (Fig. 11). Though the temperature where the dielectric anomalies take place changes to some degrees from crystal to crystal, the general trend is common to all.

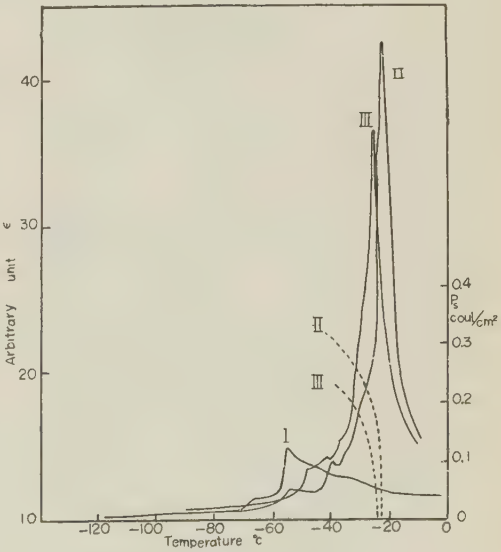

Fig. 11. Dielectric measurement at low temperature.
Full lines represent dielectric constant in arbitrary scale and dotted lines represent saturated polarization.
I. First cooling. II. Heating. III. Second cooling.

The properties as shown in Fig. 11 are obtained with an electric field along the direction inclined by 58° from the apparent optic plane, namely, the direction which is perpendicular to the polarization axis for the monoclinic single crystal. Measurements were repeated on the same crystal but with the filed perpendicular to the previous one. The results are shown in Fig. 12. Since the crystal has been once subjected to the cooling cycle, the ferroelectric transition at −24°C appears even in a first cooling run. The anomaly in dielectric constant is more considerable and the spontaneous polarization is larger than in Fig. 11. Differences of dielectric peaks and spontaneous polarization between the cooling and heating processes are noted again. It is worth mentioning that the summation of spontaneous polarizotion along the two directions in the heating process is nearly equal to that of the monoclinic single crystal.

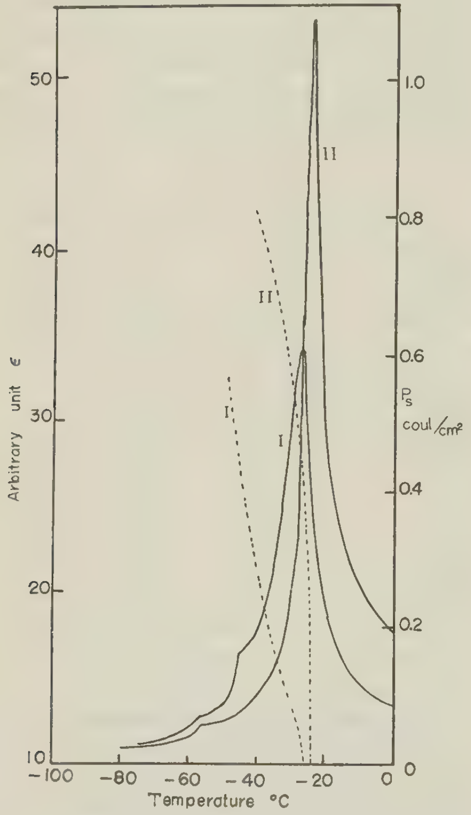

Fig. 12. Dielectric measurement along the direction perpendicular to that in Fig. 18.
Full lines represent dielectric constant in arbitrary scale and dotted lines represent saturated polarization.
I. Cooling. II. Heating.

It is interesting to note that the field cooling has no direct effect on the orientation of the monoclinic components. If the crystal examined was perfectly tetrogonal and if the transition occured homogeneously throughout the crystal, the electric field applied across the transition point would bring out a monoclinic single crystal where $[10\bar{1}]$ axis is parallel to the field direction. The observed fact suggests, therefore, that the original crystal is of the Type V with vanishing 2V angle. The composition of the crystal after the transition seems to be determined by a minute unbalance between the two biaxial components in the original state, and the effect of local crystalline field seems to be larger than that of electric field.

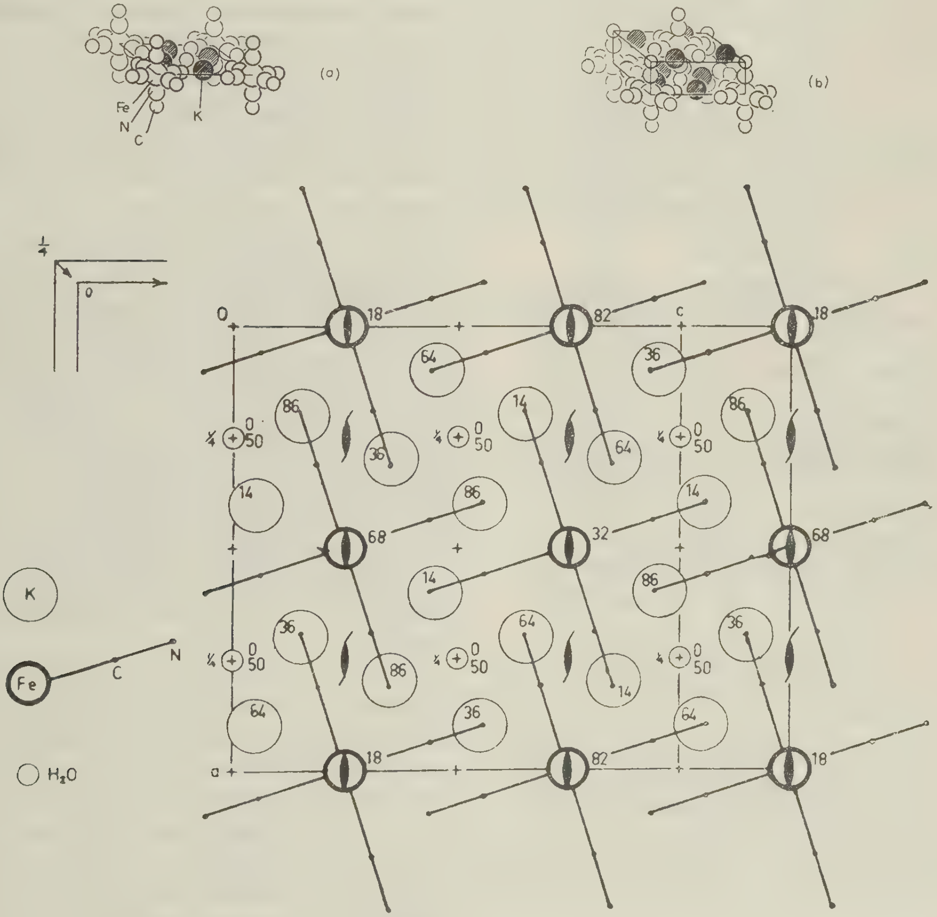
As described in Section 3, a minute change of interference color pattern occurs just above the ferroelectric transition point for a Type II crystal which has been subjected to a cooling process. The color change corresponds to the decrease of retardation due to the partial reappearance of the uniaxial component. The revived tetragonal part can not any ferroelectric contribution down to −55°C and therefore, the ferroelectric behavior in heating run is more conspicuous than that in the second cooling run.

§ 6. Discussion

To understand the optical and dielectric anomalis of KFCT crystals from the structural view point, it is worthy mentioning briefly the present knowledge on the crystal structure of the crystal. The structure determination of monoclidic KFCT (Type I) was performed by Posperov and Zdanov, except for the coordinates of some H_2O molecules. This structure can be considered as a double layer structure, the layer-staking unit of which is illustrated in Figs. 13 (a) and 13 (b). The structure projected on (010) is also shown in Fig. 13 (c).

The monoclinic unit cell is built up with successive double layers stacked with the shift by the amount $\vec{a}/2+\vec{b}/2$, namely by the C-centering vector of space group C2/c. The schematic diagram of this type of stacking is shown in Fig. 14 (a). In terms of the stacking vector, $\vec{C}$, the structure can be expressed by the symbols such as, $\vec{C}\,\vec{C}\,\vec{C}\ldots\vec{C}\,\vec{C}$. In view of pseudo-tetragonality of double layers comprising $Fe(CN)_6$ and K atoms, which can be clearly seen in Fig. 13 (c), we can conceive that the successive stacking operations $\vec{A}\,\vec{A}\,\vec{A}\ldots\vec{A}\,\vec{A}$, where $\vec{A}$ represents a vector $\vec{c}/2+\vec{b}/2$, would also result in a monoclinic structure which is rotated 90° from the former structure around the b axis. The H_2O molecules exist in layers between the double layers of heavier atoms. Among the twelve H_2O molecules in the unit cell, eight molecules are placed on equipoint 8 (f) of C2/c, and specifically at the midpoint of the centers of symmetry 4 (c) and 4 (d), according Posperov *et al.* Although the coordinates of other four molecules were not determined by them, consideration of the space group equipoints and possible interatomic distances should place them at equipoint 4 (e), namely on the two-fold axes, and approximately at the same level as the other eight molecules. Since the arrangement of H_2O molecules in layer has only two-fold symmetry, and not pseudo four-fold symmetry, the orientation of the H_2O layer with respect to double layers in the second type of stacking should be rotated 90° around the *b* axis from that in the first type.

The structure of tetragonal KFCT (Type II) has a very close relations to that of monoclinic one. These relations can be stated as follows: (1) *c* axis of tetragonal crystal is twice as large as the *b* axis of monoclinc one, while the unit cell dimensions of both crystals are otherwise almost identical: (2) The tetragonal reciprocal lattice level *hk*0 is identical to that of monoclinic *hll* except the weak intensities for h=odd, l=even. These facts indicate that the tetragonal structure may pictured as the stacking of double layers such that the unit cell dimension normal to



(c)

Fig. 13. Figures indicate the height above the plane in hundredth. (a) and (b) are reproduced from Structure Report XI, pp. 423.

(a) Single layer unit of KFCT crystal.

(b) Double layer unit of KFCT crystal.

(c) Projection of KFCT crystal structure on (010).

the layer is twice as large as that for the monoclinic one. Furthemore, the tetragonal structure shows non-space group extinctions for $l=4\,\mathrm{n}$, h and k=even, and for $=4\,\mathrm{n}\pm2$, h and k=odd. (Space group requires the extiction only for l=even, $h+k$=even). The possible stacking satisfying these observed extra extinction rules is illustrated in Fig. 14(c), referring to the monoclinic unit cell. In this model, the successive double layers are related to each other by four-fold screw axis of $\mathrm{I}\,4_1/a$. Because of the tetragonal symmetry of layers themselves, the relations can be again described by the shifts between layers, and the structure can be expressed by symbols such as, $\vec{A}\,\vec{C}\,\vec{A}\,\vec{C}\ldots\vec{A}\,\vec{C}\,\vec{A}\,\vec{C}$.

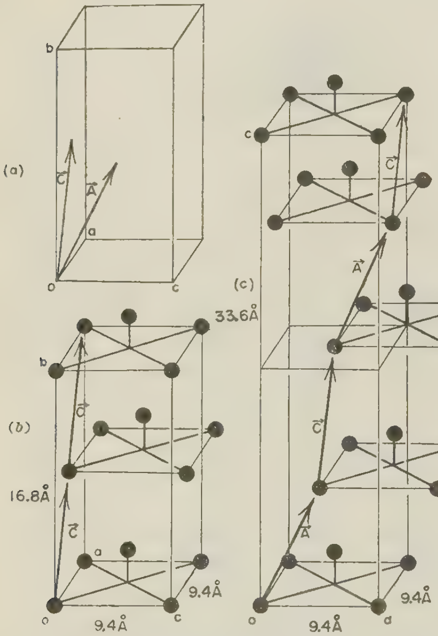


Fig. 14. Double layers are shown only with respect to Fe atoms, and the origin is arbitrarily taken at Fe atom.

(a) Vectors $\vec{A}$ and $\vec{C}$ of monoclinic lattice.

(b) Stacking scheme of double layers in monoclinic unit cell of KFCT crystal structure.

(c) Stacking scheme of double layers in tetragonal unit cell of KFCT structure with monoclinic notations.

In view of the layer structures of two modifications of KFCT, it is most probable that the oriented overgrowth between the two types of structures may take place readily, and that mistakes in stacking may occur frequently. Also the overgrowth between the two types of monoclinic stackings may be conceived to take place readily. If the type of stacking is consistent over some macroscopic dimensions, the resulting crystals may be crystallographically single crystals of Type I and II, or the macroscopic twin or oriented overgrowth described as Type III or IV. Type IV crystals can be then expresssed as; $\vec{A}\,\vec{A}\,\vec{A}\,\vec{A}\ldots\vec{C}\,\vec{C}\,\vec{C}\,\vec{C}$. If the stacking fault takes place in microscopic scale, the resulting crystal can considered as a mixture of tetragonal and monoclinic components. These crystal belong to Type V.

The mistakes in stacking take place if the adjacent layers are related by, say, the shift vector $\vec{A}$ when the normal sequence of layers should be related by vectors $\vec{C}$. Mistakes in a monoclinic structure can be represented as, $\vec{C}\,\vec{C}\,\vec{C}\ldots\vec{C}\,\vec{A}\,\vec{A}\,\vec{C}\,\vec{A}\,\vec{C}\ldots\vec{C}\,\vec{C}$.

These mistakes will give rise to the apperance of diffuse spots in X-ray diffraction photographs, especially around the reciprocal lattice points with indices $h+l$=odd. Qualitatively speaking, these diffuse spots are considered as elongated parallel to b axis of monoclinic crystal, or to c axis of tetragonal crystal. Such diffuse rows are commonly observed in rotation photographs around such axes of Type V crystals. They also appear as diffuse spots in Laue photographs of Type IV crystals, as shown in Fig. 3 (a). The Laue pattern of the same crystal with monochromatized X-ray is illustrated in Fig. 15 to show clearly the arrangement of diffuse spots. Detailed study of diffuse spots as well as the refinement of the crystal structure are in progress.

The optical, X-ray, and dielectric studies of unidirectional transition of the tetragonal phase at about −55°C result in a consistent conclusion that, after the transition of this phase into the monoclinic phase, the crystal becomes composed of oriented parallel growth of individuals with two kinds of orientation. Unidirectional transition, which is well known as monotropy in structural chemistry, may be explained by the free energy-temperature diagrams, and it is usual that the monotropic change takes place in a heating process, However, this is not the case with KFCT crystal.

The authors have recently found some evidences for an irrevercible transition from monoclinic structure to the Type V structures. When a monoclinic crystal is compressed along [101] or [10$\bar{1}$], the retardation observed along [010] decreases and remains unaltered after the removal of the external stress. The retardation increases, however, between −45° and −55°C and does not show any rapid change thereafter in the heating up to room temperature. The dielectric measument was performed also on the pressed crystal powder, and showed that the anomalies at −38°, −45° and 55°C appear both in cooling and heating processes. These facts suggest that the stability of each phase and the peculiar transitions in KFCT crystals may be affected by mechanical stresses. Further theoretical and experimental studies are in progress to understand the processes of transitions.

The authors wish to express their sincere thanks to Dr. H. Hirabayashi for his helpful discussions and to H. Iwasaki, K. Masuno and K. Nagata for their cooperations.

Appendix

Interference of light through a stacking of two thin crystals are considered. The normal to the stacking layer is chosen so as to coincide with the optic axis for uniaxial crystals, or with the X or Z axis for biaxial crystals. We consider the following two cases: A, stacking of an uniaxial and a biaxial crystals; B, two biaxial crystals of the same kind so stacked that the optic planes are perpendicular to each other with common X or Z axis.

When light passing through the stacked crystals breaks up into four linearly polarized lights, the retardations between them are given by

$$\frac{2\pi}{\lambda}d_1(n_1'-n_1''),\ \frac{2\pi}{\lambda}d_2(n_2'-n_2'')\ \text{and}$$
$$\frac{2\pi}{\lambda}\{d_1(n_1'-n_1'')\pm d_2(n_2'-n_2'')\}.$$

Suffix and prime correspond to the stacking individuals and the propagating velocities, respectively. As readily seen from the crystal optical construction, the main isogyer becomes a cross at extinction position and otherwise it suffices to consider two polarized lights with the retardation $\frac{2\pi}{\lambda}\{d_1(n_1'-n_1'')-d_2(n_2'-n_2'')\}$. The directions satisfying the condition $d_1(n_1'-n_1'')=d_2(n_2'-n_2'')$ appear as two dark points in a conoscopic pattern and are observed as the apparent optic axes. The apparent optic plane and optic angle depend on thickness ratio of component crystals.

Actual observations on the isochromats and their changes due to the reduction of thickness revealed that the Type IV crystal of KFCT contains both cases of A and B.

Thomas-Fermi-Dirac Model of Compressed Ions

By Shigehiro KOBAYASHI

Department of Physics, Kagawa University, Takamatsu

(Received April 27, 1960)

The Thomas-Fermi-Dirac (TFD) method is extended anew to ions in the compressed state and the series expansion coefficients of its TFD function near the boundary are given.

§ 1. TFD Model of Compressed Ions

In a previous paper[1] we have shown that the simple Thomas-Fermi (TF) model, which has been applied to the treatment for the compressed state of atoms as well as for the free state of atoms and ions[2], can be extended to the compressed state of ions. In this paper, we wish to formulate the TFD model of compressed positive ions in the similar way.

We shall treat a compressed ion with atomic number Z and electron number N.

The requirement that the total energy E of the TFD model of the ion shall be minimum with respect to variation of the electron density ρ, the total number of electrons being kept costant, leads to

$$\frac{5}{3}\kappa_k\rho^{2/3}-\frac{4}{3}\kappa_a\rho^{1/3}-(V-V_0)e=0 \qquad (1)$$

or

$$\rho(r)=\frac{8\pi}{3h^3}(2me)^{3/2}[\{V(r)-V_0+\tau^2\}^{1/2}+\tau]^3, \qquad (2)$$

where V_0 is the Lagrange multiplier expressing the maximum potential for the electron in the ion and

$$\kappa_k=\frac{3}{10}(3\pi^2)^{2/3}e^2a_0, \quad \kappa_a=\frac{3}{4}\left(\frac{3}{\pi}\right)^{1/3}e^2,$$

$$\tau=\left(\frac{4\kappa_a^2}{15\kappa_k e}\right)^{1/2}=\frac{(2me^3)^{1/2}}{h}.$$

Another requirement of self-consistency that the electrostatic potential V shall be created by the electronic cloud of density ρ and the nucleus of the ion is simply expressed in Poisson's equation

$$\Delta V=4\pi\rho e\,. \qquad (3)$$

Combining (2) with (3) and using the ordinary notations

$$r=\mu x, \quad \mu=\frac{1}{4}\left(\frac{9\pi^2}{2Z}\right)^{1/3}a_0\,, \qquad (4)$$

$$V-V_0+\tau^2=\frac{Ze}{r}\psi \qquad (5)$$

and

$$\beta=\tau(\mu/Ze)^{1/2}=6^{1/3}/4(\pi Z)^{2/3} \qquad (6)$$

under the assumption of the spherical symmetry, we can obtain the so-called TFD equation

$$\psi''=x[(\psi/x)^{1/2}+\beta]^3 \qquad (7)$$

and the electron density represented in terms of ψ

$$\rho(x)=\frac{Z}{4\pi\mu^3}\frac{\psi''}{x}=\frac{Z}{4\pi\mu^3}[(\psi/x)^{1/2}+\beta]^3. \qquad (8)$$

By the use of the thermodynamic relation, we can compute the pressure

$$p=-\frac{dE}{dv}=\frac{1}{3}\rho(R)^{4/3}\{2\kappa_k\rho(R)^{1/3}-\kappa_a\} \qquad (9)$$

dependent on the boundary density $\rho(R)$, where v is the volume of the ion.

The solution of (7), namely the TFD function $\psi_{Z,q,X}$ for the state of ionization degree $q=(Z-N)/Z$ and of boundary radius $R=\mu X$

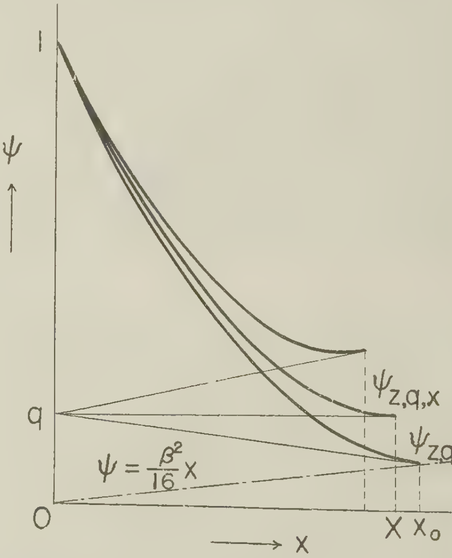

Fig. 1. The TFD function $\psi(x)$ for compressed ions. From Fig. 1 it can be seen that the particular values of Z, q and X determine uniquely a ψ-curve in the assembly of the ψ-curves starting from $\psi(0)=1$ for the particular value of Z.

must satisfy at the nucleus ($x=0$) the condition

$$\psi_{Z,q,X}(0)=1: \text{ nucleus predominates} \tag{10}$$

and at the boundary ($x=X$) the conditions

$$\psi_{Z,q,X}(X)>\frac{\beta^2}{16}X: \text{ finite pressure} \tag{11}$$

and

$$\psi_{Z,q,X}(X)-X\psi'_{Z,q,X}(X)=q: \quad \text{net charge}=(Z-N)e. \tag{12}$$

As is well known, for the free state of the ion with the boundary radius $r_0=\mu x_0(>R)$, which corresponds to the zero pressure, (9) gives the boundary density

$$\rho(r_0)=\left(\frac{\kappa_a}{2\kappa_k}\right)^3=0.002127\ a_0^{-3} \tag{13}$$

independent of Z and N. Accordingly, with $V(r_0)=(Z-N)e/r_0$ we obtain from (1)

$$V_0=\frac{Ze}{r_0}q+\frac{15}{16}\tau^2 \tag{14}$$

and from (5)

$$\psi_{Z,q,x_0}(x_0)=\frac{\beta^2}{16}x_0\,. \tag{15}$$

For the compressed state, V_0 should be chosen, following Slater and Krutter[3], in such a way that the potential V in the immediate neighborhood of the nucleus has a value independent of the boundary radius, that is

$$V=V_0-\tau^2+\frac{Ze}{\mu}\left[\frac{1}{x}+\psi'_{Z,q,X}(0)+\frac{4}{3}x^{1/2}+\dots\right] \quad : \text{ for the compressed state}$$

and

$$V=\frac{(Z-N)e}{\mu x_0}-\frac{1}{16}\tau^2+\frac{Ze}{\mu}\left[\frac{1}{x}+\psi'_{Z,q,x_0}(0)+\frac{4}{3}x^{1/2}+\dots\right] \quad : \text{ for the free state}$$

ought to agree with each other up to the constant terms as well as to those in $1/x$. Thus, V_0 takes the value

$$V_0=\left[\frac{q}{x_0}+\psi'_{Z,q,x_0}(0)-\psi'_{Z,q,X}(0)\right]\frac{Ze}{\mu}+\frac{15}{16}\tau^2 \tag{16}$$

dependent on q and X.

This expression of V_0 for our general case is naturally reduced to (14) for the free state and to the expression (7) in the previous paper[1] for the compressed TF model in which the exchange effect is neglected ($\kappa_a=0$, $\tau=0$).

The expressions (5), (8) and (16) enable us to calculate various physical quantities for ions in the compressed state.

§ 2. Series Expansion Around the Boundary

The TFD function $\psi_{Z,q,X}(x)$ for the compressed ion can be expanded around the boundary point X in a Taylor series such as

$$\psi_{Z,q,X}(x)\equiv a^2X+t_1(X-x)+t_2(X-x)^2+t_3(X-x)^3+\dots, \tag{17}$$

where $a^2\equiv\psi_{Z,q,X}(X)/X$, particularly in the free state $a=\beta/4$ due to (15).

The expansion coefficients up to and including t_7 are given in terms of $\beta(Z)$, q, $a(X)$ and X as follows;

$$t_1=-a^2+\left\{\frac{1}{X}q\right\}$$

$$t_2=\frac{X}{2}(a+\beta)^3$$

$$t_3=-\frac{1}{6}(a+\beta)^3+\left\{\frac{1}{4aX}(a+\beta)^3q\right\}$$

$$t_4=\frac{X}{16a}(a+\beta)^5+\left\{\frac{1}{32a^3X^3}(a^2-\beta^2)q^2\right\}$$

$$t_5=-\frac{1}{80a}(a+\beta)^5+\left\{\frac{3}{160a^3X}(2a-\beta)(a+\beta)^4q\right.$$

$$\left.+\frac{3}{160a^3X^4}(a^2-\beta^2)q^2-\frac{1}{320a^5X^5}(a^2-3\beta^2)q^3\right\}$$

$$t_6=\frac{X}{320a^3}(2a-\beta)(a+\beta)^7+\left\{\frac{1}{120a^3X^2}(a-\beta)(a+\beta)^4q\right.$$

$$+\frac{1}{80a^3X^5}\left[(a^2-\beta^2)+\frac{X^2}{8a^2}(3a^2-5a\beta+6\beta^2)(a+\beta)^3\right]q^2$$

$$\left.-\frac{1}{240a^5X^6}(a^2-3\beta^2)q^3+\frac{1}{1280a^7X^7}(a^2-5\beta^2)q^4\right\}$$

$$t_7=\frac{1}{6720a^3}(2a-5\beta)(a+\beta)^7$$

$$+\left\{\frac{1}{168}\frac{(a+\beta)^4}{a^4X^5}\left[(a-\beta)+\frac{3X^2}{80a^2}(16a^2-18a\beta+15\beta^2)(a+\beta)^2\right]q\right.$$

$$+\frac{1}{112}\frac{a+\beta}{a^3X^6}\left[(u-\beta)+\frac{X^3}{120a^2}(19a^2-69a\beta+150\beta^2)(a+\beta)^2\right]q^2$$

$$+\frac{1}{224}\frac{1}{a^5X^7}\left[(-a^2+3\beta^2)-\frac{X^2}{20a^4}(2a^5+4a^4\beta-4a^3\beta^2-37a^2\beta^3-56a\beta^4-25\beta^5)\right]q^3$$

$$\left.+\frac{3}{1792}\frac{1}{a^7X^8}(a^2-5\beta^2)q^4-\frac{1}{3584}\frac{1}{a^9X^9}(a^2-7\beta^2)q^5\right\}.$$

The bracketted parts depending on q in these expressions are proper to the ion, and the rest parts coincide with the coefficients for compressed neutral atoms given by March[4].

The author would like to express his sincere thanks to Professor K. Umeda of Okayama University for reading the manuscript and giving many advices. This work was supported by the Scientific Research Fund of the Ministry of Education.

On the Magnetic Properties of the Compound Mn_2As

By Motoyoshi YUZURI and Motohiko YAMADA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received May 6, 1960)

The thermomagnetic properties of a compound Mn_2As were investigated together with the phase diagram of Mn–As system. From the results of measurements of the temperature dependence of magnetic susceptibility and specific heat of the compound Mn_2As, it was found that this alloy is antiferromagnetic with the Néel point at 573°K. The reciprocal of its susceptibility obeys the Curie-Weiss law in the high temperature range, but a considerable deviation therefrom can be seen just above the Néel point as in the case of ferrimagnetism. Based on the Curie constant obtained by the present experiment, the effective magneton number was calculated to be 5.2 per manganese ion. The total heat absorption due to the vanishing of antiferromagnetic order of spins in the present alloy was estimated to be 230 Cal/mol. A discussion based on the molecular field theory is given on the nature of the above-mentioned magnetic properties.

§ 1. Introduction

In the crystal lattice of Cu_2Sb type compounds the cation sites are thought to form a deformed face-centered lattice, which is divisible into two sorts of non-equivalent sublattices. If such cations have magnetic moments, the formation of new types of spin ordering is to be expected because of the presence of such a peculiar type of magnetic lattice structure. But very few magnetic measurements for this type of compounds have hitherto been done, except those for Mn_2Sb.[1) 2) 3)] The present authors undertook a study of the magnetic properties of a compound Mn_2As, whose crystal structure was reported by Nowotny and Halla[4)] as belonging to the above-mentioned type. The phase diagram of manganese-arsenic system was once studied by Guillaud[1)] and Sweeny and Scott.[5)] The results obtained by these authors, however, were not sufficient for the preparation of our specimens. Here, the results of X-ray, thermal and magnetic analyses are also presented which have been carried out in order to study the phase diagram of the present system.

§ 2. Preparation of the Specimen

The specimens used were prepared by the ceramic method. Manganese (99.9%) and arsenic (99.9%) powders were mixed in the desired ratios in the composition range from MnAs to $Mn_{2.3}As$, sealed into evacuated quartz tubes and heated in an electric furnace. To avoid explosion of the tubes during heating, the mixtures were heated up slowly in 72 hours from room temperature up to 900°C at which they were kept for 48 hours. After the reaction was completed, the specimens were cooled slowly down to room temperature in 72 hours. Since the compound Mn_3As_2, which was supposed to be formed by a peritectoid reaction between the compounds MnAs and Mn_2As, had a transition point between 750°C and 775°C, the reaction products whose composition was nearly Mn_3As_2 were annealed more at about 700°C for 72 hours. In order to obtain homogeneous specimens, all the reaction products were crushed, well mixed, again heated to 770°C, kept for 48 hours, and then cooled to room temperature in 72 hours. Such prepared specimens, however, did not show any difference from the original ones in their magnetic properties. Every portion of the specimen thus obtained showed a similar thermo-magnetic behavior.

§ 3. Phase-diagramatic Study of Mn-As System

First, the thermal analysis was made in the composition range from x=1.0 to 2.0, x being the Mn content in the formula Mn_xAs*. The results are shown in Fig. 1. A peak of latent heat type in specific heat vs. temperature was observed invariably at 750°C, for the specimens with compositions $0<x\leq 1.6$; the peak temperature shifts to 775°C for the specimens with $1.7\leq x<2$. The amounts of such endothermic energy are plotted against Mn content in Fig. 2. As shown in the figure, the amount of heat absorption increases almost linearly with Mn atomic percent from the composition of MnAs to Mn_3As_2, reaching a value 260 Cal/mol at ca the latter. It decreases again linearly from $Mn_{1.7}As$ to Mn_2-As starting from a different value of 400 Cal/mol. Besides, the value of specific heat was not influenced by the lowering of the heating rate of the specimen down to one-third of that in the former case. Moreover the transition temperature and the amount of heat absorbed were not influenced by the annealing of the same specimen at 700°C for 24 hours. These facts can be explained by assuming the presence of a narrow single phase field near the composition Mn_3As_2, which involve a phase transition from γ to γ'. The transition point will be 750°C on the As-rich side and 775°C on the Mn-rich side. In the As-rich region, this phase coexists with the compound MnAs, and in the Mn-rich region, with the compound Mn_2As. (Fig. 3)

---

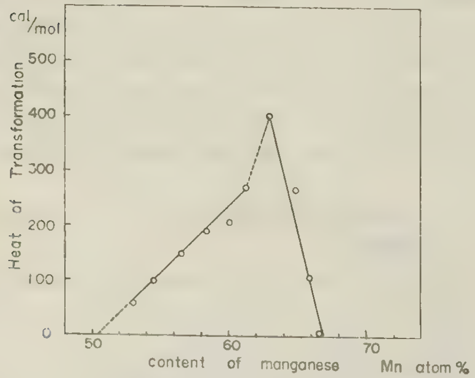

Fig. 2. Transition energy vs. composition in the system *Mn–As*.

Next, the crystal structure was investigated by means of the X-ray powder method. The diffraction lines from the specimen of the composition MnAs could be indexed as those from the NiAs structure with parameters $a=3.72$ Å and $c=5.70$ Å ($c/a=1.53$), which coincided with the result by Oftedals6), and their relative intensities also coincided with the result by calculation. On the other hand, the diffraction lines at the composition $Mn_{2.3}$-As were indexed as those from the crystal structure of Cu_2Sb type with parameters $a=3.78$ Å and $c=6.25$ Å ($c/a=1.65$) in accordance with the result due to Halla and Nowotny4). At intermediate compositions between MnAs and $Mn_{2.3}As$, the diffraction lines from the NiAs structure or that from the Cu_2Sb structure became weak with the increase of x from $x=1$ or with the decrease of x from $x=2$. At the same time, new diffraction lines which could be attributable neither to the NiAs nor to the Cu_2Sb structure became strong correspondingly. In the region between $x=1.5$ and 1.6 only these diffraction lines were seen. Combined with the result of specific heat measurements they are to be attributable to γ'-phase. (Table 1.) The intensity of these lines becomes maximum near $x=1.5$. Diffraction lines from the Cu_2Sb

structure begin to appear near $x=1.6$ and only these lines are seen at the region of x greater than 2.0. The lattice parameters corresponding to Mn_2As and γ–phase (the diffraction angles of the lines) remain unchanged for all specimens measured. On the basis of these crystallographic and thermal studies, MnAs, Mn_2As, or γ -phase is stable in a range of composition including $x=1.0$, 2.0 or 1.5 respectively. It is also established that a two-phase field is existing between MnAs and Mn_3As_2 or between Mn_3As_2 and Mn_2As.

In order to investigate the nature of $\gamma \rightleftarrows \gamma'$ transformation mentioned above, powder photographs were taken of the specimen with $x=1.5$ quenched from temperatures above the transition point, however, no change in the diffraction pattern was found. It was also confirmed by means of a high temperature camera that no change in the patterns occurred above this transition point. On the other hand, both diffraction lines from the Cu_2Sb structure and from manganese were observed near $x=2.5$, showing that this composition is inside of the two-phase region with the Cu_2Sb structure and α—Mn.

Based on the results of X-ray and thermal analyses, the phase diagram of Mn–As system was constructed, as shown in Fig. 3.

§ 4. Thermomagnetic Measurements

The magnetic properties of the specimens were measured by means of an automatically recording magnetic balance.[7] The magnetization curves of the compound Mn_3As_2 at liquid air temperature was measured up to the strength of magnetic field of 10,000 Oe, (The technical saturation was reached at 8000 Oe). As shown in Fig. 4, it is also seen the magnetization at high field changes linearly with the inverse square of magnetic field. By extrapolating the value of magnetization to infinitely strong field, the saturation magnetization is obtained to be 17 gauss/gr.

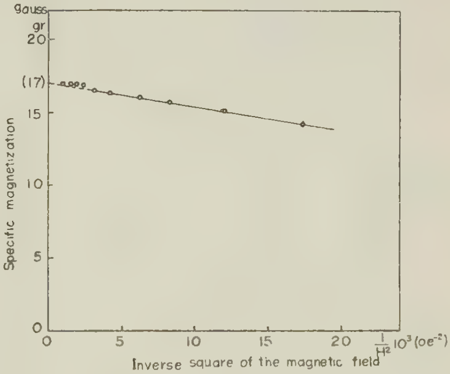

Fig. 4. Specific magnetization of Mn_3As_2 vs. inverse square of the magnetic field.

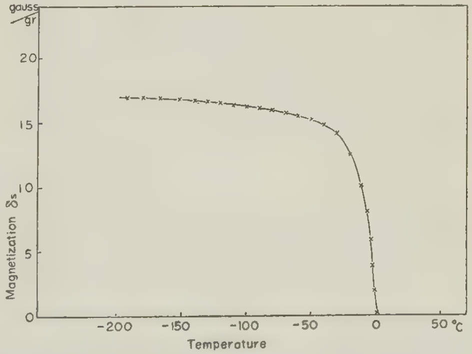

Fig. 5 (A). Thermomagnetic curve below the Curie temperature of Mn_3As_2.

The saturation magnetization varies linearly with $T^{3/2}$ below 150°K. The saturation value at absolute zero of temperature, obtained by extrapolating the linear part of the $\sigma_s - T^{3/2}$ curve, is 17.2 gauss/gr or 0.31 μ_B per Mn atom. The thermomagnetic curve of this compound under the magnetizing field of 8000 Oe is shown in Fig. 5 (A) and Fig. 5 (B), which shows the Curie point lies at 0°C. From the Curie constant, 2.1, obtained from the slope of the $1/\chi - T$ curve, the effective number of magneton per Mn ion was calculated to be 4.1.

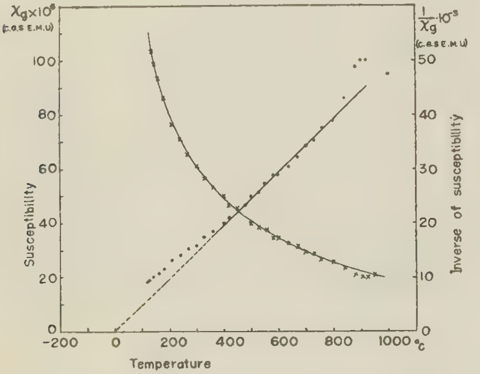

Fig. 5 (B). Thermomagnetic curve above the Curie temperature of Mn_3As_2.

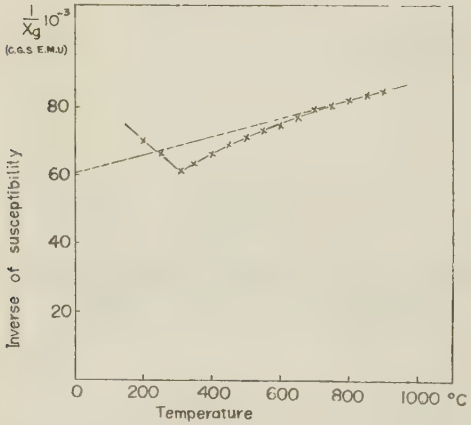

Fig. 6. Reciprocal of susceptibility vs. temperature of $Mn_{2.3}As$.

From the results of thermomagnetic measurement the compound $Mn_{2.3}As$ behaves like an antiferromagnetic substance with the Néel point at 300°C. As shown in Fig. 6, the reciprocal of susceptibility follows the Curie-Weiss law at high temperatures, but decreases rapidly just above the Néel point as is in the case of ferrimagnetism. The specimens with lower Mn concentration show a weak ferromagnetism with Curie point at 0°C as well as an antiferromagnetism with maximum susceptibility at 300°C. The molar magnetization obtained by extrapolating to 0°K at the magnetic field of 8000 Oe decreases linearly, as shown in Fig. 7, with increase of Mn concentration and vanishes at 67%, which again confirms the specimens in the region $1.6 \leq x \leq 2.0$ are the mixtures of Mn_3As_2 and Mn_2As. Actually, however, the specimens with the value of x slightly greater than 2 (e.g. $Mn_{2.1}As$) shows a negligibly weak ferromagnetism with a Curie point at 0°C. It was difficult to avoid a trace of contamination of Mn_3As_2 in this composition range.

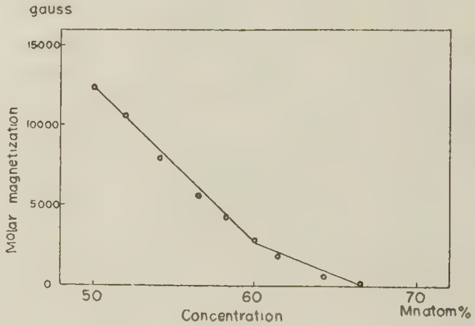

Fig. 7. Saturation magnetization vs Mn concentration.

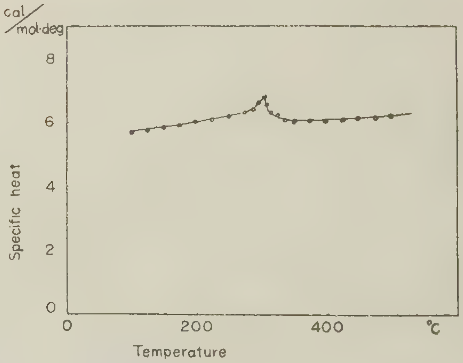

Fig. 8. Specific heat of $Mn_{2.3}As$ vs. temperature.

The measurement of specific heat near the temperature at which the susceptibility of $Mn_{2.3}As$ attained maximum was carried out by means of an adiabatic calorimeter[8]. The result of measurement is shown in Fig. 8. An anomalous peak of specific heat was observed at about 300°C corresponding to the susceptibility maximum of this compound, and the excess heat absorption is estimated to be 230 Cal per mole of mangenese.

§ 5. Discussion of the Result

Now the magnetic properties of the compound Mn_2As will be discussed. In the crystal lattice of Mn_2As there are two sorts of cation sites A and B, as shown in Fig. 9, which are surrounded by arsenic ions tetrahedrally and octahedrally respectively. If we restrict ourselves to a case in which both cation layers, A_1 and B_1, in the present crystal lattice have net spin moment, as is confirmed in the case of Mn_2Sb,[3] it is sufficient to take into account the four molecular field coefficients: (1) inter-layer molecular coefficient n between $B_1(B_4)$, and $B_2(B_3)$, (2) inter-layer molecular coefficient $n\beta_1$ between A_1 and B_1 (B_4), (3) inter-layer molecular coefficient $n\beta_2$ between A_1 and $B_2(B_3)$ and (4) intra-layer molecular coefficient $n\gamma$ in the planes A_1 as well as A_2. The molecular field H_{A1}, H_{B1}, etc. acting on an ion at a lattice point of A_1, B_1 etc. are expressible as

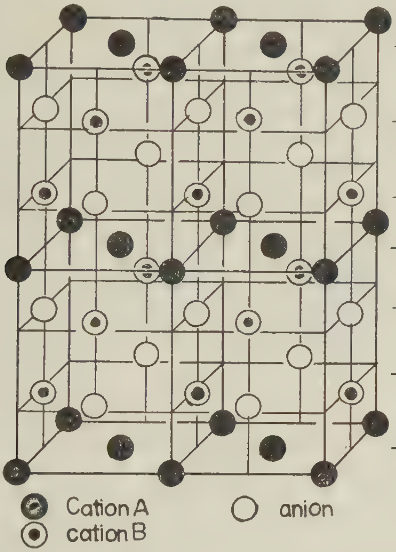

Fig. 9. Mn_2As structure and its sublattices.

$$H_{A1}=n(\beta_1 M_{B1}+\beta_1 M_{B4}+\beta_2 M_{B2}+\beta_2 M_{B3}) \\ +n\gamma M_{A1},$$

$$H_{B1}=n(\beta_1 M_{A1}+\beta_2 M_{A2})+nM_{B1}, \text{ etc.}$$

Here M_{A1} ect, represent the magnetization vectors of sublattice A_1 etc. for one mole of material respectively. In this case four types of spin ordering illustrated in Fig. 10 are expected to occur; one ferromagnetic, one ferrimagnetic and the other two antiferromagnetic (I, II).* The corresponding Néel temperature for the antiferromagnetic cases is given as follows:

$$T_N=\frac{1}{16}[n(2C_A\gamma-C_B)+|n|\{(C_B+2C_A\gamma)^2 \\ +16C_AC_B(\beta_1-\beta_2)^2\}^{1/2}].$$

In each case the paramagnetic susceptibility χ above the Néel temperature is given by following equation:

$$\frac{1}{\chi}=\frac{T-T_a}{1/2\cdot(C_A+C_B)}-\frac{\tau}{T-\theta} \tag{1}$$

Where

$$T_a=-\frac{n}{8(C_A+C_B)}(4C_AC_B\beta+C_B^2+2C_A^2\gamma),$$

$$\theta=\frac{nC_AC_B}{8(C_A+C_B)}(1+2\gamma-4\beta), \quad \beta=\beta_1+\beta_2,$$

$$\tau=\frac{n^2C_AC_B}{32(C_A+C_B)^3}\{C_B(1-2\beta)+C_A(2\beta-2\gamma)\}^2,$$

and C_A and C_B are the molar Curie constants of A and B ions respectively. The second term in the right-hand side of Eq. (1) causes an appreciable deviation from the Curie-Weiss law in the temperature range just above the Néel point.

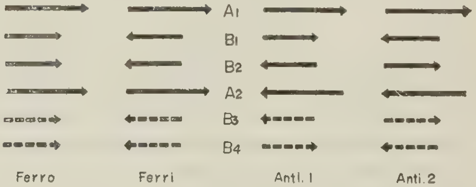

Fig. 10. Four possible types of spin ordering to structure.

If the peak in the susceptibility vs. temperature relation for the compound Mn_2As mentioned above can be attributable to an antiferro-paramagnetic transition as discussed here, the predicted deviation from the Curie-Weiss law can be seen in the magnetic susceptibility of the paramagnetic region of the compound Mn_2As: The full line of the susceptibility curve shown in Fig. 6, is given by putting $T_a=1947$°K, $(C_A+C_B)/2=3.34$, $\tau=10000$°K and $\theta=490$°K (and $T_N=570$°K) in Eq. (1). Using these values, possible values of the molecular field coefficients are calculable. If we assume sextet and quartet states for the manganese ion of A and B sites (the values 4.38 and 2.30 are adopted for C_A and C_B respectively), the molecular field coefficients can be determined as shown in table II. a., and the results for the case in which quintet states are assumed for both ions, are listed in Table II.b. In both cases the calculated Néel temperature based on these coefficents is higher than the calculated ferrimagnetic Curie temperature corresponding to the same values of coefficients, showing that the antiferromagnetic ordering is stable in general, but the calculated internal energy of ferrimagnetic structure at 0°K based on those molecular field constants is lower than that of antiferromagnetic structure, predicting an antiferro-ferrimagnetic transition may occur at low temperature. This prediction is, however, not yet confirmed. The theoretical estimation of the anomalous heat absorption in this antiferro-para transition based on the molecular field treatment is 1150 Cal/mol. Although experimental value of 230 Cal/mol is far smaller than the value, a part of the discrepancy may be attributed to a too crude estimation of the lattice heat which must be subtracted from the above value.

---

* The lattice points in the layer A_i, are also divisible into two sublayers $A_{i'}$ and $A_{i''}$. In such cases some other types of antiferromagnetic ordering are possible such as $M_{Ai'}=-M_{Ai''}$ and $\sum M_{Bi}=0$, and A ions and B ions form respectively antiferromagnetic spin ordering with different Néel temperatures.

Plasma Oscillations in a Magnetic Field

By Ikuo KAJI
The Research Institute of Applied Electricity, Hokkaido University
Masafumi KITO
The Electrotechnical Laboratory, Tokyo

(Received May 7, 1960)

In the presence of a uniform external magnetic field, the initial value problem for a longitudinal electron oscillation in a fully ionized plasma is treated in the range of the linear theory under the assumption that collisions are negligible and that the angle θ between wave vector and magnetic field is not equal to $\pi/2$, and $\mathrm{Re}(s)\neq 0$ on the complex s-plane. It is shown that, if we determine the indicial condition that the solution of initial value problem varies as $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$, where α is a complex valued frequency, then for $\mathrm{Re}(\alpha)<0$ (damped wave) there appears an indeterminancy in the dispersion equation of the potential, and for $\mathrm{Re}(\alpha)>0$ (amplified wave) each dispersion equation of the proper plasma oscillations, the perturbed velocity distribution function, and the potential are coincident. As a typical example, the case in which the equilibrium distribution is Maxwellian is discussed.

Introduction

In the presence of a uniform external magnetic field, a longitudinal small amplitude oscillation of electrons in a fully ionized plasma has been treated by I. B. Bernstein[1] and E. P. Gross[2] when collisions are negligible. The former assumed that the initial perturbed distribution function is an entire function, so that the problem was only restricted to the proper plasma oscillation. The latter discussed only the stationary solution of electron oscillations propagating perpendicular to the magnetic field. However, they did not take into account of the effect of initial perturbed distribution function.

Therefore, we solved the initial value problem for the perturbed distribution function, and determined the indicial condition that the solution of the problem varies as $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$ where α is a complex valued frequency, on the condition that the angle θ between the wave vector and the magnetic field is not equal to $\pi/2$, and $\mathrm{Re}(s)\neq 0$ on the complex s-plane. This indicial condition becomes a dispersion equation of a complex valued frequency.

The dispersion equations for the proper plasma oscillation, the perturbed distribution function, and the electrostatic potential are obtained. For amplified wave, we find that these equations are the same, and furthermore these are determined uniquely. However, although for damped wave the dispersion equations of the proper plasma oscillation and the perturbed distribution function are determined uniquely, there exists an indeterminancy in the dispersion equation of the potential, because the equation involves an arbitrary constant. When the constant is zero, the equations for the distribution function and the potential are coincident. Because of the arbitrary constant, there appears the Doppler shift which is determined by $\omega=ku\cos\theta+n\Omega$ in the distribution function providing that an initial distribution function gives a solution of the potential which varies $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$.

In §1, basic equations of the plasma oscillation are derived from the linearized Boltzmann equation and Poisson equation by use of the Laplace transform method. Initial value problem is treated in §2 and a dispersion equation for proper plasma oscillation is obtained. An indicial condition that the distribution function and the potential become a solution of the form $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$, is determined in §3. As a typical example, the case in which the equilibrium distribution is Maxwellian is discussed in §4.

§1. Basic Equations

Let $f(\boldsymbol{r},\boldsymbol{v},t)$ be the distribution function for electrons, which satisfies the Boltzmann equation

$$\frac{\partial f}{\partial t}+\boldsymbol{v}\cdot\frac{\partial f}{\partial \boldsymbol{r}}-\frac{e}{m}\left\{-\nabla\varphi+\frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}(\boldsymbol{r},t)\right\}\cdot\frac{\partial f}{\partial \boldsymbol{v}}=\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} ,$$

where φ represents the electrostatic potential and $-e$ is the electronic charge. The problem is restricted to merely longitudinal electron oscillation, so that, instead of the full set of Maxwell equations, the Poisson equation is employed. Considering a system which departs only slightly from thermal equilibrium in an external magnetic field, we linearize the Boltzmann equation, neglecting the collision term into

$$\frac{\partial f_1}{\partial t}+\boldsymbol{v}\cdot\frac{\partial f_1}{\partial \boldsymbol{r}}+\frac{e}{m}\nabla\varphi\cdot\frac{\partial f_0}{\partial \boldsymbol{v}}+\frac{e}{mc}\boldsymbol{B}_0\cdot\boldsymbol{v}\times\frac{\partial f_1}{\partial \boldsymbol{v}}=0 , \tag{1.1}$$

and the Poisson equation into

$$\Delta\varphi=4\pi e\int f_1(\boldsymbol{r},\boldsymbol{v},t)\,d^3\boldsymbol{v} , \tag{1.2}$$

where the subscript 0 refers to the steady state, and 1 to a small perturbation. Since (1.1) and (1.2) are linear, it is sufficient to consider a solution of the form $f_{1\boldsymbol{k}}(\boldsymbol{v},t)\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ and $\varphi_{\boldsymbol{k}}(t)\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$. In terms of the Fourier component and the Laplace transform, (1.1) and (1.2) become

$$(s+i\boldsymbol{k}\cdot\boldsymbol{v})F(\boldsymbol{v},s)+\frac{e}{mc}\boldsymbol{B}_0\cdot\boldsymbol{v}\times\frac{\partial F(\boldsymbol{v},s)}{\partial \boldsymbol{v}}=-i\frac{e}{m}\psi(s)\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}}-F^*(\boldsymbol{v}) , \tag{1.3}$$

$$-\boldsymbol{k}\cdot\boldsymbol{k}\psi(s)=4\pi e\int F(\boldsymbol{v},s)\,d^3\boldsymbol{v} , \tag{1.4}$$

where

$$F(\boldsymbol{v},s)=\int_0^\infty f_{1\boldsymbol{k}}(\boldsymbol{v},t)\,e^{-st}\,dt , \qquad \psi(s)=\int_0^\infty \varphi_{\boldsymbol{k}}(t)\,e^{-st}\,dt , \tag{1.5}$$

and we use $f_{1\boldsymbol{k}}(\boldsymbol{v},0)=F^*(\boldsymbol{v})$. Introducing the cylindrical co-ordinates in the velocity space

$$\boldsymbol{v}=\boldsymbol{e}_1 w\cos\phi+\boldsymbol{e}_2 w\sin\phi+\boldsymbol{e}_3 u , \tag{1.6}$$

and putting

$$\boldsymbol{k}=\boldsymbol{e}_1 k\sin\theta+\boldsymbol{e}_3 k\cos\theta , \qquad \boldsymbol{B}_0=\boldsymbol{e}_3 B_0 , \tag{1.7}$$

we have from (1.3)

$$\frac{\partial F}{\partial\phi}+\frac{1}{\Omega}(s+i\boldsymbol{k}\cdot\boldsymbol{v})F=\frac{1}{\Omega}\left(F^*-i\frac{e}{m}\psi\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}}\right) , \tag{1.8}$$

where $\Omega=eB_0/mc$ is the gyration frequency. The deduction of (1.8) is essentially the same as in Bernstein's procedure.

Substituting (1.4) into (1.8) we have the equation for $F(\boldsymbol{v},s)$

$$\frac{\partial F}{\partial\phi}+\frac{1}{\Omega}\{s+ik(w\sin\theta\cos\phi+u\cos\theta)\}F=\frac{1}{\Omega}\left\{F^*+i\frac{4\pi e^2}{mk^2}\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}}\int F\,d^3\boldsymbol{v}\right\} . \tag{1.9}$$

From Appendix A, the periodic solution of (1.8) is given by

$$F(\boldsymbol{v},s)=\frac{1}{\Omega}\int_{-\infty}^{\phi}G(s,\phi,\phi')F^*(\boldsymbol{v}')\,d\phi'-\frac{ie}{\Omega m}\psi\int_{-\infty}^{\phi}G(s,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}\,d\phi' ; \quad \mathrm{Re}\,(s)>0 , \tag{1.10}$$

where

$$G(s,\phi,\phi')=\exp\left\{-\frac{(s+iku\cos\theta)}{\Omega}(\phi-\phi')-\frac{ikw\sin\theta}{\Omega}(\sin\phi-\sin\phi')\right\}. \tag{1.11}$$

Combining (1.4) and (1.10), we obtain for $\mathrm{Re}(s)>0$

$$\phi(s)=\frac{-\dfrac{4\pi e}{\Omega}\displaystyle\int d^3\boldsymbol{v}\int_{-\infty}^{\phi}G(s,\phi,\phi')F^*(\boldsymbol{v}')\,d\phi'}{k^2-\dfrac{i}{\Omega}\dfrac{4\pi e^2}{m}\displaystyle\int d^3\boldsymbol{v}\int_{-\infty}^{\phi}G(s,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}d\phi'}. \tag{1.12}$$

(1.9) and (1.12) are our basic equations.

§ 2. Initial Value Problem

For any given initial distribution function $F^*(\boldsymbol{v})$, we can express the potential, given by (1.12), as a function of the variable t by means of the inversion integral. This integral can be evaluated by using the residues of the poles which arise from the analytic continuation of (1.12) assuming that there does not exist any complication such as a branch point. Then $\varphi_k(t)$ is expressed by the modes corresponding to the poles. After a sufficiently long time, there will remain only a mode having the smallest damping factor, so that we obtain the dispersion equation from this single mode. In (1.12), the poles consist of poles of the numerator which depend on the initial distribution function, and zeros of the denominator which depend on the proper characteristics of the plasma. If $F^*(\boldsymbol{v}')$ in (1.12) is an entire function of u, the numerator is also an entire function providing $\theta\neq(\pi/2)$, as we see in Appendix C. Therefore, the singularities of (1.12) consist only of zeros of the denominator, and these correspond to the proper plasma oscillations. Thus we have, for $\mathrm{Re}(s)>0$, the dispersion equation

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{m}\int d^3\boldsymbol{v}\int_{-\infty}^{\phi}G(s,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}d\phi'=0\,;\qquad \mathrm{Re}(s)>0\,. \tag{2.1}$$

For $\mathrm{Re}(s)<0$, putting $P\equiv\boldsymbol{k}\cdot\partial f_0/\partial\boldsymbol{v}'$ in (B.3) of Appendix B, we have

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{m}\left[\int d^3\boldsymbol{v}\int_{+\infty}^{\phi}G(s,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}d\phi'\right.$$
$$\left.+\frac{4\pi^2\Omega}{k\cos\theta}\sum_n\sum_m\exp\left(-i\frac{n\pi}{2}\right)H_{nm}\left(\frac{is+\frac{1}{2}(n-m)\Omega}{k\cos\theta}\right)\right]=0\,;\qquad\mathrm{Re}(s)<0 \tag{2.2}$$

by using (C.4).

§ 3. Dispersion Equations of a Complex Valued Frequency

In this section, let us decide an indicial condition that each solution of the basic equations (1.9) and (1.12) becomes a solution of the form $e^{\alpha t}$ where α is a complex valued frequency, by choosing an initial distribution function $F^*(\boldsymbol{v})$ properly. These conditions are dispersion equations of a complex valued frequency. In what follows, the dispersion equations of the perturbed velocity distribution function and the electrostatic potential will be discussed.

3.1 *Dispersion equation of distribution function*

Consider the indicial condition that $f_{1\boldsymbol{k}}(\boldsymbol{v},t)\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ becomes a solution of the form $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$, where α is a complex valued frequency and $\mathrm{Re}(\alpha)\neq0$. Putting

$$f_{1\boldsymbol{k}}(\boldsymbol{v},t)\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}}=F^*(\boldsymbol{v})\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t}\,, \tag{3.1}$$

we have

$$f_{1\boldsymbol{k}}(\boldsymbol{v},t)=F^*(\boldsymbol{v})\,e^{\alpha t}\,. \tag{3.2}$$

Therefore, the Laplace transform of (3.2) gives

$$F(\boldsymbol{v}, s)=\frac{F^*(\boldsymbol{v})}{s-\alpha} . \tag{3.3}$$

Substituting (3.3) into (1.9), and multiplying both sides of (1.9) by $(s-\alpha)$, we have

$$\frac{\partial F^*}{\partial\phi}+\frac{1}{\Omega}\{\alpha+ik(w\sin\theta\cos\phi+u\cos\theta)\}F^*=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}}\int F^*\,d^3\boldsymbol{v} . \tag{3.4}$$

Normalizing as

$$\int F^*(\boldsymbol{v})\,d^3\boldsymbol{v}=1 , \tag{3.5}$$

we obtain

$$\frac{\partial F^*}{\partial\phi}+\frac{1}{\Omega}\{\alpha+ik(w\sin\theta\cos\phi+u\cos\theta)\}F^*=\frac{1}{\Omega}\frac{4\pi e^2}{mk^2}\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}} . \tag{3.6}$$

This can be solved by using Appendix A; therefore, we have for $\mathrm{Re}(\alpha)>0$ (amplified wave)

$$F^*(\boldsymbol{v})=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int_{-\infty}^{\phi}G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}\,d\phi' , \tag{3.7}$$

and for $\mathrm{Re}(\alpha)<0$ (damped wave)

$$F^*(\boldsymbol{v})=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int_{+\infty}^{\phi}G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}\,d\phi' . \tag{3.8}$$

If we substitute (3.7) and (3.8) into the indicial condition (3.5) we obtain the dispersion equations;

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int d^3\boldsymbol{v}\int_{-\infty}^{\phi}G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}\,d\phi'=0 ; \qquad \mathrm{Re}(\alpha)>0 , \tag{3.9}$$

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int d^3\boldsymbol{v}\int_{+\infty}^{\phi}G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}\,d\phi'=0 ; \qquad \mathrm{Re}(\alpha)<0 . \tag{3.10}$$

Inversely, if we take (3.7) and (3.8) as $F^*(\boldsymbol{v})$, on the condition that (3.9) and (3.10) hold, then we obtain a solution $f_1(\boldsymbol{r},\boldsymbol{v},t)$ of the form $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$, therefore, we can prove that the solution is uniquely determined by the indicial condition (3.5). Furthermore, under the above indicial condition, we can obtain a solution of the potential $\varphi_k(t)$ which varies as $e^{\alpha t}$, but we find that the solution of the potential satisfies a more general condition than (3.5). These affairs will be seen in the next section.

3.2 *Dispersion equation of electrostatic potential*

In the proceeding section, we have obtained a dispersion equation for the distribution function. But what we observe in the laboratory is a fluctuation of the electrostatic potential. In this section, therefore, we consider a solution of the potential which varies as $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$. In what follows, it will be shown that for damped wave an indeterminancy appears in the dispersion relation.

Generalizing (3.6), we consider the equation, provided that $\theta\neq(\pi/2)$,

$$\frac{\partial F^*}{\partial\phi}+\frac{1}{\Omega}\{\alpha+ik(w\sin\theta\cos\phi+u\cos\theta)\}F^*=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\left\{\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}}+C\,h(w)\right\} , \tag{3.11}$$

where C is an arbitrary constant, and $h(w)$ is a function of w. From Appendix A, the solution of (3.11) for F^* is given by

$$F^*=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int_{-\infty}^{\phi}G(\alpha,\phi,\phi')\left\{\boldsymbol{k}\cdot\frac{\partial f_0}{\partial\boldsymbol{v}'}+C\,h(w)\right\}d\phi' ; \qquad \mathrm{Re}(\alpha)>0 , \tag{3.12}$$

$$F^*=\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int_{+\infty}^{\phi} G(\alpha,\phi,\phi')\left\{\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}+C\,h(w)\right\}d\phi' ;\qquad \mathrm{Re}\,(\alpha)<0. \tag{3.13}$$

Ve multiply the derivative of $G(s,\phi,\phi')$ in (1.11),

$$\frac{\partial G(s,\phi,\phi')}{\partial\phi'}=\frac{1}{\Omega}\{s+ik(w\sin\theta\cos\phi'+u\cos\theta)\}G(s,\phi,\phi')\ ,$$

y $F^*(\boldsymbol{v}')$ and multiply (3.11) by $G(s,\phi,\phi')$. We integrate over ϕ' the difference of both quations thus obtained, then we have for $\mathrm{Re}\,(s)>0$

$$\int_{-\infty}^{\phi} G(s,\phi,\phi')F^*d\phi'=\frac{\Omega}{s-\alpha}\left[F^*-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int_{-\infty}^{\phi} G(s,\phi,\phi')\left\{\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}+C\,h(w)\right\}d\phi'\right]. \tag{3.14}$$

3y use of this equation, the numerator, I_N, of the basic equation (1.12) is given by

$$I_N=-\frac{4\pi e}{s-\alpha}\left[\int F^*d^3\boldsymbol{v}-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(s,\phi,\phi')\left\{\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}+C\,h(w)\right\}d\phi'\right]. \tag{3.15}$$

f we take in (3.15)

$$\int F^*d^3\boldsymbol{v}-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(s,\phi,\phi')C\,h(w)\,d\phi'=1 \tag{3.16}$$

ıs an indicial condition, then for the potential ϕ in (1.12), we have

$$\phi(s)=-\frac{4\pi e}{k^2}\cdot\frac{1}{s-\alpha}\ . \tag{3.17}$$

This shows that for any value of α satisfying (3.16) the potential $\varphi(\boldsymbol{r},t)$ varies as $\exp(i\boldsymbol{k}\cdot\boldsymbol{r}+\alpha t)$. From the substitution of (3.12) and (3.13) into the indicial condition (3.16), we find implicitly the following dispersion equation:

for $\mathrm{Re}\,(\alpha)>0$ (amplified wave)

$$\begin{aligned}\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\Big[\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}\,d\phi'\\ +\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(\alpha,\phi,\phi')C\,h(w)\,d\phi'-\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(s,\phi,\phi')C\,h(w)\,d\phi'\Big]=1\ ,\end{aligned} \tag{3.18}$$

for $\mathrm{Re}\,(\alpha)<0$ (damped wave)

$$\begin{aligned}\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\Big[\int d^3\boldsymbol{v}\int_{+\infty}^{\phi} G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}\,d\phi'\\ +\int d^3\boldsymbol{v}\int_{+\infty}^{\phi} G(\alpha,\phi,\phi')C\,h(w)\,d\phi'-\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(s,\phi,\phi')C\,h(w)\,d\phi'\Big]=1\ .\end{aligned} \tag{3.19}$$

In order to express (3.18) and (3.19) in the form of explicit formulas, let us examine the integral concerning $h(w)$ with the aid of Appendix B. Putting $P\equiv h(w)$ in (B.3), we have

$$\begin{aligned}I^{\pm}(s)&=\int d^3\boldsymbol{v}\int_{\mp\infty}^{\phi} G(s,\phi,\phi')\,h(w)\,d\phi'=2\pi\Omega\sum_m H_m\int_{-\infty}^{\infty}\frac{du}{(s-im\Omega/2)+iku\cos\theta}\\ &=\pm\frac{2\pi^2\Omega}{k\cos\theta}\sum H_m=\pm\frac{2\pi^2\Omega H(0)}{k\cos\theta}\ ;\qquad \mathrm{Re}\,(s)\gtrless 0\ ,\\ &=I^{\pm}(\alpha)\ ;\qquad \mathrm{Re}\,(\alpha)\gtrless 0\ ,\end{aligned}$$

where $H(0)=\int_0^{\infty} w\,h(w)\,dw\neq 0$. These are independent of both s and α. Therefore, (3.18) and (3.19) are reduced respectively to

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{m}\int d^3\boldsymbol{v}\int_{-\infty}^{\phi} G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}\,d\phi'=0\,;\qquad \mathrm{Re}\,(\alpha)>0\,, \qquad \text{(3.20}$$

$$k^2-\frac{i}{\Omega}\frac{4\pi e^2}{m}\left[\int d^3\boldsymbol{v}\int_{+\infty}^{\phi} G(\alpha,\phi,\phi')\boldsymbol{k}\cdot\frac{\partial f_0}{\partial \boldsymbol{v}'}\,d\phi'-\frac{4\pi^2 C\Omega}{k\cos\theta}H(0)\right]=0\,;\qquad \mathrm{Re}\,(\alpha)<0\,. \qquad \text{(3.21}$$

It is very interesting to note, for a damped wave, as we have seen in (3.21), that ther appears an indeterminancy in the dispersion relation, because (3.21) involves an arbitra constant C. When θ is equal to zero, (3.20) and (3.21) become Berz's result[5], namely, (3.20 and (3.21) correspond to her Eqs. (12) and (10) respectively;

$$\left(\frac{k}{\omega_0}\right)^2=\int_{-\infty}^{\infty}\frac{f_0'(u)}{u-\omega/k}\,du\,,$$

$$\left(\frac{k}{\omega_0}\right)^2=\int_{-\infty}^{\infty}\frac{f_0'(u)}{u-\omega/k}\,du+2\pi ikC_0\,.$$

Next, let us investigate the behaviour of the distribution function $F(\boldsymbol{v},s)$ in (1.10) unde the above indicial condition (3.16). Substituting (3.14) and (3.17) into (1.10), we have

$$F(\boldsymbol{v},s)=\frac{F^*}{s-\alpha}-\frac{i}{\Omega}\frac{4\pi e^2}{mk^2}\cdot\frac{1}{s-\alpha}\int_{-\infty}^{\infty}G(s,\phi,\phi')C\,h(w)\,d\phi'\,. \qquad \text{(3.22}$$

In (3.22), if we take $C=0$, it gives a sufficient condition which the distribution functio varies as $e^{\alpha t}$. Let $C\neq 0$. The relation

$$\exp\{iz\sin\phi\}=\sum_n J_n(z)\,e^{in\phi}$$

leads to

$$\int_{-\infty}^{\phi}G(s,\phi,\phi')\,h(w)\,d\phi'=\sum_n\frac{h(w)J_n(kw\sin\theta/\Omega)}{s+i(ku\cos\theta+\Omega)}\exp\left\{-\frac{ikw}{\Omega}\sin\theta\sin\phi+in\phi\right\}.$$

Substituting this integral into (3.22), we have

$$F(\boldsymbol{v},s)=\frac{1}{s-\alpha}\left\{F^*-\frac{i}{\Omega}\frac{4\pi e^2C}{mk^2}\sum_n\Gamma_n\right\}+\frac{i}{\Omega}\frac{4\pi e^2C}{mk^2}\sum_n\frac{\Gamma_n}{s+i(ku\cos\theta+n\Omega)}\,, \qquad \text{(3.23}$$

where

$$\Gamma_n=\frac{\Omega\,h(w)\,J_n(kw\sin\theta/\Omega)\exp\{-(ikw/\Omega)\sin\theta\sin\phi+in\phi\}}{\alpha+i(ku\cos\theta+n\Omega)}\,.$$

Since $\mathrm{Re}\,(\alpha)\neq 0$, Γ_n is not infinite. From the inverse Laplace transform, we have

$$f_{1\boldsymbol{k}}(\boldsymbol{v},t)=\left\{F^*-\frac{i}{\Omega}\frac{4\pi e^2C}{mk^2}\sum_n\Gamma_n\right\}e^{\alpha t}+\frac{i}{\Omega}\frac{4\pi e^2C}{mk^2}\sum_n\Gamma_n\exp\{-i(ku\cos\theta+n\Omega)t\}\,. \qquad \text{(3.24}$$

Therefore, there appears an angular frequency $\omega=ku\cos\theta+n\Omega$, which is determined by the Doppler shift.

§ 4. The Case of Maxwellian Distribution

As a typical example for each dispersion equation obtained in § 2 and § 3, let us take the case of Maxwellian distribution

$$f_0(v)=N\left(\frac{m}{2\pi\kappa T}\right)^{3/2}\exp\left(-\frac{mv^2}{2\kappa T}\right).$$

Putting $P(u,w,\phi')\equiv\boldsymbol{k}\cdot(\partial f_0/\partial\boldsymbol{v}')$ in (B.3) of Appendix B, we have

$$P(u, w, \phi')=h_{-1}(u, w)\, e^{-i\phi'}+h_0(u, w)+h_1(u, w)\, e^{i\phi'}$$

vhere

$$h_1(u, w)=h_{-1}(u, w)=A_0 w \exp\left\{-\frac{m}{2\kappa T}(u^2+w^2)\right\},$$

$$h_0(u, w)=A_1 u \exp\left\{-\frac{m}{2\kappa T}(u^2+w^2)\right\},$$

$$A_0=-N\frac{m}{2\kappa T}\left(\frac{m}{2\pi\kappa T}\right)^{3/2} k\sin\theta\,,$$

$$A_1=-N\frac{m}{\kappa T}\left(\frac{m}{2\pi\kappa T}\right)^{3/2} k\cos\theta\,.$$

Hence from (B.4), we have

$$H_0(u, \beta)=A_1 u\left(\frac{\kappa T}{m}\right)\exp\left\{-\frac{mu^2}{2\kappa T}-2\lambda\sin^2\beta\right\},$$

$$H_1(u, \beta)=A_0\left(\frac{\kappa T}{m}\right)^2\frac{2k\beta\sin\theta}{\Omega}\exp\left\{-\frac{mu^2}{\kappa T}-2\lambda\sin^2\beta\right\},$$

and

$$H_{-1}=-H_1\,,$$

where

$$\lambda=k^2\frac{\kappa T}{m\Omega^2}\sin^2\theta\,,\qquad \mu=k^2\frac{\kappa T}{m\Omega^2}\cos^2\theta\,.$$

Therefore (B.7) is reduced to

$$I^+(s)=2\pi\int_{-\infty}^{+\infty}du\int_0^{\infty}d(2\beta)\Big[H_0(u, \beta)-i(e^{i\beta}+e^{-i\beta})H_1(u, \beta)\Big]\exp\left\{-(s+iku\cos\theta)\frac{2\beta}{\Omega}\right\}. \tag{4.1}$$

Integrating over u and replacing $2\beta=y$, we have

$$I^+(s)=i\Omega N\left(\frac{m}{\kappa T}\right)\int_0^{\infty}dy(\lambda\sin y+\mu y)\exp\left\{-\frac{sy}{\Omega}-\frac{1}{2}\mu y^2-\lambda(1-\cos y)\right\}. \tag{4.2}$$

Using

$$\frac{d}{dy}\left[\exp\left\{-\frac{1}{2}\mu y^2-\lambda(1-\cos y)\right\}\right]=-(\lambda\sin y+\mu y)\exp\left\{-\frac{1}{2}\mu y^2-(1-\cos y)\right\},$$

we obtain for $\lambda\geqslant 0$, and $\mu>0$, i.e., $\theta\neq(\pi/2)$

$$I^+(s)=i\Omega N\left(\frac{m}{\kappa T}\right)\left\{1-\frac{s}{\Omega}\int_0^{\infty}A(s, y)\,dy\right\};\qquad \mathrm{Re}\,(s)>0 \tag{4.3}$$

where

$$A(s, y)=\exp\left\{-\frac{sy}{\Omega}-\frac{1}{2}\mu y^2-\lambda(1-\cos y)\right\}.$$

For $I^-(s)$, we can apply the same procedure, so that we have

$$I^-(s)=i\Omega N\left(\frac{m}{\kappa T}\right)\left\{1+\frac{s}{\Omega}\int_{-\infty}^{0}A(s, y)\,dy\right\};\qquad \mathrm{Re}\,(s)<0\,. \tag{4.4}$$

On account of the condition $0\neq(\pi/2)$, both $I^+(s)$ and $I^-(s)$ converge for any value of s and define the analytic functions on the s-plane throughout. Moreover, the difference of $I^+(s)$ and $I^-(s)$ gives rise to

$$I^{+}(s)-I^{-}(s)=-iNs\left(\frac{m}{\kappa T}\right)\int_{-\infty}^{\infty}A(s,y)\,dy\,. \qquad (4.5$$

From the above evaluation, each dispersion equation is given as follows.

1) *Amplified waves*; Re $(s)>0$

In this case the dispersion equations for the proper plasma oscillation, the distributio function and the potential are coincident and are given by

$$1+k^2a^2=\frac{s}{\Omega}\int_{0}^{\infty}A(s,y)\,dy\,, \qquad (4.6$$

where a is the Debye length. It is interesting to note that there exists no indeterminan in (4.6). Bernstein showed that there exists no root in this equation.

2) *Damped waves*; Re $(s)<0$

a) The proper plasma oscillation

The dispersion equation is obtained by analytic continuation of (1.12), but since $I^{+}(s)$ is a analytic function throughout the s-plane, the equation is (4.6). Using (4.5) we find that

$$1+k^2a^2=-\frac{s}{\Omega}\int_{-\infty}^{0}A(s,y)+\frac{s}{\Omega}\int_{-\infty}^{+\infty}A(s,y)\,dy=\frac{s}{\Omega}\int_{0}^{\infty}A(s,y)\,dy\,. \qquad (4.7$$

b) The perturbed distribution function

From (3.10) we have

$$1+k^2a^2=-\frac{s}{\Omega}\int_{-\infty}^{0}A(s,y)\,dy\,. \qquad (4.8$$

c) The potential

From (3.21) we have

$$1+k^2a^2=-\frac{s}{\Omega}\int_{-\infty}^{0}A(s,y)\,dy-\frac{4\pi^2 iC}{k\cos\theta}\,\frac{\omega_p{}^2a^2}{N}\,H(0)\,, \qquad (4.9$$

where $\omega_p{}^2$ is defined by $\omega_p{}^2=(4\pi e^2N)/m$.

The writers wish to express their sincere thanks to Professor Y. Ozawa of University o Hokkaido for his continual guidance and encouragement.

Appendix A

Let $H(\phi)$ be a bounded periodic function of the period 2π in ϕ, then the periodic solutio of the period 2π for the equation

$$\frac{dF}{d\phi}+\frac{1}{\Omega}\{s+ik(w\sin\theta\cos\phi+u\cos\theta)\}F=H(\phi) \qquad (A.1$$

is given by

$$F(\phi)=\int_{-\infty}^{\phi}G(s,\phi,\phi')H(\phi')\,d\phi'\;; \qquad \mathrm{Re}\,(s)>0\,, \qquad (A.2$$

$$F(\phi)=\int_{+\infty}^{\phi}G(s,\phi,\phi')H(\phi')\,d\phi'\;; \qquad \mathrm{Re}\,(s)<0\,, \qquad (A.3$$

where

$$G(s,\phi,\phi')=\exp\left\{-\frac{s+iku\cos\theta}{\Omega}(\phi-\phi')-\frac{ikw\sin\theta}{\Omega}(\sin\phi-\sin\phi')\right\}. \qquad (A.4$$

A proof is as follows. For the general solution of (A.1), we have

$$F(\phi)=AG(s,\phi,0)+\int_0^{\phi} G(s,\phi,\phi')H(\phi')\,d\phi' \tag{A.5}$$

where A is an arbitrary constant. Since $F(\phi)=F(\phi+2n\pi)$; $n=\pm1,\pm2,\cdots$, we have

$$AG(s,\phi,0)=\frac{\int_{-2n\pi}^{0} G(s,\phi,\phi')H(\phi')\,d\phi'}{1-\exp(-2n\pi\delta)} \tag{A.6}$$

where

$$\delta=(s+iku\cos\theta)/\Omega\ .$$

To obtain A, which is independent of n, let n be a positive integer and $l=0,1,\cdots,n-1$. Furthermore, if we put $\phi'+2(n-l-1)=\phi''$, and consider the l subdivision of interval $[0,-2n]$, then we have

$$\begin{aligned}&\int_{-2n\pi}^{0} G(s,\phi,\phi')H(\phi')\,d\phi'\\&=[\exp\{-2(n-1)\pi\delta\}+\exp\{-2(n-2)\pi\delta\}+\cdots+1]\int_{-2\pi}^{0} G(s,\phi,\phi')\,H(\phi')\,d\phi'\\&=\frac{1-\exp(-2n\pi\delta)}{1-\exp(-2\pi\delta)}\int_{-2\pi}^{0} G(s,\phi,\phi')\,H(\phi')\,d\phi'\ .\end{aligned}$$

Therefore, (A.6) becomes

$$AG(s,\phi,0)=\frac{\int_{-2\pi}^{0} G(s,\phi,\phi')\,H(\phi')\,d\phi'}{1-\exp(-2\pi\delta)}\ . \tag{A.7}$$

For a negative integer n, it is easily shown that

$$AG(s,\phi,0)=\frac{\int_{2n\pi}^{0} G(s,\phi,\phi')\,H(\phi')\,d\phi'}{1-\exp(2n\pi\delta)} \tag{A.8}$$

and, by the same way, becomes again (A.7). Since (A.6) and (A.8) converge to

$$\int_{-\infty}^{0} GH\,d\phi'\ ; \qquad \text{for}\quad \mathrm{Re}(\delta)>0\ ,$$

and

$$\int_{+\infty}^{0} GH\,d\phi'\ ; \qquad \text{for}\quad \mathrm{Re}(\delta)<0$$

respectively as $n\to\infty$, we obtain (A.2) and (A.3).

Appendix B

We consider the typical integral

$$I^{+}(s)=\int d^3v\int_{-\infty}^{\phi} G(s,\phi,\phi')P(v')\,d\phi'\ ; \qquad \text{for}\quad \mathrm{Re}(s)>0\ , \tag{B.1}$$

$$I^{-}(s)=\int d^3v\int_{+\infty}^{\phi} G(s,\phi,\phi')P(v')\,d\phi'\ ; \qquad \text{for}\quad \mathrm{Re}(s)<0\ , \tag{B.2}$$

where $G(s,\phi,\phi')$ is given by (A.4). If we introduce the cylindrical co-ordinates

$$\boldsymbol{v}'=\boldsymbol{e}_1 w\cos\phi'+\boldsymbol{e}_2 w\sin\phi'+\boldsymbol{e}_3 u$$

in the velocity space, and if we assume that $P(v')$ can be expressed such that

$$P(v')=P(w\cos\phi', w\sin\phi', u)=\sum_{n=-\infty}^{+\infty} h_n(u,w)\,e^{in\phi'} \tag{B.3}$$

$$H_n(u,z)=\int_0^\infty wJ_n(zw)h_n(u,w)\,dw \tag{B.4}$$

$$H_n\left(u, \frac{2k\sin\theta\sin\beta}{\Omega}\right)=\sum_{m=-\infty}^{\infty} H_{nm}(u)\,e^{im\beta}\,, \tag{B.5}$$

if we assume furthermore, that each right hand side of the above relations converges uniformly, then (B.1) and (B.2) are reduced to

$$I^{\pm}(s)=\sum_m\sum_n 2\pi\Omega\exp\left(\frac{-in\pi}{2}\right)\int_{-\infty}^{+\infty}\frac{H_{nm}(u)}{s+i(n-m)\Omega/2+iku\cos\theta}\,du\,; \quad \text{for} \quad \mathrm{Re}\,(s)\gtrless 0\,. \tag{B.6}$$

For $I^+(s)$ a proof is given in the following. (B.3) is obvious since $P(v')$ is a function of the period 2π with respect ϕ'. Substituting $G(s,\phi,\phi')$ given by (A.4) into (B.1) and setting $\phi-\phi'=2\beta$, we have

$$I^+(s)=\sum_{n=-\infty}^{+\infty}\int_{-\infty}^{+\infty}du\int_0^\infty d(2\beta)\exp\left\{-\frac{(s+iku\cos\theta)}{\Omega}2\beta\right\}$$
$$\times\int_0^\infty w\,dw\,h_n(u,w)\int_0^{2\pi}\exp\left\{-\frac{i\beta}{\Omega}2\cos(\phi-\beta)\sin\beta-in(\phi-2\beta)\right\}d\phi\,.$$

Considering the transform $\phi-\beta=\gamma$ of the variables, and the periodicity of the integrand concerning the integral over ϕ, we have

$$I^+(s)=\sum_{n=-\infty}^{+\infty}\int_{-\infty}^{\infty}du\int_0^\infty d(2\beta)\exp\left\{-\frac{(s+iku\cos\theta)}{\Omega}2\beta-in\left(\beta+\frac{\pi}{2}\right)\right\}$$
$$\times 2\pi\int_0^\infty w\,J_n\left(\frac{2k\sin\theta\sin\beta}{\Omega}w\right)h_n(u,w)\,dw\,. \tag{B.7}$$

Let H_n be the Fourier-Bessel transform of h_n, then putting $z=(2k\sin\theta\sin\beta)/\Omega$ we have (B.4). Moreover, noting that H_n is a function of the period 2π for β, we have the Fourier expansion (B.5). Substituting (B.5) into (B.7), after the transform $y=2\beta$, we have

$$I^+(s)=\sum_m\sum_n 2\pi\exp\left(\frac{-in\pi}{2}\right)\int_{-\infty}^{+\infty}du H_{nm}(u)$$
$$\times\int_0^\infty dy\exp\left[-\frac{1}{\Omega}\left\{s+iku\cos\theta+i\frac{\Omega}{2}(n-m)\right\}y\right]. \tag{B.8}$$

For $I^-(s)$, we make the same reduction, and the result is given by

$$I^-(s)=\sum_m\sum_n 2\pi\exp\left(\frac{-in\pi}{2}\right)\int_{-\infty}^{+\infty}du\,H_{nm}(u)$$
$$\times\int_0^{-\infty} dy\exp\left[-\frac{1}{\Omega}\left\{s+iku\cos\theta+i\frac{\Omega}{2}(n-m)\right\}y\right]. \tag{B.9}$$

Integrating (B.8) and (B.9) with respect to y, we have (B.6).

Appendix C

In this appendix, a function is the analytic continuation of $I^+(s)$ given by (B.8), is obtained and compared with $I^-(s)$.

Consider the analytic continuation of the typical integral of $I^+(s)$;

$$Y_{nm}(s)=\int_{-\infty}^{+\infty}\frac{H_{nm}(u)}{u-i\dfrac{s+i(n-m)\Omega/2}{k\cos\theta}}\,du \tag{C.1}$$

to the left half of the s-plane. If all $H_{nm}(u)$ are an entire function of u, $Y_{nm}(s)$ for $\mathrm{Re}(s)>0$ can be continued by Landau's method[3]. Hence, let us displace the path of integration in the complex u-plane in such a way that the point $u=i\{s+i(n-m)\Omega/2\}/k\cos\theta$ always lies above the path of integration, then

$$\tilde{Y}_{nm}(s)=\int_{C}\frac{H_{nm}(u)}{u-i\dfrac{s+i(n-m)\Omega/2}{k\cos\theta}}du$$

is also an entire function. Therefore, we have

$$\tilde{Y}_{nm}(s)=Y_{nm}(s)\ ; \qquad \text{for} \quad \mathrm{Re}(s)>0 \tag{C.2}$$

and

$$\tilde{Y}_{nm}(s)=Y_{nm}(s)+2\pi i H_{nm}\left(i\frac{s+i(n-m)\Omega/2}{k\cos\theta}\right); \qquad \text{for} \quad \mathrm{Re}(s)<0\ . \tag{C.3}$$

Using (C.2) and (C.3) we obtain the analytic continuation of $I^{+}(s)$ to the left half s-plane

$$I^{+}(s)=I^{-}(s)+\frac{4\pi^{2}\Omega}{k\cos\theta}\sum_{m}\sum_{n}\exp\left(-\frac{in\pi}{2}\right)H_{nm}\left(i\frac{s+i(n-m)\Omega/2}{k\cos\theta}\right). \tag{C.4}$$

It should be noted that the condition $\theta\neq(\pi/2)$ is necessary for this continuation.

Pulse Photoconductivity of Additively Colored KBr

By Masami Onuki and Hiroshi Ohkura

Department of Applied Physics, Osaka City University, Osaka

(Received May 18, 1960)

The space charge effect in the measurement of a photocurrent of additively colored KBr was investigated by using the repeated pulsive illumination and applying the d.c. and a.c. electric fields. The space charge polarization may arise from the accumulation of the electrons trapped in the surface states, the depth of which is about 0.3 ev. The condition for the absence of space charge was ascertained to be realized by adopting the a.c. field and the pulsive illumination synchronized with plus and minus peaks of the a.c. field. The temperature-dependence of pulse photocurrent was measured by varying the duration of the pulsive illumination. The time constants of current-decay after switching-off of illumination were also observed. Three kinds of electron-traps were found, the one corresponding to *F* center and the other two to the unknown centers. The activation energies for releasing the electrons trapped in these centers were estimated to be 0.44, 0.35 and 0.43 ev respectively. The growth and bleaching of optical absorption bands were investigated in relation to the above electron-traps. A detailed analysis for the trapping kinetics was made to apply to additively colored KBr crystals.

§1. Introduction

In the measurement of photocurrent in colored alkali halides crystals, the d.c. method has been adopted for its simplicity, in which the d.c. field and the light pulse of comparatively long duration were used in almost all cases.(1)(2)(3) In this method the space charge field should be built up in a specimen. One must decrease light intensity or change the polarity of the applied field alternatively for each measurement, to avoid the undesired effect. Further, in the d.c. method, the time constant of decay of the photocurrent after the switch-off of illumination conld not be measured accurately, because of the non-uniform field in a specimen and the inherent long time constant of a d.c. electrometer.

The photoconductivity due to the F-band light in additively colored alkali halide crystals shows abrupt increases at two different temperature ranges, The first relates to the steep variation of the quantum efficiency of an electron from F center to the conduction band and the second to the thermal release of an electron trapped in F′ center. Von Gerick investigated these problems by means of the pulse photoconductivity measurements in KCl. He used light pulses of 10^{-4} sec and 1.5×10^{-6} sec and applied the d.c. field. He observed that the thermal release of the electron of F′ center occurs at +20°C and +100°C for the above pulse durations respectively.(4) The releasing temperature of F′ electron was known to be −100°C for the light pulse of the order of 1 sec. From these data Seitz estimated the binding evergy ϵ and the time factor τ_0 of F′ electron to be 0.42 ev and 10^{-11} sec, respectively.(5) It is desirable to get ϵ and τ_0 from the direct observation of the decay time of photoconductivity in each temperature.

In the present work we used additively colored KBr crystals purified by the recrystalization technique and adopted both the a.c. field and the light pulse to avoid the space charge effect. The condition for the absence of space charge was ascertained and the temperature-dependence of pulse photoconductivity under the condition was investigated, varying the duration of light pulse. A decay time of conductivity after turn-off of illumination was measured between −170°C and room temperature. From the above two experiments ϵ and τ_0 of some trapping centers which are effective at these temperatures were estimated. The characters of traps were discussed, taking into account the information from the thermal bleaching and recovery of the optical absorption bands.

§ 2. Experimentals and Results

The KBr crystals employed in this investigation were purified by repeating the Kyropoulos method and colored additively. The concentrations of F center were $1\times10^{16}/\text{cm}^3$, $2\times10^{16}/\text{cm}^3$ and $9.7\times10^{16}/\text{cm}^3$, and the dimenssions of specimens were about $1\times2\times3\,\text{mm}^3$. The distance between electrodes was about 1 mm. A specimen was attached to electrodes directly by silver paint, or thin mica sheets were inserted between a specimen and electrodes. The property of photoconductivity was not different so much in the above two cases under the condition free from space charge described latter. For this reason almost all the specimens used in this work were attached to electrodes directly by silver paint unless otherwise stated.

The skelton diagram of measuring apparatus is shown in Fig. 1. The pulsive illumination was synchronized to the commercial power supply of 60 cps. There peated light pulses of the duration ranging from 90μ sec to 800μ sec were made by using a rotating mirror and the light pulses of 30 μ sec by the instant discharge of a Xenon lamp. The light was filtered by an interference filter the transmission peak of which lies in F band of KBr and the pass band of which is about 40 mμ, and was soft-forcused so as to illuminate a surface of a specimen uniformly. The electric field applied to a specimen was supplied from the commercial power line, the peak voltage being synchronized to each light pulse by shifting the phase.

The current pulses caused by pulsive illumination were amplified by the A–1 wide band amplifier improved so as to have a better low frequency characteristics,⁽⁶⁾ and the rejection device for 60 cps was put between the preamplifier and the main one to avoid picking up the 60 cps voltage through a capacity of a specimen. The total gain of the amplifier is 1.4×10^5 in maximum and its band width of amplification ranges from 200 cps to about 10^6 cps. A decay-time shorter than 20 μsec could not be detected practically because of the comparatively dull shape of the illumination pulse.

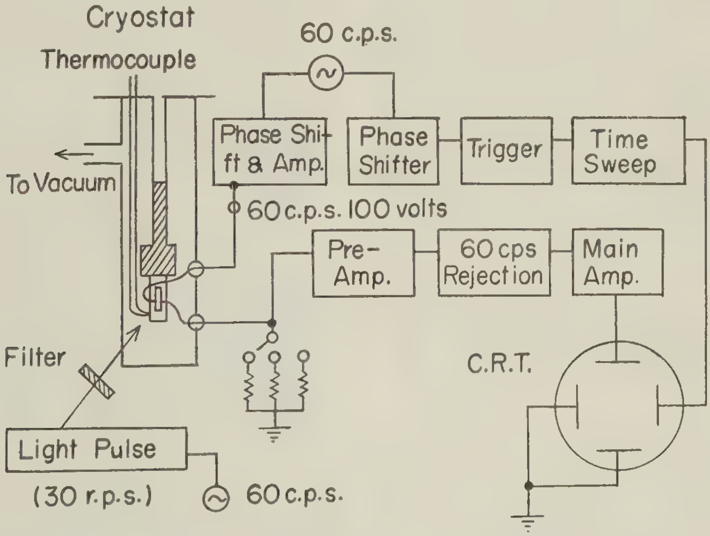

Fig. 1. The measuring device of pulse photocurrent.

A decay-time constant longer than 1.5 msec could not be measured by the above device for the low frequency character of the amplifier used, so the device for measuring the photoconducting Hall effect used by one of us was applied for observing a long decay-time.⁽⁷⁾ This device is applicable for measuring the a c. photoconductivity and consists of a 330 cps oscillator, a tuned amplifier and a differential one, and a cathode-ray oscilloscope. In our experiment a sodium glow lamp was used for a light source because of its rapid quenching illumination. After the stationary alternative photocurrent was built up in the specimen by applying the a.c. 330 cps field and irradiating with the steady F–band light, the illumination was suddenly switched off. Then the horizontal time sweep of the oscilloscope was started to observe the decay-time of the alternative photocurrent in the vertical axis of the oscilloscope. The dacay time was obtained from the envelope curve of the 330 cps photocurrent-decay on the oscilloscope. The band pass amplifier used for this method had a broad band width to avoid the inherent decay effect of the amplifier due to its Q–value. The input impedance was less than 2 MΩ. Using this device, a time constant of current-decay longer than 2×10^{-2} sec was measurable.

(1) *Space Charge Effect*

In the measurement of photocurrent in insulators such as alkali halides and silver halides, it has been well known that the photocurrent decays gradually as time passes on account of the space charge polarization due to accumulation of carriers.(8)(9)(10) To investigate this effect in detail, the variation of photocurrent with time due to the repeating pulsive illumination was measured by applying the a.c. and d.c. fields. The applied electric field was 1×10^3 volts/cm in both cases, and in the case of the a.c. field the pulsive illumination was synchronized to the peak value of the a c. field. Fig. 2 shows the experimental results. In the figure the zero point of the abscissa corresponds to the time when the initial light pulse irradiates the specimen, while the electric field is being applied.

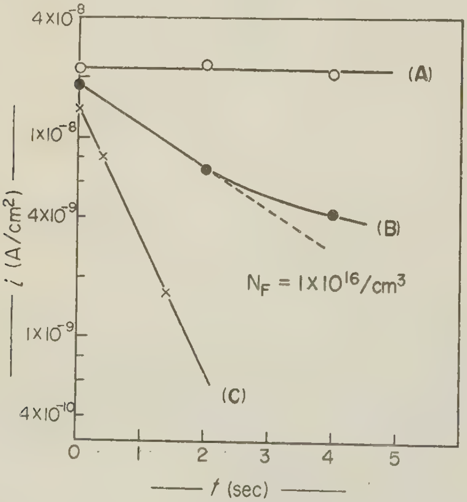

Fig. 2 The variation of pulse photocurrent with time.

(**A**) a.c. field of 60 cps, light pulse of 120 μ sec and 30 rps.

(**B**) d.c. field, light pulse of 120 μ sec and 30 rps.

(**C**) d.c. field, light pulse of 560 μ sec and 30 rps. The field strength is 10^3 volts/cm in all cases.

At room temperature the a.c. field led to the constant value of pulse photocurrent and the values at every time were nearly equal to the initial value of the pulse photocurrent of the d.c. field. Curve **A** in the figure corresponds to i (pulse photocurrent) vs t (time) curve under the condition that the pulse duration was 120 μ sec and the repetition of the pulse was 30 rps and the applied peak field was 10^3 volts/cm. From Curve **A** the condition for the absence of space charge seems to be realized in the a.c. field at least at room temperature. On the contrary, if the applied field was d.c., the pulse photocurrent due to the repeated photopulse decreased as time passed. The larger was the duration of the photopulse and the stronger was the intensity of it, the smaller the decay time of phococurrent resulted. Curve **B** and **C** in the figure show the decays of the repeating pulse photocurrent corresponding to the cases that the durations of the light pulse were 120 μ sec 560 μ sec respectively and the d.c. fields of 10^3 volts/cm were applied. In both cases the intensity of illumination and the repetition of the light pulse were the same. The total charges which flowed before the currents decreased to $1/e$ of their initial value are equal for the above two cases. From the fact, the space charge field due to the charge of about 1.5×10^{-10} coulomb/cm² flowing in one direction decreases the pulse photocurrent, when the d.c. field of 10^3 volts/cm is applied.

We measured the initial photocurrents both under the condition that the pulsive illumination was set on when the d.c. electric field was being applied, and under the condition that the d.c. field was applied suddenly under illumination of the repeating light pulses. In both cases initial currents were equal, so the ionic space charge is negligible in the period of measuring time even at room temperature.

Further, we measured the temperature-dependence of pulse photocurrent under the following condition, (1) the light pulses of

30 rps were synchronized to both the plus and minus peaks of the applied a.c. field (Case **I**), (2) the light pulses of 30 rps were synchronized to only either of plus or minus peaks of the applied a.c. field (Case **II**). The cycles of the applied voltages and the intensities and durations of illumination were the same in both cases. In Fig. 3, Curve **I** corresponds to Case **I** and Curve **II** to Case **II**. In the temperature region above about −80°C. the absolute values of pulse photocurrents in both cases were nearly equal, but in the region below −80°C the photocurrent in Case **II** was smaller than the one in Case **1**. Strictly speaking, in the latter region of temperature the pulse photocurrent in Case **II** was equal to one in Case **1** at the initial time when illumination was turned on, but decayed slowly to the value on Curve **II** after 10∼30 sec. This result indicates that at low temperatures the free charges swept to one direction were immobile and accumulated near the one of the electrodes, neither being drawn backward nor spread uniformly over the specimen by the a.c. field. In conclusion the condition for the absence of space charge in all temperature region of this work can be realized by using the light pulses synchronized to both plus and minus peaks of the applied a.c. field.

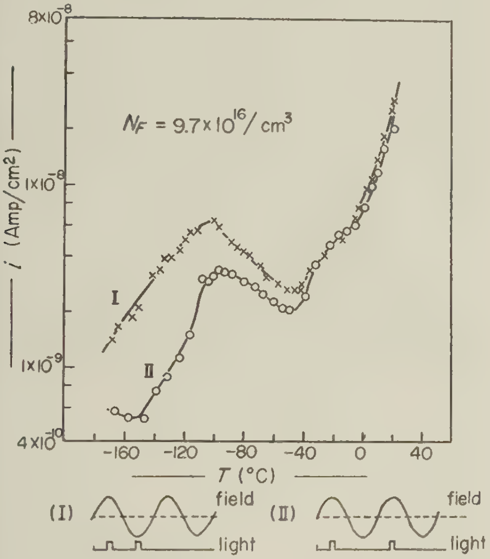

Fig. 3. The temperature-dependence of pulse photocurrent. In the figure the conditions of synchronization between the periods of illuminations and fields are different in the two curves. The periodic relation of the light pulses to the a.c. fields are shown in each case, too.

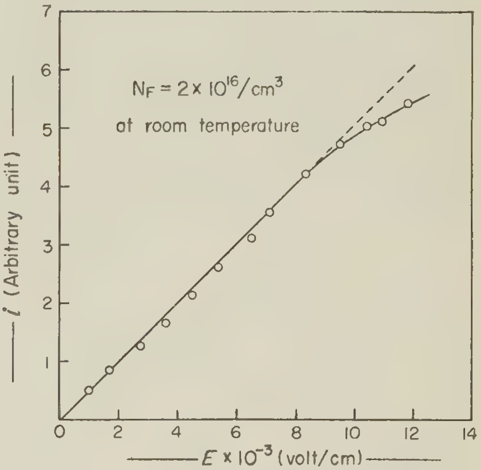
The field-dependence of the pulse photocurrent under the condition for the absence of space charge was examined at room temperature. Thin mica films were inserted to prevent the field emission effect due to the high electric field used in this experiment. As shown in Fig. 4 the pulse photocurrent is linear to the applied field up to 9×10^3 volts/cm, and then the saturation effect appeared gradually at higher fields. These results show that the condition for the absence of space charge was realized. The effect of inserting mica sheets (about 10^{-3} cm thick) between a specimen and electrodes to the pulse photocurrent was as follows. If the a.c. field synchronized to the pulsive illumination in the peaks was applied and the condition for the space charge free state is satisfied, the insertion of the mica sheets is hardly effective to the pulse photocurrent. But when the d.c. field was applied, a tenth of the initial pulse photocurrent was lasting to flow even after very long time, if mica sheets were not inserted. While the pulse photocurrent disappeared at last completely, if mica sheets were inserted. This effect may be attributed to the fact that the space charge polarization should be weakened by the field emission from the electrode, if the mica sheets were not inserted.



N_F

Fig. 4. The field-dependence of pulse photocurrent. The thickness of the specimen is 4×10^{-1} cm, and the concentration of F center is $2\times10^{16}/\text{cm}^3$.

(2) *The Effect of Light Pulse Duration on the Temperature-Dependence of Photocurrent*

The maximum values of pulse photocurrents for the light pulse durations of 30 μ sec, 90 μ sec and 800 μ sec respectively were measured under the condition free from space charge as mentioned in Subsection (1) of this section, by varying the temperature from −170°C to room temperature. Fig. 5 shows the results of the measurement. The scale of the ordinates in the figure is arbitrary, and we shall discuss only the inclinations of these curves in this figure. Curve **I**, **II** and **III** are the photocurrent vs temperature curves for 30 μ sec, 90 μ sec and 800 μ sec light durations respectively. In the figure the cusps at −32°C and +2°C in Curve **I** correspond to −50°C and −8°C in Curve **II** and to −74°C and −30°C in Curve **III**, respectively. It is observed that the cusp points shift towards lower temperatures, as the pulse duration is increased. However, it is noticable that the cusps at −105°C in all curves do not shift. We shall call these cusps $\mathbf{O}_1$, $\mathbf{O}_2$ and $\mathbf{O}_3$ from low to high temperature. On the other hand, the a.c. photocurrent induced by steady illumination and 330 cps a.c. field was measured. In this case the stationary state was attained in several sec. The temperature-variation of the photocurrent was shown in Curve **IV** of Fig. 5. The definite cusps can hardly be seen in this case. This result is nearly the same as Glaser's one for the d.c. field case.(1)

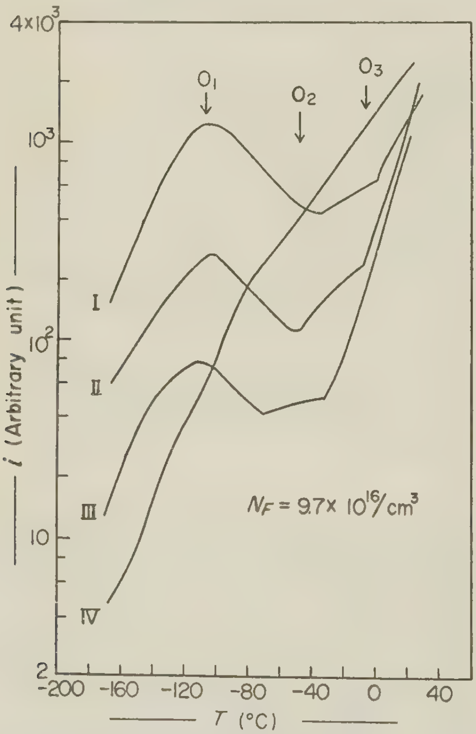


Fig. 5. The temperature-dependence of pulse photocurrent in various pulse durations.

The current-decay were observed at $\mathbf{O}_2$, $\mathbf{O}_3$ and about −100°C. The facts that the pulse photocurrent increases abruptly at the temperatures of $\mathbf{O}_2$ and $\mathbf{O}_3$ and the inclination of the photocurrent-temperature curve under steady illumination differs very much from these of other curves under pulsive illuminations at the higher temperatures above −100°C, are closely related with the temperatures of the current-decay.

(3) *The Current-Decay after Turn-off of Light Pulse*

In this measurement the pulsive illumination synchronized to the plus and minus peaks of the applied a.c. field was used. In Fig. 6 the time constant τ_f for the decay-current after turn-off of pulsive illumination is plotted in each temperature. The extremely small values of τ_f ($\simeq$20 μ sec) at the low temperatures are insignificant. They are only the indication of the upper limits of τ_f. The fast current decay was observed in the vicinities of $\mathbf{O}_2$ and $\mathbf{O}_3$ point, as seen in the figure. Both the maximum value of τ_f and the temperatures for the maximum were almost independent of F-concentration of specimens.

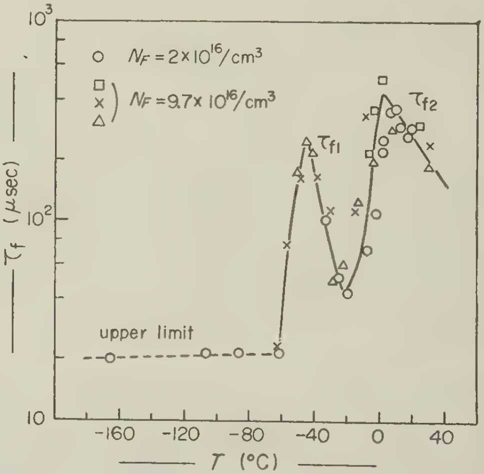

Fig. 6. The temperature-dependence of the fast current-decay.

The maximum values of τ_f decreased to about a quarter of the original values by deforming the specimens by 10%.

(4) *Slow Decay after Steady Illumination*

The apparent difference between the features of pulse and steady photocurrent was seen at the higher temperature than −100°C as seen in Fig. 5. This fact suggested that a slow decay of a comparatively long time constant ($>10^{-2}$ sec) should be concealed in the measurement of pulse photocurrent.

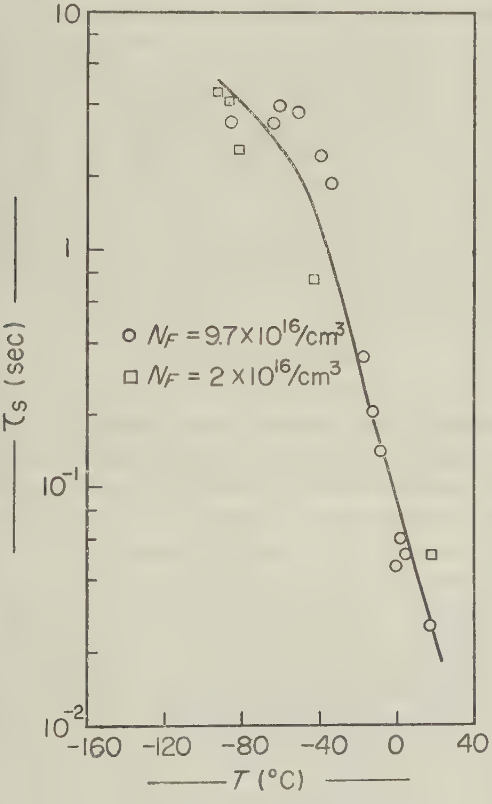

Fig. 7. The temperature-dependence of slow current-decay.

The time constant τ_s of the slow decay was determined by measuring the photocurrent under 330 cps alternative field after switching-off the steady illumination. The results were shown in Fig. 7. The decay of the a.c. photocurrent could not be observed below −100°C. This may be due to the fact that at lower temperatures the number of the electrons trapped in the center is small because of the small yield for photoexcitation of F-electrons to the condition band during illumination and the long time is necessary to release the electrons from the center.

From the results described in this and the last subsection, the slow current-decay of τ_s should be followed by the fast decay of τ_f immediately after the illumination had been switched off in the complete absence of space charge.

(5) *The Field-Dependence of Pulse Photocurrent*

One of us estimated μ_a (apparent mobility of electron)$\times\tau_a$ (apparent lifetime) to be $1\sim3\times10^{-6}$ sec in uncolored KBr crystals, from the observation of the dependence of the internal secondary electron current caused by pulsive electron bombardment with its duration of 10 μ sec on the a.c. field strength applied to the crystal.(11) In the present work the dependence of pulse photocurrent on the applied field was investigated for additively colored crystals. The duration of light pulse was 90 μ sec and F-concentration of the specimen was $9.7\times10^{16}/cm.^3$ Fig. 8 shows the results, where the thickness of the specimen was 5×10^{-2}cm. The saturation effect of the current was not so clearly observed, because the light was irradiated on the whole surface of the specimen. Using the Hecht formula for the points deviated from the straight line by more than 10%, $\mu\tau_a$ was estimated roughly as shown in Fig. 9. In the figure, the values of $\mu\tau_a$ for the specimens of 2×10^{16}/cm F-concentration and for uncolored ones at room temperature are plotted for comparison.

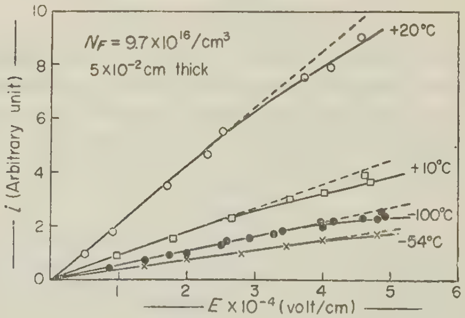

Fig. 8. The field-dependence of pulse photocurrent in each temperature.

§ 2. Discussion

(1) *Space Change Effect*

Space change formation occurs whenever

charge carriers cannot pass freely across the junction between the specimen and one or both of its electrodes. Von Hippel and others performed nearly the same experiment as the present work and proposed that the space charge should be formed near the cathode of a specimen.(8)

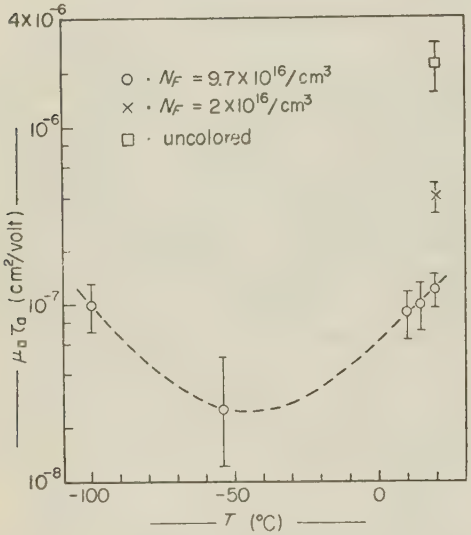

Fig. 9. The temperature and F–concentration dependence of $\mu_a\tau_a$. The circular correspond to $9.7\times10^{16}/cm^3$ of F–concentration, the cross to $2\times10^{19}/cm^3$ of F–concentration and the square to uncolored.

According to the present results, however, an amount of total charge which flowed in the d.c. field untill the space charge field was formed was so small as 1.5×10^{-10} coulomb/cm², which was about several hundredths of the value estimated by von Hippel under the condition for no field-emission.

In our experimental condition electrons may be accumulated near the anode and vacant F centers or negative ion vacancies near the cathode, because both electrodes seem to have the blocking properties. So, it seems to be unsuitable to adopt the von Hippel theory for the present results. Suppose that the electrons are accumulated near the anode and the vacant F centers whose amount is far smaller than the concentration of F center contained are formed near the cathode. The current ceases to flow when the reverse electric field produced by the electrons drawn to the anode becomes sufficient to cancel the applied field. The number of electrons on the surface will be estimated by the following formula,(10)

$$E=4\pi ne/\kappa, \qquad \text{(in e.s.u.)} \qquad (1)$$

where E is the applied field, n the number of electrons on the surface per cm², e the electronic charge and κ the dielectric constant. n is estimated to be 3×10^9 electrons/cm² using (1), for $E=10^3$ volts/cm. This value is nearly equal to the experimental value which was about 1×10^9 electrons/cm².

If the electrons of the space charge were spread uniformly over some region near the anode instead of being concentrated on a plane, the internal electric field should be large enough to flow more current. So, the space charge polarization may arise from the electrons accumulated on a plane near the anode. From the results shown in Fig. 3, it may be reasonable to assume the surface state which can trap electrons. In the current glow curve, the trap-depth will be computed from an approximate equation according to Grossweiner:(12)

$$E\simeq1.51kT_cT'/(T_c-T'), \qquad (2)$$

where T_c is the temperature at the maximum value of the current glow curve, T' the temperature at the half maximum at the low temperature side. Applying this analysis to the differenciation curve $d[(i_I-i_{II})/i_I]/dT$ vs T obtained from Fig. 3, where T is a temperature, and using that $T_c=-90°C$ and $T'=-106°C$, we obtained 0.3 ev as the trap depth of the surface state.

In the case of steady illumination and the a.c. field, the electrons going to the anode surface at a half cycle of the a.c. field may fill the ionized F center formed near the surface at the previous half cycle. For this reason both electrodes should become neutral. The condition for the absence of space charge is supposed to be realized in this case, too.(13) The effect of the capacities of the blocking junctions between a specimen and the electrodes was negligible in the case of the pulsive and steady illumination of the present experiment, because of the applied a.c. field. The investigation for this effect will be published in near future.

(2) *Traps in Colored KBr Crystals*

At least the three kinds of traps should exist in colored KBr, if one considers the characteristics of the temperature-dependence curves of the pulse photocurrent in Fig. 5 and the current-decay effects in Fig. 6 and 7.

At present we shall discuss the time constant of current-decay in term of the trapping kinetics. Supposing that N traps of the one kind normally unfilled exist in the crystal per unit volume, the excess density n of electrons in the conduction band and the excess density n_1 of electrons in traps will vary with time after the turn-off of illumination according to the following formulas,(14)

$$dn/dt = -rn + gn_1 - (N-n_1)nSv, \tag{3}$$

$$dn_1/dt = -gn_1 + (N-n_1)nSv, \tag{4}$$

where $r \equiv 1/\tau_r$ is the rate of recombination of excess electrons in the conduction band (or the rate of trapping by very deep traps), $g \equiv 1/\tau_g$ the rate of generation of electrons from traps, S its cross section for capture of electrons in traps, v the arithmetic mean thermal velocity, and $NSv = 1/\tau_t$ the rate of trapping of electrons when all traps are empty. In the present cases, $N \gg n_1$, because of a small amount of trapped electrons due to small excitation for the case of pulsive light and a large value of N (the number of F center as shown latter) for the case of steady illumination. Using the condition $N \gg n_1$, (3) and (4) lead to the following relation,

$$n \propto \exp(-t/\tau_\infty), \tag{5}$$

where $$\tau_\infty = \tau_r + \tau_g + (\tau_r \tau_g)/\tau_t. \tag{6}$$

The decay current should be proportional to the density n of excess electrons in the conduction band. From the current-decay curve just after the turn-off of illumination, τ_r and τ_t was estimated to be smaller than 20 μ sec at least and negligible in the measurement of a decay time. The time constants observed in this work should be τ_∞ which is simply expressed as follows,

$$\tau_\infty \simeq \tau_g(1 + \tau_r/\tau_t). \tag{7}$$

(τ_r/τ_t) seems to be almost constant over the present temperature region and may be of the order of $1 \sim 10^2$ for the various traps. In conclusion the temperature-dependence of decay times observed in this experiment should be due to τ_g contained in τ_∞.

Fig. 10 shows the time constants τ_{f1} and τ_{f2} of the fast decay as the function of $1/T$. In the figure the points with soild dot of circle and square are obtained from the direct observation of the current-decay and the points with circle and square are obtained from the pulse durations and the shifting temperatures of the cusps in Fig. 5. From Fig. 10, the activation energies $E_{f1} = 0.35$ ev and $E_{f2} = 0.43$ ev are obtained, assuming $\tau_{01} = \tau_{02} = 10^{-11}$ sec in the following formulas,

$$\tau_{f1} = \tau_{01} \exp(E_{f1}/kT), \tag{8}$$

$$\tau_{f2} = \tau_{02} \exp(E_{f2}/kT). \tag{9}$$

None of these traps can be regarded as F center from the following reasons. As shown in Fig. 5, the photocurrent of the steady illumination (Curve **IV**) is about ten times as the pulse photocurrent (Curve **I**~**III**) above −80°C, the above values being adjusted to be equal at **O**$_1$ temperature in the figure. The most effective traps should be F centers. So, it may be reasonable to regard the traps of the slow decay time τ_s to be F centers. In

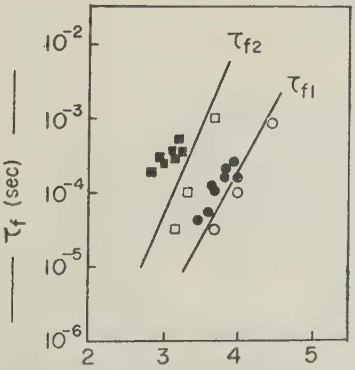

Fig. 10. The time constants τ_{f1} and τ_{f2} of the fast decay as the function of $1/T$.

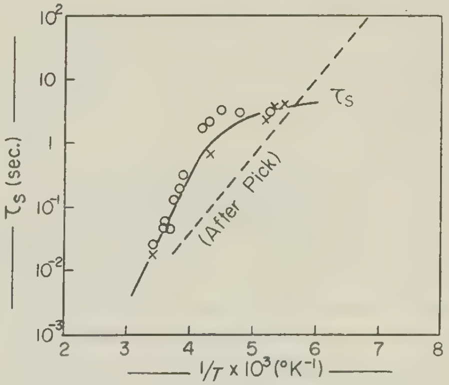

Fig. 11. The time constant τ_s of slow decay as the function of $1/T$. The soild line shows the time constant of slow current-decay, and the dashed line the thermal life of F′ center after Pick.

Fig. 11 the time constant τ_s of the slow decay is plotted against $1/T$. The thermally releasing time of F′ electrons from the optical measurement is plotted against temperature according to Pick for comparison.(15) The optical values for high temperatures are extrapolated from the values measured at low temperatures. From the similarity of the two curves, the trap corresponding to the slow decay may be concluded to be F center. From Fig. 11,

$$\tau_{0s}=1\times10^{-9}\ \text{sec},$$
$$E_s=0.44\ \text{ev},$$

are estimated for this trap. This time factor is inaccurate due to the large value of τ_r/τ_t ($\simeq$100) contained in (7).

Now we shall try to discuss the $\mu_a\tau_a$ in Fig. 8 and 9. μ_a and τ_a are the effective values appeared in the experiment. They are correlated with the microscopic μ and τ through the following relations,

$$\mu_a\simeq(\mu\tau_t)/(\tau_g+\tau_t), \tag{10}$$
$$\tau_a\simeq\tau_g+\tau_t, \tag{11}$$

where $\tau_t\rangle\rangle\tau_r$ is assumed. This assumption is reasonable, because τ_t which is due to F center may be much smaller than τ_r which may due to the unknown imperfections. From (10) and (11), the following formula results,

$$\mu_a\tau_a\simeq\mu\tau_t \tag{12}.$$

In Fig. 9, τ_a can be considered to be equal to τ_t, if we put μ_a equal to μ. Using the law of the temperature-variation of polaron mobility in KBr, μ can be obtained for each temperature. On the other hand, τ_t is written as $1/N_FS_Fv$, where $N_F=$ concentration of F center and $S_F=$ the effective cross section of F center for electron capture. Then S_F is estimated to be $1\sim3\times10^{-16}\text{cm}^2$ and does not vary so much with temperature.

In the uncolored specimen there are about $4\times10^{15}/\text{cm}^3$ traps, if we use the results shown in Fig. 9, the cross section of the unknown traps being taken to be equal to that of F center. The density of the unknown trap in the uncolored specimen in the present case ($<4\times10^{15}/\text{cm}^3$) is nearly equal to the value obtained from the saturation effect of Hall mobility in KCl below 25°K measured by Brown.(16)

For the pulse photocurrent the traps of the fast decay may be as effective as F center. Although these traps seem to be due to thermal treatments or impurities, there is no clear information about their natures. Our optical measurement concerning to these traps shows the following results. (1): The four definite bands lying in the lower energy side of F center are produced by the irradiation of F-light for a long time at −150°C, and the slight bleaching of F-band occurs. These centers vanish thermally at about −50°C completely with the recovery of F-band. (2): By the long time irradiation of F-light at −180°C, F-band bleaches by up to 15% and F′-band is observed. The F′-band changes to F-band thermally by heating the specimen to −150°C in dark. According to our results, the thermal life of F′ center is several hundredths as short as Pick's value in the temperature region below −130°C. F′ center recovered to F center by the irradiation of 2000 mμ light at −180°C.

From the above optical results, it seems that the traps of the fast decay correspond to the centers described in (1) and that of slow decay to F′ center. The short life time of F′ center obtained by our optical measurement almost coincides with τ_s in the measurement of photocurrent decay.

§ 3. Conclusion

In the measurement of photocurrent in colored alkali halide such as KBr, it is better to adopt the a.c. field and pulsive illumination synchronized to plus and minus peaks of the a.c. field, to avoid the space charge polarization effect. The space charge effect may arise from electrons trapped in the surface states whose depth is about 0.3 eV.

The three kinds of traps were found in additively colored KBr purified by the recrystalization technique. One of them is the F center and the other two are the unknown centers probable due to thermal treatments or impurities. The thermal activation energies of the electrons from these traps to the conduction band are 0.44, 0.35 and 0.43 ev respectively.

The mean range of electrons obtained was found to be much larger than the ones obtained by Pohl and Inchauspe.(17)(12) This may be due to the a.c. method adopted and the purer crystal used in this work.

By the measurement of pulse photocurrent under the condition for the absence of space charge, the typical curve of the temperature-dependence of photocurrent in alkali halides such as KCl and NaCl was obtained in KBr. The pulse photocurrent was proportional to μ_H measured by one of us in the temperature region from −100°C to −50°C.(7)

It is expected that the degree of purification of crystal could be determined by the measurement of the mean range of electrons and the time constants of current-decay under the condition free from space charge described in this paper.

We wish to express deep thanks to Prof. Kawamura and Mr. Tomura for their useful discussions and continual encouragements, and to Mr. Kozaki and Mr. Awane for their laborious assistances.

Dichroism of Z_4 and F Bands

By Masakazu ISHIGURO and Nozomu TAKEUCHI

Institute of Scientific and Industrial Research, Osaka University
Kitahanada, Sakai, Osaka, Japan

(Received June 16, 1960)

To investigate the dichroic property of the Z_4 band, the experiment on the anisotropic bleaching was made. It was found that the symmetry axis of Z_4 center is parallel to <110> direction and the Cole and Friauf's A model is in conformity with this symmetry. It was also found that there exists the same correlation in dichroism between F and Z_4 band as that between F and M band.

§1. Introduction

It is widely known that additively colored KCl crystals doped with strontium show an interesting series of the optical absorption bands called Z_1, Z_2 and Z_3. Pick[1] and Seitz[2] have proposed different models of the centers responsible to these bands.

More recently, Cole and Friauf[3] found a new absorption band of this series at about 860 mμ. It was named Z_4 band and two probable models for the Z_4 center named A and B were proposed by them. (See Fig. 1)

The Z_4 band in KCl:Sr has been found, (1) to be formed by F–irradiation of an additively colored and subsequently quenched crystal, (2) to be thermally bleached at about 110°C accompanying the disappearence of Z_1 band, (3) to give emission at $1.68\,\mu$ with excitation in the F, Z_1, Z_2 or R band whose wavelength is shorter than the Z_4 band, or the Z_4 band itself.3)4).

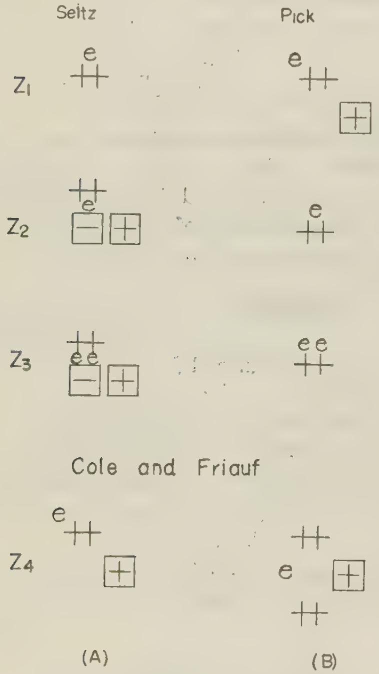

Fig. 1 Models of Z centers.

The present study on the dichroic properties of the Z_4 band of KCl:Sr crystal was undertaken for the following reasons: (1) The two models of Z_4 center above mentioned have different symmetries and the study on the polarization of emission of this center induced with polarized exciting light of 860 mμ reported by West and Compton4) could not decide the orientation of the optical dipole clearly; the degrees of polarization observed were $P(011)=0.39$ and $P(010)=0.34$. If we assume model A or model B for the Z_4 center, the former namely that the optical dipole is solely along the axis of ⟨110⟩, we would predict that $P(010)=0.66$ and $P(010)=0.33$, the later namely that the optical dipole is solely along the axis of ⟨100⟩, we would predict that $P(010)=1.00$ and $P(011)=0.00$. (2) The dichroic F band accompanying the dichroic M band which has been reported by van Doorn and Haven5) in a pure crystal is now one of the intersting problems in this fields. They have suggested that the M center posseses a second and small absorption band hidden under the F band, in addition to the M band. But it leaves a question in the coincidence of the assumed hidden band with the F band for many different kinds of alkali halides. On the other hand, Lambe and Compton6) have suggested another hypothesis dipole-dipole energy transfer between F and M centers. In this case, however, there exist a strong implication that the centers are not situated randomly, but are concentrated mainly in a relatively small volume of the crystal. Besides, it is difficult to interpret the details of the dichroic spectrum by this hypothesis.

In addition to this famous example of F–M dichroism, we have lately reported F–Z_2 dichroism7) which is somewhat more complicated than the former. So it is very attractive to ascertain whether F–Z_4 dichroism also exists or not.

§2. Experimental Procedure

The KCl:Sr crystal was grown in our laboratory by the standard Kyropoulos method and estimated to contain about 10^{-4} mole fraction of strotium—the impurity doping was done in the molton state. The additive coloration of the crystals was made as follows: The block crystals were heated in potassium vapour at about 600°C for 3 hours and then cooled slowly to room temperature. Next, the blocks were cleaved into thin plates between 0.6 and 0.3 mm in thickness and quenched in the dark after heated again at about 600°C for a few minutes. The samples thus prepared show the dominent F

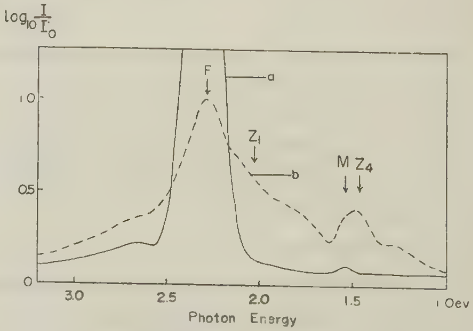

Fig. 2. Absorption spectra
Absorption, (a) before F–light irradiation, (b) after F–light irradiation.

band as in the case of the pure KCl crystal.

Upon irradiating this sample at room temperature with a 500 W tungsten lamp through Matsuda VB3 glass filter for one hour, Z_1, Z_4, M, N and other bands are formed at the expense of the F band. The relative height of the Z_4 band to the F band clearly depends upon the F–irradiation time and quenching rate—the quenching is done quicker, the ratio of Z_4 to F is larger. These situations are shown in Fig. 2, and the characteristic curve of the Matsuda glass filters are shown in Fig. 3.

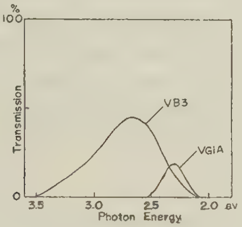

Fig. 3. Gharacteristics of VB3 and VG1A filters.

Throughout this experimental study, we used the samples thus prepared as the virgin crystal. All irradiations were done at room temperature, and all measurements were made at −150°C unless otherwise stated.

In anisotrpic bleaching experiments, the absorption spectra of the crystals were measured with the polarized lights whose electric vectors were perpendicular and parallel to [011] or [010] directions before and after irradiation with [011] or [010] polarized light which were incident on the (100) surface. The dichroic spectra were taken to be the difference between the absorptions as measured with [011] and [0$\bar{1}$1], or with [010] and [001] polarized light.

§ 3. Experimental Results

The absorption curve shown in Fig. 2b was obtained after one hour F–irradiation upon newly quenched crystal at room temperature. Though the F, Z_1 and Z_4 bands are the most prominent, other small absorption bands appear among them. The ratios of Z_1 to Z_4 obtained in various samples were found in largely different values, indicating that Z_1 and Z_4 bands are due to distinct centers—Cole and Friauf[3)] have had the question that both bands might be due to the same center.

The results on the anisotropic bleaching of the Z_4 band where a monochromator or a 100 W tungsten lamp through a set of two filters VV1A and VR1D were used as the light source in the bleaching are shown in Figs. 4A and 4B.

In Fig. 4A, curves b_1 and c_1 show the absorption spectra measured with the light polarized along [011] and [0$\bar{1}$1] respectively after a brief bleaching with the light polarized along [011] direction, and curve a shows

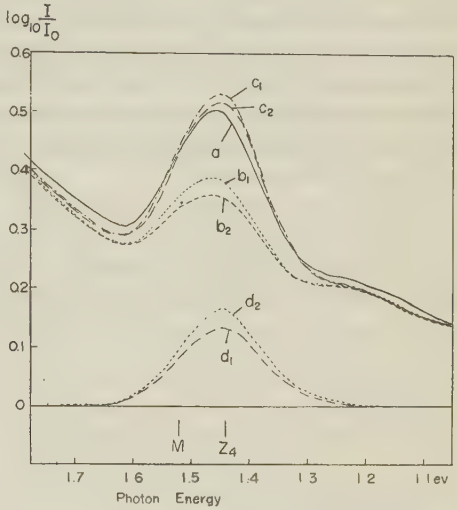

Fig. 4A. Dichroism induced after partial bleaching with [011] polarized light in the Z_4 band. (a) Absorption before bleaching as measured with either [011] or [0$\bar{1}$1] polarized light. Absorption after bleaching, (b) measured with [011] polarized light, (c) measured with [0$\bar{1}$1] polarized light. (d) Dichroic spectra.

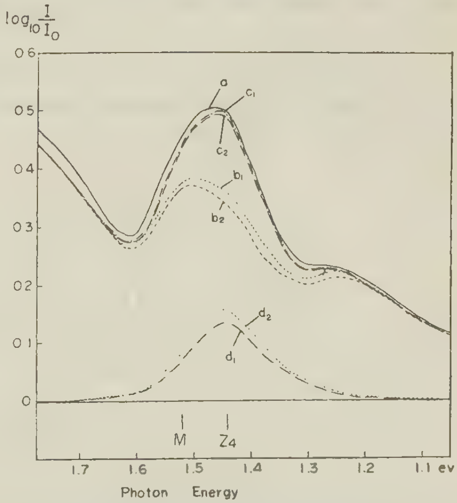

Fig. 4B. The same as Fig. 4A except that [010] and [001] polarized light was used.

the one measured before the bleaching. The absorption measured with the light polarized parallel to the bleaching light decreases markedly, while the one measured with the light polarized perpendicular to the bleaching light increases, indicating that more centers which could absorb $[0\bar{1}1]$ light exist after the bleaching than before. Curves b_2 and c_2 show the succesive bleaching and curves d_1 and d_2 show the dichroic spectra. The above results indicate that not only preferential bleaching of this ceter, but also some reorientation should occur during the polarized light exposure. In Fig. 4B, the similar saturation is observed on the opticalanisotropy induced by the bleaching with the light polarized along [010] direction.

Since both the irradiations with [011] and [010] polarized light induce the dichroism and the peaks of these dichroic spectra precisely coincide with that of the normal Z_4 absorption band, it may be considered that the optical transition corresponding to the Z_4 band is due to an optical dipole oriented parallel to ⟨110⟩ direction. When the anisotropic bleaching is prolonged, the M band also begins to show dichroism considerably.

Then it is striking that during the exposure of the polarized light in Z_4 band there appears another dichroism in the F band region with opposite sign to that in the Z_4 band.

This appearence of the reverse dichroism in the F band region is quite akin to the well-known case of M–F dichroism, but its shape is somewhat different in details. When a crystal is irradiated by the polarized F band light, the dichroism whose sign is opposite to that of the case of the irradiation with Z_4 light appears in both the Z_4 and F band regions. (See Figs. 6A and 6B.)

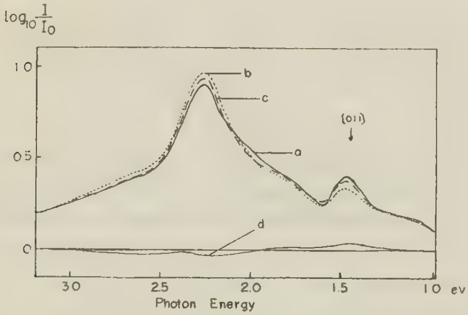

Fig. 5A. Dichroism induced by partial bleaching with [011] polarized light in the Z_4 band. (a) Absorption before bleaching as measured with either [011] or $[0\bar{1}1]$ polarized light.

Absorption after bleaching, (b) measured with [011] polarized light, (c) measured with $[0\bar{1}1]$ polarized light. (d) Dichroic spectra.

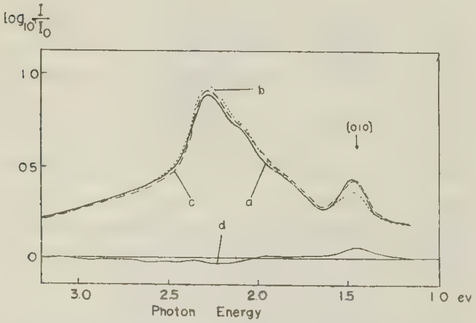

Fig. 5B. The same as Fig. 5A except that [010] and [001] polarized light were used.

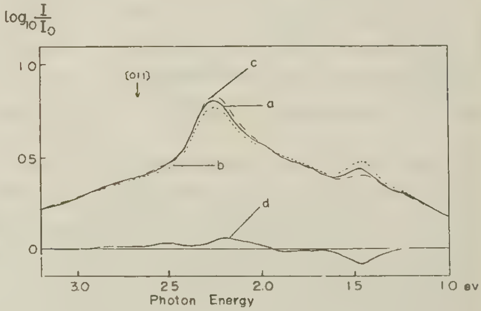

Fig. 6A The same as Fig. 5A except that polarized light in the F band was used as the bleaching light.

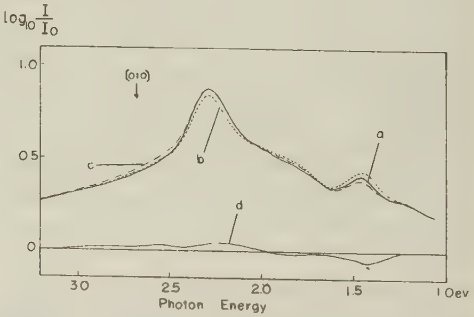

Fig. 6B. The same as Fig. 5B except that polarized light in the F band was used as the bleaching light.

When a virgin crystal is irradiated through VG1A filter, keeping other conditions to be quite the same as in the case of the VB3 filter mentioned above, the strong F–M dichroism appears overlapping with the F–Z_4 dichroism, suggesting that the F–Z_4 dichroism is distinct from the F–M dichroism. (See Fig. 7)

§ 4. Discussion

The results of anisotropic bleaching of the Z_4 band suggest that the center responsible for this band has an axis of symmetry along ⟨110⟩ direction. The A model of this center proposed by Cole and Friauf[3] which is an electron trapped at a divalent ion with a positive ion vacancy bound in the nearest cation site is the one that satisfies the above situation. Thus, Pick's model for Z_1[1] which is quite the same as Cole and Friauf's A model corresponds rather to Z_4.

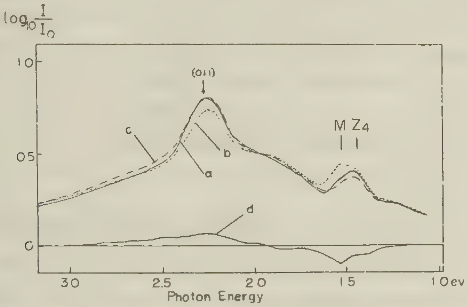

Fig. 7. Dichroism induced by partial bleaching with [011] polarized light through VG1A filter.

Considering the crystalline field of the environment, the symmetry of this center is C_{2V} which is the same as that of the Seitz's model for the M center.

It is interesting that there is the same correlation in dichroism between F and Z_4 bands as that between F and M bands, in addition to that between F and Z_2 bands which has recently been reported by the present authors[7]. Besides, the dichroic spectrum in the F and region is very like that in the case of F–M dichroism.

If the van Doorn hypothesis is taken into account of the correlation in dichroism also in this case, from the C_{2V} symmetry above, the three types of the optical dipoles corresponding to the transitions, A_1–A_1, A_1–B_1 and A_1–B_2 should be taken into consideration for the bands hidden under the F band region. The fact that the F band has a correlation in dichroism also to Z_2 and Z_4 band besides to M band will further add a question to the above hypothesis. Nevertheless, some studies along the van Doorn hypothesis will be reported by the present authors in the near future.

Wall-effect upon Two-dimensional Stokes Flow of an Electrically Conducting Liquid in a Uniform Magnetic Field

By Yorisaburo TAKAISI

Department of Physics, Faculty of Education,
Ehime University, Matsuyama

(Received June 10, 1960)

This paper deals with the steady slow motion of a circular cylinder in a semi-infinite viscous and electrically conducting liquid parallel to its bounding plane wall in the presence of a uniform magnetic field, using Stokes approximation. Detailed calculation is carried out for the flow produced by the cylinder in two cases: one in a parallel magnetic field and the other in a transverse magnetic field. The expansion formulae for the drag per unit span of the cylinder are obtained in terms of the Hartmann number in each case.

§1. Introduction

In a quite recent paper[1], applying Chester's idea[2] to the two-dimensional Stokes flow, Yosinobu and Kakutani have investigated the effect of magnetic field upon the flow of a viscous and electrically conducting liquid past a circular cylinder in two cases: one in a uniform magnetic field parallel to the main stream and the other in a transverse uniform magnetic field.

In this paper, using Faxén's image method[3], we study the steady slow motion of a circular cylinder in a semi-infinite viscous and electrically conducting liquid parallel to its bounding plane wall on the basis of Stokes approximation in two cases: the first case, where the uniform magnetic field is parallel to the bounding plane wall and the second case, where the uniform magnetic field is perpendicular to the bounding plane wall. The bounding plane wall is assumed to be non-magnetic and non-conducting.

Thus, the expansion formulae for the drag per unit span of the cylinder are obtained in power series of the Hartmann number. Numerical results show that the drag coefficients in both cases are almost independent of the Hartmann number, for its small values, and consequently they are equal to each other and are also equal to that obtained by the classical Stokes approximation.

To this order of approximation, no lift appears in both cases.

§2. Fundamental Equations and Solutions

The fundamental equations for a two-dimensional steady flow of an unbounded, viscous and electrically conducting liquid past a cylindrical body in the presence of a uniform magnetic field have been obtained by Yosinobu and Kakutani to the order of Stokes approximation. Since the equations constitute the starting point of the present study, we shall first recapitulate briefly their analysis for the sake of reference, making modifications so as to be applicable to the motion of the liquid produced by the cylinder moving in the liquid otherwise at rest.

The fundamental equations of magnetohydrodynamics are:

(1) Maxwell's equations:

$$\mathrm{curl}\,\boldsymbol{H}=\boldsymbol{J}\,, \tag{2.1}$$

$$\mathrm{div}\,\boldsymbol{H}=0\,, \tag{2.2}$$

$$\mathrm{curl}\,\boldsymbol{E}=0\,, \tag{2.3}$$

$$\varepsilon\,\mathrm{div}\,\boldsymbol{E}=q\,; \tag{2.4}$$

(2) Ohm's law:

$$\boldsymbol{J}=\sigma(\boldsymbol{E}+\mu\boldsymbol{V}\times\boldsymbol{H})+q\boldsymbol{V}\,; \tag{2.5}$$

(3) The equation of continuity:

$$\mathrm{div}\,\boldsymbol{V}=0\,; \tag{2.6}$$

(4) The modified Navier-Stokes equation:

$$\rho(\boldsymbol{V}\cdot\mathrm{grad})\boldsymbol{V}=-\mathrm{grad}\,P+\rho\nu\nabla^2\boldsymbol{V}+q\boldsymbol{E}+\mu\boldsymbol{J}\times\boldsymbol{H}\,; \tag{2.7}$$

where $\boldsymbol{E}$ is the electric field, $\boldsymbol{H}$ the magnetic field, $\boldsymbol{J}$ the current density, q the excess charge density, ε the dielectric constant, μ

e magnetic permeability, σ the electrical nductivity of the liquid, $\boldsymbol{V}$ the liquid velo-ty, P the pressure, and ρ and ν are respec-vely the density and the kinematic viscosity the liquid. In the above seven equations, e have adopted the rationalized M.K.S. stem. We have also assumed the liquid to homogeneous and isotropic.

We choose the origin of coordinates at the ntre of a cross section of the cylinder and e take the x_1-axis parallel to the direction the undisturbed magnetic field, the x_3-axis ong the axis of the cylinder and the x_2-axis rpendicular to both the x_1- and x_3-axes. The locity of the cylinder is supposed to be rallel to the x_1-axis in the first case and to e x_2-axis in the second case.

First, we neglect the terms involving excess arge q in (2.5) and (2.7) as in usual mag-etohydrodynamic problems. We then assume wo-dimensionality of the problem: namely (1) the quantities in (2.1)~(2.7) are independ-nt of x_3, so that all the derivatives in x_3 sappear in the above equations, and (2) the quid velocity $\boldsymbol{V}$ and the magnetic field $\boldsymbol{H}$ e in the x_1x_2-plane. In consequence of these ssumptions, we have, in both cases,

$$\boldsymbol{J}=\mu\sigma(\boldsymbol{V}\times\boldsymbol{H}) . \qquad (2.8)$$

ubstituting (2.8) into (2.1) and (2.7), and troducing non-dimensional variables $\boldsymbol{v}=\boldsymbol{V}/V_1$, $=\boldsymbol{H}/H_1$, $p=[a/(\rho\nu V_1)]P$ and $(x, y, z)=(x_1/a$, $/a, x_3/a)$, we have, in both cases,

$$R_m(\boldsymbol{v}\times\boldsymbol{h})=\nabla\times\boldsymbol{h} , \qquad (2.9)$$

$$R(\boldsymbol{v}\cdot\nabla)\boldsymbol{v}=-\nabla p+\nabla^2\boldsymbol{v}+M^2(\nabla\times\boldsymbol{h})\times\boldsymbol{h} \qquad (2.10)$$

here a is, for instance, the representative ength of the cylinder, $R_m=\mu\sigma aV_1$ the mag-etic Reynolds number, $R=aV_1/\nu$ the Reynolds umber, $M=(\sigma/\rho\nu)^{1/2}a\mu H_1$ the Hartmann num-er, and ∇ stands for $\boldsymbol{i}(\partial/\partial x)+\boldsymbol{j}(\partial/\partial y)$, here $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k})$ are the fundamental unit vectors.

We assume R_m to be small and apply the tokes approximation to Eq. (2.9). Then we ave

$$\nabla\times\boldsymbol{h}=0 . \qquad (2.11)$$

ssuming that the permeabilities of the liquid nd the cylinder are effectively equal, we btain, from (2.2) and (2.11),

$$\boldsymbol{h}=\boldsymbol{i} , \qquad (2.12)$$

so that to the present approximation the magnetic field is everywhere uniform and parallel to the x_1-axis. Inserting (2.12) into (2.10), and assuming R to be small, we have, to the Stokes approximation,

$$-\nabla p+\nabla^2\boldsymbol{v}+M^2(\boldsymbol{v}\times\boldsymbol{i})\times\boldsymbol{i}=0 \qquad (2.13)$$

We now introduce the non-dimensional perturbed velocities $\boldsymbol{v}'=\boldsymbol{v}-\boldsymbol{i}$ in the first case, and $\boldsymbol{v}'=\boldsymbol{v}-\boldsymbol{j}$ in the second case in (2.13). Thus, we have finally the following equation, in both cases:

$$-\nabla p+\nabla^2\boldsymbol{v}'-M^2v\boldsymbol{j}=0 , \qquad (2.14)$$

which should be solved in combination with the equation of continuity for $\boldsymbol{v}'$:

$$\nabla\cdot\boldsymbol{v}'=0 , \qquad (2.15)$$

where (u, v) are the x- and y-components of $\boldsymbol{v}'$, respectively.

Eliminating p from (2.14), we have

$$\nabla^2\omega-M^2\frac{\partial v}{\partial x}=0 , \qquad (2.16)$$

where $\omega=\partial v/\partial x-\partial u/\partial y$ is the vorticity. Eq. (2.15) shows that the perturbed velocity field has a stream function ψ such that

$$u=\frac{\partial\psi}{\partial y} , \qquad v=-\frac{\partial\psi}{\partial x} , \qquad (2.17)$$

and

$$\omega=-\nabla^2\psi . \qquad (2.18)$$

Substituting (2.17) and (2.18) into (2.16) we obtain the equation for ψ as:

$$\left(\nabla^4-M^2\frac{\partial^2}{\partial x^2}\right)\psi=0 . \qquad (2.19)$$

The solution of this equation can be expressed in the form:

$$\psi=\psi_1+\psi_2 , \qquad (2.20)$$

where ψ_1 and ψ_2 are solutions of equations

$$\left(\nabla^2-M\frac{\partial}{\partial x}\right)\psi_1=0 , \qquad (2.21)$$

and

$$\left(\nabla^2+M\frac{\partial}{\partial x}\right)\psi_2=0 , \qquad (2.22)$$

respectively. The appropriate solutions of (2.21) and (2.22) which satisfy the boundary conditions at infinity are given respectively by

$$\psi_1=A_0e^{kx}K_0(kr)+B_1\int_0^{\theta}kr[K_1(kr)+K_0(kr)\cos\theta]e^{kr\cos\theta}d\theta$$
$$+e^{kx}\sum_{n=1}^{\infty}K_n(kr)(A_n\cos n\theta+B_n\sin n\theta) , \qquad (2.23)$$

and

$$\psi_2=C_0e^{-kx}K_0(kr)+D_0\int_0^\theta kr[K_1(kr)-K_0(kr)\cos\theta]e^{-kr\cos\theta}d\theta$$
$$+e^{-kx}\sum_{n=1}^{\infty}K_n(kr)(C_n\cos n\theta+D_n\sin n\theta)\ , \tag{2.24}$$

where $k=\frac{1}{2}M,\qquad x=r\cos\theta,\qquad y=r\sin\theta$ and

$$B_0+D_0=0\ . \tag{2.25}$$

$K_n(x)$ is the modified Bessel function of the second kind. The condition (2.25) ensures that the stream function ψ is one-valued and continuous throughout the whole field of flow.

We introduce conjugate complex velocities w_n's defined as:

$$w_n=u_n-iv_n\qquad(n=1,\ 2)\ . \tag{2.26}$$

Inserting (2.23) and (2.24) into (2.26), and expanding the functions with respect to $e^{i\theta}$, then we have the Fourier series for w_n's as:

$$\begin{aligned}\left.\begin{matrix}w_1\\w_2\end{matrix}\right\}=ik\begin{Bmatrix}A_0\\C_0\end{Bmatrix}&[\pm(K_0I_0-K_1I_1)+e^{-i\theta}(K_0I_1-K_1I_0)+e^{i\theta}(K_0I_1-K_1I_2)\\&\pm e^{-2i\theta}(K_0I_2-K_1I_1)\pm e^{2i\theta}(K_0I_2-K_1I_3)+e^{-3i\theta}(K_0I_3-K_1I_2)]\\+k\begin{Bmatrix}B_0\\D_0\end{Bmatrix}&[\pm(K_0I_0+K_1I_1)+e^{-i\theta}(K_0I_1+K_1I_0)+e^{i\theta}(K_0I_1+K_1I_2)\\&\pm e^{-2i\theta}(K_0I_2+K_1I_1)\pm e^{2i\theta}(K_0I_2+K_1I_3)+e^{-3i\theta}(K_0I_3+K_1I_2)]\\+\frac{1}{2}ik\begin{Bmatrix}A_1\\C_1\end{Bmatrix}&[-K_0I_0+2K_1I_1-K_2I_2\mp e^{-i\theta}(K_0I_1-K_1I_0-K_1I_2+K_2I_1)\\&\mp e^{i\theta}(K_0I_1-K_1I_0-K_1I_2+K_2I_3)-e^{-2i\theta}(K_0I_2-K_1I_1-K_1I_3+K_2I_0)\\&-e^{2i\theta}(K_0I_2-K_1I_1-K_1I_3+K_2I_4)\mp e^{-3i\theta}(K_0I_3-K_1I_2-K_1I_4+K_2I_1)]\\+\frac{1}{2}k\begin{Bmatrix}B_1\\D_1\end{Bmatrix}&[-K_0I_0+K_2I_2\mp e^{-i\theta}(K_0I_1+K_1I_0-K_1I_2-K_2I_1)\\&\mp e^{i\theta}(K_0I_1-K_1I_0+K_1I_2-K_2I_3)-e^{-2i\theta}(K_0I_2+K_1I_1-K_1I_3-K_2I_0)\\&-e^{2i\theta}(K_0I_2-K_1I_1+K_1I_3-K_2I_4)\mp e^{-3i\theta}(K_0I_3+K_1I_2-K_1I_4-K_2I_1)]\\+\cdots\ ,&\end{aligned} \tag{2.27}$$

where the argument kr of the functions K_n and I_n has been omitted for brevity.

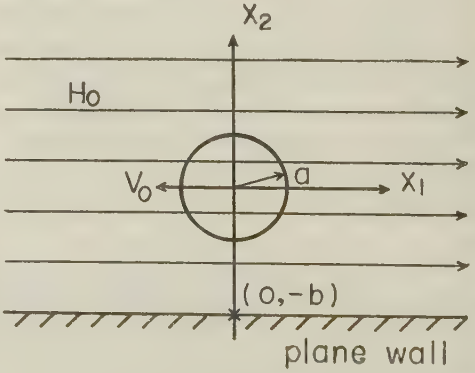

Fig. 1.

§ 3. First Case

Suppose that a circular cylinder of radius a is moving, with constant slow velocity $-V_0$ along the x_1-axis, in the presence of a uniform magnetic field parallel to the x_1-axis, in a semi-infinite viscous and electrically conducting liquid otherwise at rest parallel to its bounding plane wall (Fig. 1). The wall is assumed to be non-magnetic and non-conducting.

3.1. *Method of solution*

If we confine ourselves to the calculation of the forces experienced by the cylinder correct to the order of M^2, the lowest terms being $O(1)$, it suffices to take the first four terms in (2.23) and (2.24) respectively. Then, as shown in our previous paper[4)], we obtain integral expressions for ψ_1 and ψ_2 as:

$$\psi_1=\frac{1}{2}\int_{-\infty}^{\infty}\left\{\frac{1}{\lambda_1}\left(A_0-\frac{i\alpha-k}{k}A_1\right)+\frac{|y|}{y}\left(\frac{i\alpha-2k}{\lambda^2{}_1}B_0+\frac{1}{k}B_1\right)\right\}e^{i\alpha x-\lambda_1|y|}d\alpha\ , \tag{3.1}$$

$$\psi_2=\frac{1}{2}\int_{-\infty}^{\infty}\left\{\frac{1}{\lambda_2}\left(C_0-\frac{i\alpha+k}{k}C_1\right)+\frac{|y|}{y}\left(\frac{i\alpha+2k}{\lambda_2{}^2}D_0+\frac{1}{k}D_1\right)\right\}e^{i\alpha x-\lambda_2|y|}d\alpha\ , \tag{3.2}$$

where $\lambda_1=\sqrt{\alpha^2+2ik\alpha}$ and $\lambda_2=\sqrt{\alpha^2-2ik\alpha}$.

In order to satisfy the boundary conditions on the bounding plane wall, we now superpose, as done by Faxén, a flow due to images, which is derived from a stream function ψ^* defined as:

$$\psi^*=\psi_1{}^*+\psi_2{}^*\ , \tag{3.3}$$

where

$$\psi_1{}^*=\frac{1}{2}\int_{-\infty}^{\infty}f_1(\alpha)e^{i\alpha x-\lambda_1(y+2\delta)}d\alpha\ , \tag{3.4}$$

and

$$\psi_2{}^*=\frac{1}{2}\int_{-\infty}^{\infty}f_2(\alpha)e^{i\alpha x-\lambda_2(y+2\delta)}d\alpha\ , \tag{3.5}$$

where $\delta=b/a$ and $f_n(\alpha)$'s are unknown functions to be determined by the under-mentioned boundary conditions.

The boundary conditions at infinity are satisfied automatically by w_n's and $w_n{}^*$'s. Then, we have only to consider the boundary conditions on the bounding plane wall $y=-\delta$ as well as at the surface of the cylinder. They are

$$(w_1+w_2+w_1{}^*+w_2{}^*)_{y=-\delta}=0\ , \tag{3.6}$$

and

$$(w_1+w_2+w_1{}^*+w_2{}^*)_{r=1}=-1\ . \tag{3.7}$$

3.2. *Determination of the functions $f_n(\alpha)$'s*

Inserting (3.1), (3.2) and (3.4), (3.5) into (3.6), the functions $f_n(\alpha)$'s so far undetermined can be expressed in terms of the unknown constants A_0, B_0, $\cdots$ and D_1 as:

$$\begin{aligned}f_1(\alpha)=&\frac{\lambda_1+\lambda_2}{\lambda_1(\lambda_1-\lambda_2)}\left(A_0-\frac{i\alpha-2k}{\lambda_1}B_0-\frac{i\alpha-k}{k}A_1-\frac{\lambda_1}{k}B_1\right)\\&+\frac{2}{\lambda_1-\lambda_2}\left(C_0-\frac{i\alpha+2k}{\lambda_2}D_0-\frac{i\alpha+k}{k}C_1-\frac{\lambda_2}{k}D_1\right)e^{(\lambda_1-\lambda_2)\delta}\ ,\end{aligned} \tag{3.8}$$

and

$$\begin{aligned}f_2(\alpha)=&-\frac{2}{\lambda_1-\lambda_2}\left(A_0-\frac{i\alpha-2k}{\lambda_1}B_0-\frac{i\alpha-k}{k}A_1-\frac{\lambda_1}{k}B_1\right)e^{-(\lambda_1-\lambda_2)\delta}\\&-\frac{\lambda_1+\lambda_2}{\lambda_2(\lambda_1-\lambda_2)}\left(C_0-\frac{i\alpha+2k}{\lambda_2}D_0-\frac{i\alpha+k}{k}C_1-\frac{\lambda_2}{k}D_1\right)\ .\end{aligned} \tag{3.9}$$

3.3. *Determination of the constants A_0, B_0, $\cdots$ and D_1*

If we insert (3.8) and (3.9) into (3.4) and (3.5) respectively and expand the integrands with respect to $e^{i\theta}$, we obtain, after some lengthy calculations, the Fourier series for w^* as:

$$\begin{aligned}w^*=w_1{}^*+w_2{}^*=&k\{(F_1+iF_2)+k^2r^2(F_5+iF_6)\}A_0+k\{(F_3+iF_4)+k^2r^2(F_7+iF_8)\}B_0\\&+k\{(F_1-iF_2)+k^2r^2(F_5-iF_6)\}C_0+k\{-(F_3-iF_4)-k^2r^2(F_7-iF_8)\}D_0\\&+k(F_9+iF_{10})A_1+k(F_{11}+iF_{12})B_1-k(F_9-iF_{10})C_1+k(F_{11}-iF_{12})D_1\\&+ik^2re^{-i\theta}(F_{13}A_0+F_{14}B_0+F_{13}C_0-F_{14}D_0)\\&+k^2re^{i\theta}\{(F_{15}+iF_{16})A_0+(F_{17}+iF_{18})B_0-(F_{15}-iF_{16})C_0+(F_{17}-iF_{18})D_0\}\\&+\cdot\cdot\cdot\ ,\end{aligned} \tag{3.10}$$

where F_n's are functions of $l=2k\delta$.

We may expand the constants in powers of k as:

$$\left.\begin{aligned}(A_0, B_0, C_0, D_0)&=k^{-1}(A_{00}, B_{00}, C_{00}, D_{00})+k(A_{01}, B_{01}, C_{01}, D_{01})+\cdots ,\\ (A_1, B_1, C_1, D_1)&=k(A_{10}, B_{10}, C_{10}, D_{10})+\cdots .\end{aligned}\right\} \tag{3.11}$$

We insert (2.27) and (3.10) together with (3.11) into (3.7), and we neglect all terms higher than k^3. Then, on equating to zero the terms of the same powers of k in the coefficients of $e^{ni\theta}$ and separating the real and imaginary parts, we obtain linear algebraic equations for the constants A_{00}, A_{01}, $\cdots$ and D_{10}. Solving these equations successively, we obtain

$$\left.\begin{aligned}A_{00}&=C_{00}=0 ,\\ B_{00}&=-D_{00}=-\frac{1}{2\Omega+1+2F_3} ,\\ A_{01}&=C_{01}=-\frac{F_{14}}{2\Omega+1+2F_3} ,\\ B_{01}&=-D_{01}=\frac{4\Omega+1+8F_7-4F_{11}+8F_1F_{14}-16F_9F_{18}}{4(2\Omega+1+2F_3)^2} ,\\ A_{10}&=-C_{10}=\frac{2F_{18}}{2\Omega+1+2F_3} ,\\ B_{10}&=D_{10}=\frac{1}{2(2\Omega+1+2F_3)} ,\end{aligned}\right\} \tag{3.12}$$

where $\Omega=-\gamma-\ln(M/4)$, $\gamma=0.57721\cdots$being Euler's constant.

Making use of the relations $F_{11}=-2F_7$, $F_{14}=-F_1$ and $F_{18}=F_9$, we obtain from (3.11) and (3.12)

$$A_0=C_0=-\frac{2F_{14}}{2\Omega+1+2F_3}\left(\frac{M}{4}\right), \tag{3.13}$$

$$B_0=-D_0=-\frac{2}{M(2\Omega+1+2F_3)}\left\{1-\frac{4\Omega+1-8F_1{}^2+16F_7-16F_9{}^2}{2\Omega+1+2F_3}\left(\frac{M}{4}\right)^2\right\}, \tag{3.14}$$

$$A_1=-C_1=\frac{4F_9}{2\Omega+1+2F_3}\left(\frac{M}{4}\right), \tag{3.15}$$

$$B_1=D_1=\frac{1}{2\Omega+1+2F_3}\left(\frac{M}{4}\right). \tag{3.16}$$

The functions F_n's necessary for the calculation of (3.13)~(3.16) are given by

$$F_1=S_{2,0}(l)+S_{2,1}(l)+\tfrac{1}{2}l\Lambda_0(l)-\tfrac{1}{2}\Lambda_1(l) , \tag{3.17}$$

$$F_3=S_{1,0}(l)+S_{1,1}(l)+C_{1,-1}(l)+C_{1,1}(l)-\Lambda_0(l)-(\tfrac{1}{2}l^{-1}+\tfrac{1}{2}l)\Lambda_1(l)+l , \tag{3.18}$$

$$F_7=\tfrac{1}{2}\{S_{1,-1}(l)-S_{1,1}(l)-C_{1,-1}(l)+C_{1,3}(l)\} , \tag{3.19}$$

$$F_9=S_{2,0}(l)+S_{2,1}(l)+C_{2,-1}(l)-C_{2,3}(l)+\tfrac{1}{2}l^{-1}\Lambda_0(l)-(l^{-2}+\tfrac{1}{2})\Lambda_1(l)+1 , \tag{3.20}$$

where

$$\left.\begin{aligned}S_{1,n}(l)&=\int_0^\infty\frac{1}{(1+\xi^2)^n}e^{-l\xi}\sin\frac{l\xi}{(1+\xi^2)^{1/2}}d\xi ,\\ S_{2,n}(l)&=\int_0^\infty\frac{\xi}{(1+\xi^2)^n}e^{-l\xi}\sin\frac{l\xi}{(1+\xi^2)^{1/2}}d\xi ,\\ C_{1,n}(l)&=\int_0^\infty\frac{1}{(1+\xi^2)^{n/2}}e^{-l\xi}\cos\frac{l\xi}{(1+\xi^2)^{1/2}}d\xi ,\\ C_{2,n}(l)&=\int_0^\infty\frac{\xi}{(1+\xi^2)^{n/2}}e^{-l\xi}\cos\frac{l\xi}{(1+\xi^2)^{1/2}}d\xi ;\end{aligned}\right\} \tag{3.21}$$

and

$$A_n(l)=\pi\{\mathbf{H}_n(l)-Y_n(l)\}\ , \tag{3.22}$$

where $Y_n(x)$ is Neumann's Bessel function of the second kind and $\mathbf{H}_n(x)$ is Struve's function[5] defined as:

$$\mathbf{H}_n(x)=\sum_{m=0}^{\infty}\frac{(-)^m(\frac{1}{2}x)^{n+2m+1}}{\Gamma(m+\frac{3}{2})\Gamma(n+m+\frac{3}{2})}\ . \tag{3.23}$$

3.4. *Forces on the cylinder*

The forces experienced by the cylinder can be calculated by integrating the viscous and Maxwell's stresses on the surface of the cylinder, as done by Yosinobu and Kakutani in the case of no wall. Thus, the lift L^{I} and the drag D^{I} experienced by the cylinder under discussion per unit span can be expressed as:

$$L^{\mathrm{I}}=0\ , \tag{3.24}$$

$$D^{\mathrm{I}}=-4\pi\rho\nu MV_0B_0\ . \tag{3.25}$$

To the present approximation, the Maxwell's stress makes no contributions to the lift and drag. Hence, if use is made of (3.14), we have for the drag coefficient $C_D{}^{\mathrm{I}}$

$$C_D{}^{\mathrm{I}}=\frac{D^{\mathrm{I}}}{\rho\nu V_0}=\frac{8\pi}{2\Omega+1+2F_3}\left\{1-\frac{4\Omega+1-8F_1{}^2+16F_7-16F_9{}^2}{2\Omega+1+2F_3}\left(\frac{M}{4}\right)^2\right\}\ . \tag{3.26}$$

If we expand the functions $\sin\{l\xi/(1+\xi^2)^{1/2}\}$ and $\cos\{l\xi/(1+\xi^2)^{1/2}\}$ in (3.21) into Taylor's series with respect to l, and if use is made of the formula[6]

$$\int_0^\infty(1+\xi^2)^{n-1/2}e^{-l\xi}d\xi=2^{n-1}\pi^{-1/2}\Gamma(n+\tfrac{1}{2})l^{-n}A_n(l)\ , \tag{3.27}$$

together with its derivatives with respect to l, we obtain a series expression with respect to l for the drag coefficient $C_D{}^{\mathrm{I}}$, which is valid for $l\leqq 1$. Thus, an approximate expansion formula correct to $O(l^2)$, for instance, is expressed as:

$$C_D{}^{\mathrm{I}}=\frac{4\pi}{\ln 2\delta-(T-\frac{1}{2})l^2}\left[1+\frac{4l^{-2}-2\Omega-14T+\frac{43}{6}-\frac{64}{3}l+12\left(T^2-\frac{17}{16}T+\frac{10093}{8640}\right)l^2}{\ln 2\delta-(T-\frac{1}{2})l^2}\left(\frac{M}{4}\right)^2\right]\ , \tag{3.28}$$

where $T=-\gamma-\ln(M\delta/2)$.

In the case of no magnetic field so that $M=0$ and $l=0$, (3.28) reduces simply to

$$C_{D0}=\lim_{\substack{M\to 0\\ l\to 0}}C_D{}^{\mathrm{I}}=\frac{4\pi}{\ln 2\delta-\frac{1}{4}\delta^{-2}}\ , \tag{3.29}$$

which is in perfect agreement with the result obtained previously by the present writer for the classical Stokes approximation[7].

On the other hand, for $l>1$, the integrals represented by (3.21) can be evaluated numerically by making use of Simpson's rule. The values of $A_n(l)$ ($n=0$, 1) up to $l=16$ can be found in tables of Bessel functions*. For larger values of l, we make use of the asymptotic expansion[5], which is expressed as:

$$A_n(x)=\sum_{m=0}^{p-1}\frac{\Gamma(m+\frac{1}{2})}{\Gamma(n+\frac{1}{2}-m)(\frac{1}{2}x)^{2m-n+1}}+O(x^{n-2p-1})\ . \tag{3.30}$$

Thus, the drag coefficient $C_D{}^{\mathrm{I}}$ can be evaluated numerically for any value of l.

When the bounding plane wall recedes far away to infinity from the centre of the cylinder, the value of l tends to infinity and our case is reduced to the case of a circular cylinder in an unbounded viscous and electrically conducting liquid in the presence of a parallel magnetic field. The value of M, however, should be kept to be small. Making use of (3.21) and (3.30), we easily find that

---

* See, for example, G. N. Watson: *A Treatise on the Theory of Bessel Functions* (Cambridge, 1922) 666.

$$\lim_{l\to\infty} F_n(l)\to 0 \ .$$

Thus, we have ultimately, from (3.26),

$$C_{D\infty}^{\mathrm{I}}=\lim_{l\to\infty} C_D{}^{\mathrm{I}}=\frac{8\pi}{2\Omega+1}\left\{1-\frac{4\Omega+1}{2\Omega+1}\left(\frac{M}{4}\right)^2\right\} . \tag{3.31}$$

As should be expected, (3.31) is in perfect agreement with the result obtained by Yosinobu and Kakutani for the case of no wall.

§ 4. Second Case

In the case of a transverse magnetic field, the axes of coordinates and the bounding plane wall may be taken as shown in Fig. 2. In this case also the fundamental equations (2.21), (2.22) and their solutions (2.23), (2.24) respectively, and consequently the expressions for the conjugate complex velocities represented by (2.27), hold good. However, as for the integral expressions for ψ_n's and ψ^*'s we have to take

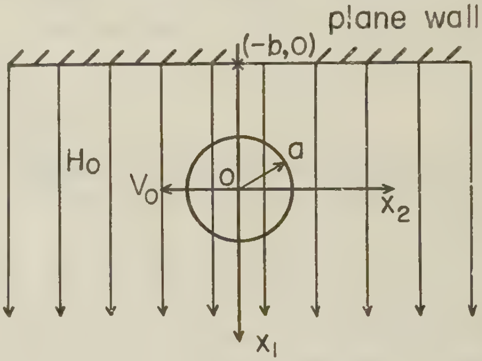

Fig. 2.

$$\psi_1=\frac{1}{2}\int_{-\infty}^{\infty}\left[\frac{1}{\lambda}A_0+\frac{1}{k}\frac{|x|}{x}A_1-i\left\{\frac{1}{\beta}\left(\frac{|x|}{x}+\frac{k}{\lambda}\right)B_0+\frac{\beta}{k\lambda}B_1\right\}\right]e^{i\beta y+kx-\lambda|x|}d\beta\ , \tag{4.1}$$

$$\psi_2=\frac{1}{2}\int_{-\infty}^{\infty}\left[\frac{1}{\lambda}C_0+\frac{1}{k}\frac{|x|}{x}C_1-i\left\{\frac{1}{\beta}\left(\frac{|x|}{x}-\frac{k}{\lambda}\right)D_0+\frac{\beta}{k\lambda}D_1\right\}\right]e^{i\beta y-kx-\lambda|x|}d\beta\ , \tag{4.2}$$

$$\psi_1{}^*=\frac{1}{2}\int_{-\infty}^{\infty}g_1(\beta)e^{i\beta y+(k-\lambda)(x+2\delta)}d\beta\ , \tag{4.3}$$

and

$$\psi_2{}^*=\frac{1}{2}\int_{-\infty}^{\infty}g_2(\beta)e^{i\beta y-(k+\lambda)(x+2\delta)}d\beta\ , \tag{4.4}$$

where $\lambda=\sqrt{\beta^2+k^2}$.

The boundary conditions to be satisfied on the bounding plane wall as well as at the surface of the cylinder are

$$(w_1+w_2+w_1{}^*+w_2{}^*)_{x=-\delta}=0\ , \tag{4.5}$$

and

$$(w_1+w_2+w_1{}^*+w_2{}^*)_{r=1}=i\ . \tag{4.6}$$

By carrying out calculations similar to those in case 1, we have

$$\left.\begin{aligned}
g_1(\beta)=&\left\{-\frac{k+\lambda}{k\lambda}A_0-i\frac{\beta}{k\lambda}B_0+\frac{k+\lambda}{k^2}A_1+i\frac{\beta(k+\lambda)}{k^2\lambda}B_1\right\}e^{-2k\delta}\\
&+\left(-\frac{1}{k}C_0-i\frac{k+\lambda}{k\beta}D_0+\frac{\lambda}{k^2}C_1+i\frac{\beta}{k^2}D_1\right),\\
g_2(\beta)=&\left(\frac{1}{k}A_0-i\frac{k-\lambda}{k\beta}B_0-\frac{\lambda}{k^2}A_1-i\frac{\beta}{k^2}B_1\right)\\
&+\left\{-\frac{k-\lambda}{k\lambda}C_0+i\frac{\beta}{k\lambda}D_0+\frac{k-\lambda}{k^2}C_1+i\frac{\beta(k-\lambda)}{k^2\lambda}D_1\right\}e^{2k\delta}\ ,
\end{aligned}\right\} \tag{4.7}$$

$$\begin{aligned} w^* = w_1^* + w_2^* = {} & ik(G_1 + k^2r^2G_2)A_0 + k(G_3 + k^2r^2G_4)B_0 + ik(G_5 + k^2r^2G_6)C_0 \\ & + k(G_7 + k^2r^2G_8)D_0 + ikG_9A_1 + kG_{10}B_1 + ikG_{11}C_1 + kG_{12}D_1 \\ & + k^2re^{-i\theta}(iG_{13}A_0 + G_{14}B_0 + iG_{15}C_0 + G_{16}D_0) \\ & + k^2re^{i\theta}(iG_{17}A_0 + G_{18}B_0 + iG_{19}C_0 + G_{20}D_0) \\ & + \cdots , \end{aligned} \tag{4.8}$$

where G_n's are functions of $l = 2k\delta$, and

$$\left.\begin{aligned} A_0 = {} & \frac{2}{M(2\Omega - 1 + G_1 - G_5)} \\ & \times \left\{1 - \frac{8\Omega + 1 + 4(G_2 - G_6) - 2(G_9 + G_{11}) - 4(G_9 - G_{11})(G_{17} - G_{19}) - 2(2\Omega - 1 - 2G_5)(G_{13} - G_{15})}{2\Omega - 1 + G_1 - G_5}\left(\frac{M}{4}\right)^2\right\} , \\ C_0 = {} & -\frac{2}{M(2\Omega - 1 + G_1 - G_5)} \\ & \times \left\{1 - \frac{8\Omega + 1 + 4(G_2 - G_6) - 2(G_9 + G_{11}) - 4(G_9 - G_{11})(G_{17} - G_{19}) + 2(2\Omega - 1 + 2G_1)(G_{13} - G_{15})}{2\Omega - 1 + G_1 - G_5}\left(\frac{M}{4}\right)^2\right\} , \\ A_1 = {} & -\frac{2(G_{17} - G_{19}) + 1}{2\Omega - 1 + G_1 - G_5}\left(\frac{M}{4}\right) , \\ C_1 = {} & \frac{2(G_{17} - G_{19}) - 1}{2\Omega - 1 + G_1 - G_5}\left(\frac{M}{4}\right) , \end{aligned}\right\} \tag{4.9}$$

$$B_0 = D_0 = 0 , \qquad B_1 = D_1 = 0 . \tag{4.10}$$

Finally, we have for the drag coefficient C_D^{II}

$$\begin{aligned} C_D^{\mathrm{II}} = \frac{D^{\mathrm{II}}}{\rho\nu V_0} = {} & \frac{8\pi}{2\Omega - 1 + G_1 - G_5} \\ & \times \left\{1 - \frac{8\Omega^2 + 4\Omega + 1 + 4\Omega(G_1 - G_5) + 4(G_2 - G_6) - 2(G_9 + G_{11}) - 2(G_1 + G_5)^2 - 4(G_9 - G_{11})^2}{2\Omega - 1 + G_1 - G_5}\left(\frac{M}{4}\right)^2\right\} \\ & + \pi(\sigma^*/\sigma)M^2 , \end{aligned} \tag{4.11}$$

where σ^* is the electric conductivity of the cylinder, and

$$\left.\begin{aligned} G_1 &= -\tfrac{1}{2}(K_0 - K_2) - \tfrac{1}{2}e^{-l}(K_0 + 2K_1 + K_2) , \\ G_2 &= -\tfrac{1}{8}(2K_0 - K_1 - 2K_2 + K_3) - \tfrac{1}{8}e^{-l}(4K_0 + 7K_1 + 4K_2 + K_3) , \\ G_5 &= \tfrac{1}{2}(K_0 - K_2) + \tfrac{1}{2}e^{l}(K_0 - 2K_1 + K_2) , \\ G_6 &= \tfrac{1}{8}(2K_0 + K_1 - 2K_2 - K_3) + \tfrac{1}{8}e^{l}(4K_0 - 7K_1 + 4K_2 - K_3) , \\ G_9 &= \tfrac{1}{4}(K_1 - K_3) + \tfrac{1}{4}e^{-l}(2K_0 + 3K_1 + 2K_2 + K_3) , \\ G_{11} &= -\tfrac{1}{4}(K_1 - K_3) + \tfrac{1}{4}e^{l}(2K_0 - 3K_1 + 2K_2 - K_3) . \end{aligned}\right\} \tag{4.12}$$

The argument l of the functions K_n's has been omitted for brevity, and the relations $G_{17} = G_9$, $G_{19} = G_{11}$ and $G_{13} - G_{15} = -(G_1 + G_5)$ have been used.

The term $\pi(\sigma^*/\sigma)$ in (4.11) arises from the Maxwell's stress, and the other terms are the contributions from the viscous stress.

In this case also no lift appears.

In the case of no magnetic field, the formula (4.11) reduces also to (3.29), the result for the classical Stokes approximation.

On the other hand, when $\delta \to \infty$ and consequently $l \to \infty$, keeping the value M small, we have

$$\lim_{l\to\infty} G_n\to 0\ ,$$

and consequently

$$C^{\mathrm{II}}_{D\infty}=\lim_{\delta\to\infty} C_D{}^{\mathrm{II}}=\frac{8\pi}{2\Omega-1}\left\{1-\frac{8\Omega^2+4\Omega+1}{2\Omega-1}\left(\frac{M}{4}\right)^2\right\}+\pi\left(\frac{\sigma^*}{\sigma}\right)M^2\ , \tag{4.13}$$

which is in perfect agreement with the result obtained by Yosinobu and Kakutani for the corresponding case.

§ 5. Numerical Discussions

The values of the drag coefficient $C_D{}^{\mathrm{I}}$ have been calculated numerically by using (3.26), as was mentioned in § 3, for various values of the Hartmann number M up to unity as well as for various values ranging from 5 to 100 of the ratio $\delta=b/a$. They are given in Table I and are also plotted in Fig. 3 against M.

The values of $C_D{}^{\mathrm{II}}$ have been calculated by using (4.11) for various values of M up to 0.5 as well as for various values ranging from 5 to 100 of the ratio δ, where we have put $\sigma^*=0$ for simplicity. They are tabulated in Table II and are shown graphically in Fig. 3.

For the sake of reference, the values of $C^{\mathrm{I}}_{D\infty}$ and $C^{\mathrm{II}}_{D\infty}$ have been computed by (3.31) and (4.13) respectively. The results are also given in the corresponding tables, and are shown in Fig. 3.

It is worth noticing that, as can be seen from Tables I, II and Fig. 3, the drag co-

Glass Transition Phenomena and Rheological Properties of Petroleum Asphalt

By Yasaku WADA and Hidenori HIROSE

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo, Japan

(Received May 23, 1960)

Volume dilatometry was made for nine kinds of asphalt in a wide range of asphaltene content X. The glass transition temperature T_g becomes higher with increase of X. The discontinuity in thermal expansion coefficient at T_g decreases with X and T_g can no more be observed for $X>70\%$.

The complex shear modulus and shear creep compliance of five samples of asphalt were measured. Above T_g, asphalt is viscoelastic. The temperature-time reducibility applies very well to asphalt. The temperature dependence of retardation times as well as steady flow viscosity obeys to Williams-Landel-Ferry's equation, the standard temperature involved in this equation being 56° higher than T_g for all the samples. The distribution function of retardation times is approximately of a wedge shape when plotted in logarithmic scales, the slope being 0.5 or less according to X. The steady flow viscosity and the maximum retardation time reduced to 20°C markedly increase with X.

These facts allow us some predictions about molecular behaviors in asphalt.

§ 1. Introduction

Asphalts are the highly viscous residue of petroleum obtained by removing most of its volatile components. The elimination of volatile components is often combined with chemical treatment, chiefly oxidation. This treatment is carried out by blowing air through a distilation residue. In this case the products are distinguished by the name "blown asphalt", whereas those prepared by distilation only are called "straight asphalt".

Asphalts are mainly used in protective coatings and as binding materials especially in road constructions. Their suitability for these uses accordingly is largely dependent on their rheological properties. Besides, asphalts are widely used as a material of a polishing disk in glass polishing practice. In this application the rheological properties of asphalts play a particularly important role and for a correct judgement of their suitability, therefore, a thorough knowledge of these properties is indispensable. In fact, the present research has started from this standpoint.

Not a few investigations on the rheological properties of asphalts have so far been carried out by many authors and have been summarized in some reviews.[1-2] In this paper, a more systematic study of rheological properties as well as glass transition phenomena of several kinds of asphalt will be presented. The scheme of the present approach is based on the method which has been developed by Tobolsky, Ferry and many others and found to be very effective in studying the linear viscoelasticity of amorphous polymers.

§ 2. Samples

Asphalt is a mixture of hydrocarbons and compounds of a predominantly hydrocarbon character. Most asphalts contain high-molecular components ("asphaltenes"), which may be precipitated as a solid by diluting the asphalt with low-boiling saturated hydrocarbons. The remaining part is a highly viscous oil of low-molecular weight ("maltenes"). Blown asphalts are richer in asphaltene content than straight asphalts. The elementary analysis reveals[3] that asphaltenes have high carbon/hydrogen ratio, so are rich in cyclic hydrocarbons. On the other hand, maltenes have low carbon/hydrogen ratio and accordingly are rich in linear hydrocarbons.

Nine kinds of samples are used in this investigation (see Table 1). Five samples, C through G, are blown asphalts manufactured for the use of lens polishing. The sample H is a straight asphalt. The content of asphaltenes in these samples was determined by the following procedures: One gram of a sample is completely dissolved in 10 cc of benzene, the solution is added by 50 cc of acetone and leaved at 25°C for one day, then the precipitate is filtered through a filter paper and weighed. The samples A and I are pure asphaltenes and maltenes respectively, being separated from the sample E by the above procedures. The sample B is a mixture of A and I in a weight ratio of 3:1.

In the experiments described in later sections, samples are moulded in suitable forms. In the process of moulding, care must be taken not to overheat the sample in order to prevent it from thermal decomposition. The moulded specimens are leaved in warm water so as to become free from any residual stress.

§ 3. Volume dilatometry

In Table I is given the density of the samples at 20°C measured by the Archimedes method. The density increases with asphaltene content.

Table I.

Sample	Asphaltene (wt. %)	Density (20°C) (g/cc)	Glass transition temp. (°C)	Thermal expansion coeff. (10^{-4}/deg) above T_g	below T_g	difference
A	100	1.079	none			
B	75	1.053	none			
C	61.9	1.039	2	5.8	3.7	2.1
D	58.6	1.034	0	6.0	3.8	2.2
E	57.1	1.030	− 2	6.3	4.0	2.3
F	52.5	1.027	− 6.5	6.6	3.9	2.7
G	50.8	1.026	− 7.5	6.8	3.9	2.9
H	28.6	1.014	−22.5	6.9	3.7	3.2
I	0	1.004	−37.5	7.6	3.4	4.2

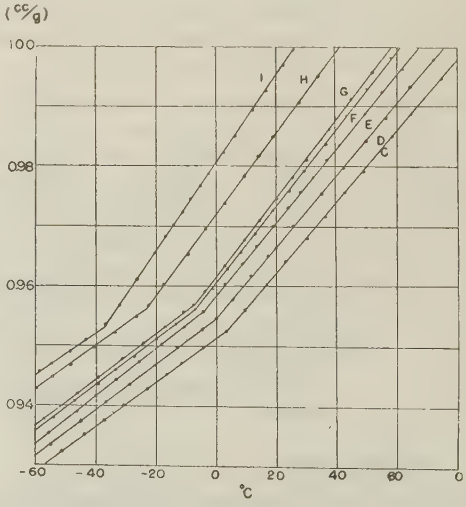

Fig. 1. Cubical thermal expansion of seven kinds of asphalt.

The volume dilatometry was carried out for all the samples. Cubical thermal expansion was determined by placing a specimen in the bulb of a Pyrex-glass dilatometer, surounding it with silicone oil and reading the evel of the oil in the capillary of the dilatoneter as the temperature was lowered. The volume of the dilatomerter bulb was 7.04 cc and the radius of the capillary was 0.633 mm. The temperature range of observation was from 110 down to −60°C and the cooling rate was about 20°C/hour.

The volume-temperature relation of all the samples except A and B shows distinctly a break at a specified temperature, that is, the specific volume continuously varies with temperature, but its slope (thermal expansion coefficient) suddenly decreases below this temperature (Fig. 1). This type of behavior is very widely observed at the glass transition temperature of amorphous polymers and other glass-forming substances. In the case of asphalt also, therefore, the break probably corresponds to the glass transition temperature. In this connection a more positive and convincing discussion will later be given from rheological study.

Anyway, it is clear that the glass transition temperature, so we call here hypothetically, becomes higher with increase of asphaltene content, as is plotted in Fig. 2. Furthermore, one sees that the difference of thermal coefficients above and below the transition temperature, which primarily reflects the "strength" of the transition, decreases with increase of asphaltenes (see Fig. 2) and for the samples A and B, the transition can no more be observed.

The above-mentioned facts suggest some pictures about the glass transition of asphalts. In the transition, linear hydrocarbons, the major component of maltenes, may play a principal role, whereas cyclic hydrocarbons in asphaltenes may have rather a negative influence upon the transition. These considerations will further be discussed and confirmed in the later sections from rheological behaviors above the transition temperature.

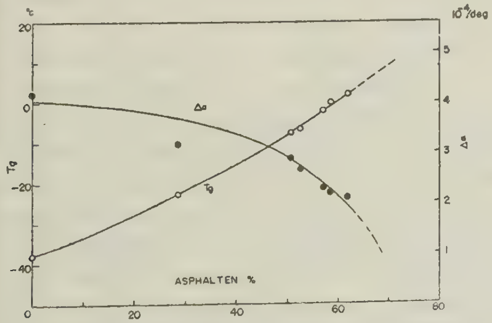

Fig. 2. Glass transition temperature T_g (circle) and difference of thermal expansion coefficient above and below T_g (dot) plotted against asphaltene content.

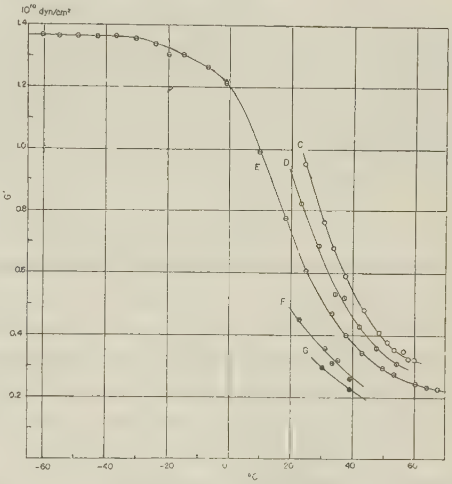

Fig. 3. Real part of complex shear modulus at 33 kc/s *versus* temperature.

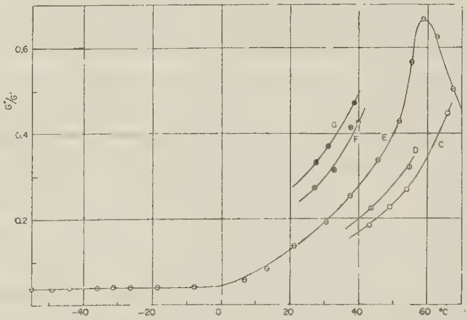

Fig. 4. Loss factor at 33 kc/s *versus* temperature.

§ 4. Complex rigidity of asphalts

The real and imaginary part of complex rigidity were measured at 33 kc/s for samples C through G by means of the composite oscillator method. The details of experimental procedures have been described in a previous paper.[4]

The data are plotted in Figs. 3 & 4, giving typical temperature dispersion curves above the glass transition temperature. One sees in the case of sample E that the storage modulus G′ begins to descend at the transition temperature (−2°C) and, on the other hand, the loss factor G″/G′ begins to rise at this temperature, reaching a maximum at 58°C. The temperature of maximum loss seems to become higher for samples of higher asphaltene content.

No values, according to the authors, have yet been published on the dynamic mechanical properties of asphalt at high frequencies before this work. Dielectric dispersion at frequencies from 50 up to 2×10^6 c/s observed by Saal[5] can only be compared with our data. The temperature region of dispersion observed in both the works very well agrees with each other, when compared at the same frequency.

§ 5. Shear creep compliance measurements

The dynamic test described in the previous section has shown that asphalt is a socalled viscoelastic body. In order to see the overall features of viscoelasticity, it is indispensable to investigate the mechanical properties in as wide a range of times as possible. For this purpose the torsional creep experiment of a specimen in shape of a circular rod was carried out in the present study.

The test specimen was 2.0 cm in length and 0.57 cm in diameter. One end of the specimen was clamped by a fixed chuck, the other end was attached to a rotative chuck which was supported by a ball-bearing. A circular disk of 5.8 cm diameter was fixed to the rotating axis and the torque was applied to the specimen by suspending a weight at the lower end of the thread which was wound around the disk. A small mirror was attached to the disk and the angle of torsion of the specimen after loading was read by a scale and telescope. The whole equipment was set in an air thermostat, whose temperature was regulated within one tenth degree during one run of experiment.

A preliminary test was first made for experimental verification of the proportionality between stress and strain. The curves in Fig. 5 show the plot of torsional deformation for different loads at each time after loading. From the curves we see that, in the measured range of strain at least, the linear relationship between stress and strain holds very well for asphalt. All the experiments in the following, therefore, were made at a constant torque, using a weight of 20 g.

Besides, Fig. 5 gives us another important knowledge. All the straight lines in the figure fall on one point on the abscissa, corresponding to the load of 2.3 g. This value means the frictional force of the bearing, thus the net weight imposed on the specimen was 17.7 g throughout the following study.

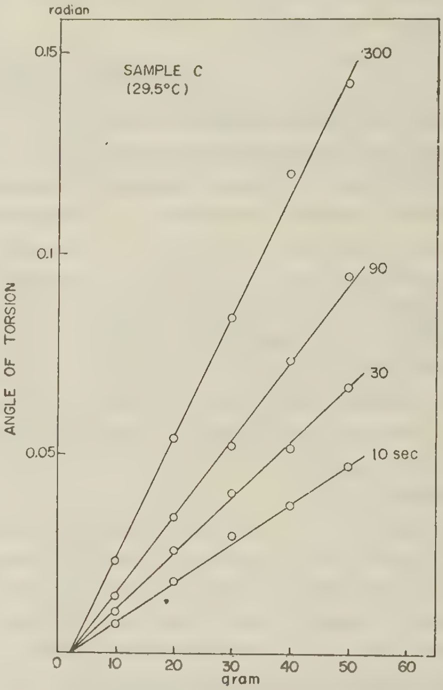

Fig. 5. Torsional creep deformation of sample C for different loads at 29.5°C.

Assuming the linear relationship between stress and strain, the shear creep compliance as a function of time was calculated by

$$J(t)=\frac{\pi r^4}{2l}\cdot\frac{\theta(t)}{N}, \qquad (1)$$

where r and l are the radius and length of the specimen respectively, N the torque, θ the angle of torsion.

Following the above-mentioned procedures, the creep compliance of five samples, C through G, was measured at several temperatures from just above the transition temperature up to about 40°C. The angle of torsion was read from 5 sec to 10 min after loading at appropriate intervals. Fig. 6 illustrates an example of the data over the logarithmic time scale.

In many of the previous investigations on the viscoelasticity of amorphous substances the principle of time-temperature reducibility,[6] developed by Tobolsky, Ferry etc., has been very successfully employed. This principle is founded on the basis that all the retardation times as well as the steady flow viscosity have the same temperature dependence. In the present case also, the creep curves at different temperatures obey very well to this principle. Namely, one can superimpose these curves by a horizontal shift, thus providing a single master curve reduced to an arbitrary reference temperature.

Fig. 7 is the master curve for the sample E reduced to 18°C, the reduced time scale extending from 10^{-3} to 10^{6} sec. In carrying out this reduction, the vertical shift of $J(t)$ was neglected in our case, because, since the temperature range of the data is rather narrow, the vertical shift $T\rho/T_0\rho_0$ would modify only slightly the result and, moreover, the physical meaning of the vertical shift is not *a priori* endent for the asphalt, whose molecular structure is not well understood.

§ 6. Temperature dependence function and activation energy

In the process of determining the master creep curve, the shift factor a_T was evaluated from the amount by which the creep curve at a temperature T was horizontally shifted so as to fit the curve at a reference temperature T_0. Fig. 8 shows the relation between log a_T and temperature for the five samples, T_0 being taken as 20°C.

Since a_T is the factor by which all the re-

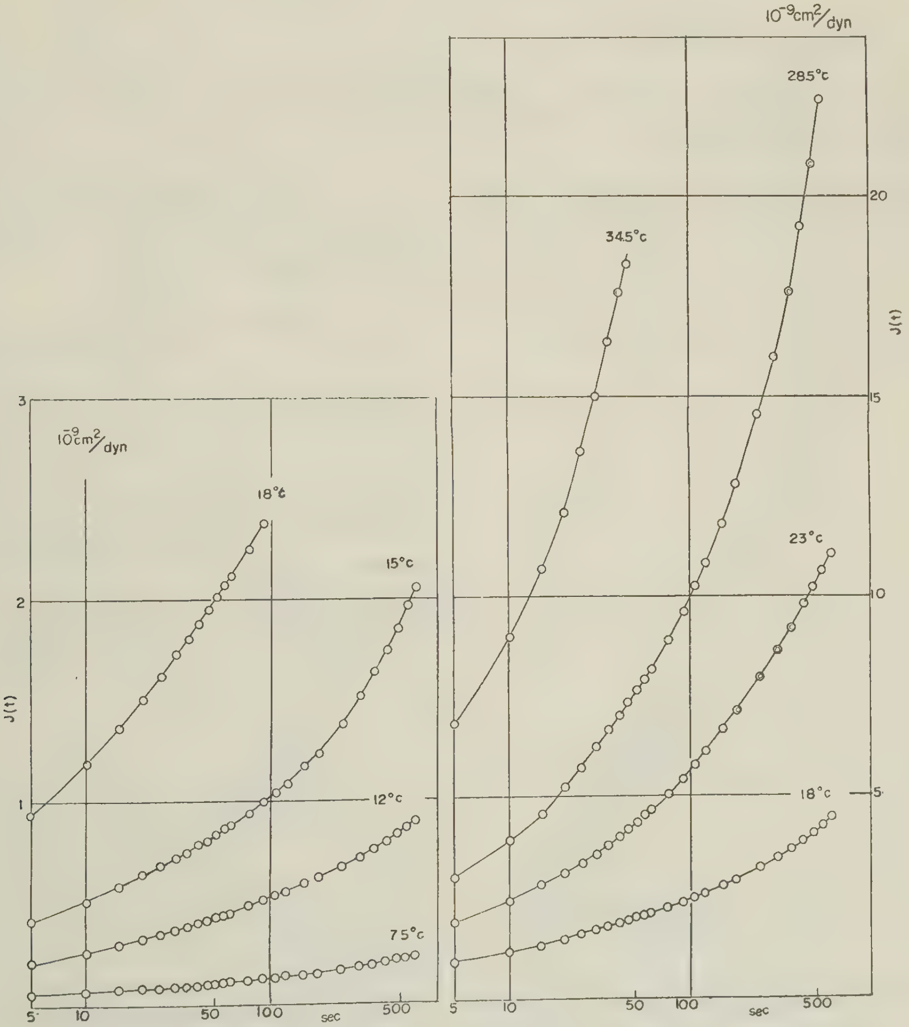

Fig. 6. Creep compliance curves for sample E. Curves below and above 18°C are separately illustrated.

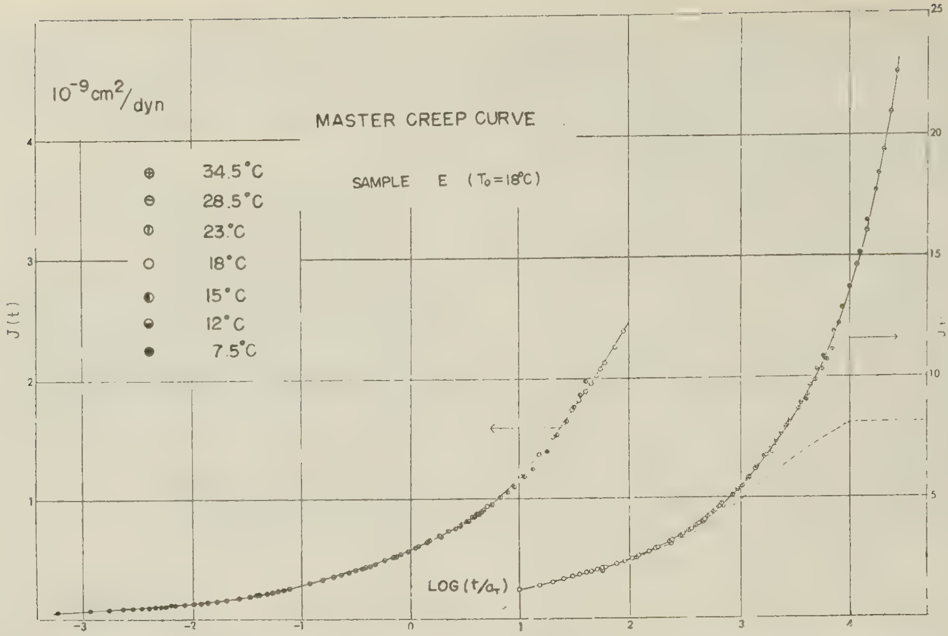

Fig. 7. Master creep compliance for sample E reduced to 18°C, plotted against reduced time (sec). Curve is divided into two portions, each illustrated in different scales. Broken line represents elastic compliance.

tardation times as well as viscosity change when the temperature is changed from T_0 to T, the apparent activation energy H can be expressed by $a_T \infty \exp(H/RT)$, so is calculated by the equation:

$$H = 2.30\,R\,\frac{d(\log a_T)}{d\left(\frac{1}{T}\right)}, \qquad (2)$$

where R is the gas constant and T is absolute temperature. This quantity is plotted in Fig. 9.

Williams, Landel and Ferry have found[7)] that, when the shift factor is reduced to the standard temperature T_s which must be suitably chosen for each substance, the following equation holds to all glass-forming subs-

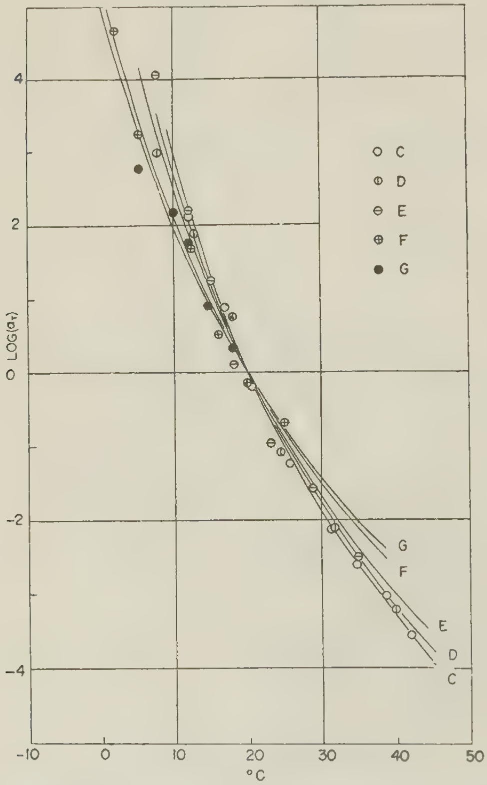

Fig. 8. Shift factor a_T reduced to 20°C for five samples.

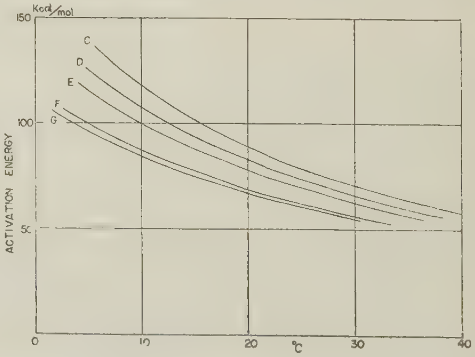

Fig. 9. Apparent activation energy plotted against temperature.

tances ever studied:

$$\log a_T = \frac{-8.86(T-T_s)}{101.6+(T-T_s)} . \qquad (3)$$

Moreover, according to them, T_s is always about 50° higher than the glass transition temperature.

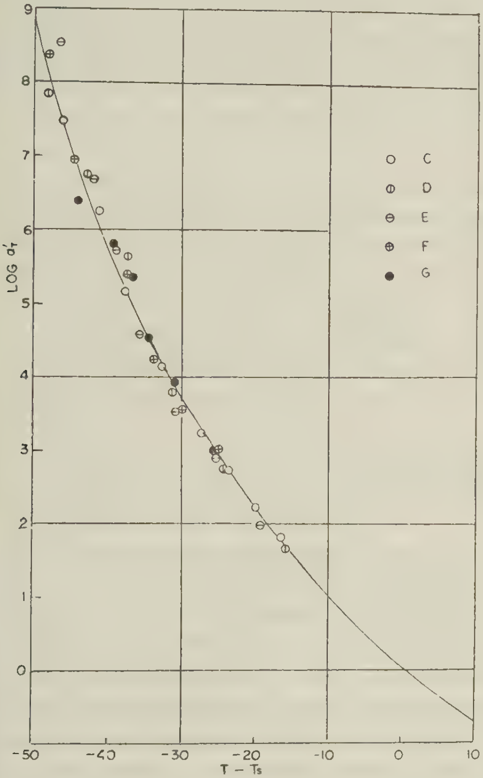

Fig. 10. Temperature dependence of shift factor reduced to standard temperature T_s, which is 56° higher than T_g. Solid line represents Williams-Landel-Ferry's equation.

Fig. 10 shows that Eq. (3) applies very well to asphalt also. T_s was determined by the following procedures: An experimental plot of log a_T (for arbitrary reference temperature) against T is matched to the plot of Eq. (3) with horizontal and vertical translations, using transparent paper, for the best coincidence in shape. T_s can be determined in this manner within ±1°C. The values of T_s thus obtained are listed in Table II. It must be realized that T_s is 56° higher than T_g in Table I for all the samples. This fact offers a clear evidence to the prediction referred in § 3 that the break found in volume-temperature curves should correspond to the glass transition temperature.

§ 7. Steady flow viscosity

The master creep curve, an example of which is shown in Fig. 7, has a linear portion for large values of time when plotted over not logarithmic, but linear time scale (see Fig. 11). Since in this time interval the increase of deformation is only ascribed to viscous flow, the slope of this linear portion is equal to the reciprocal of viscosity. In Table III the viscosity at 20°C is evaluated from the master curves. Viscosities at other temperatures can be obtained from $\eta(T)=\eta(20°\text{C})\,a_T$, using a_T given in Fig. 8. As far as Eq. (3) can be applied, $\eta(T)$ can also be expressed by

Table II.

Sample	T_s(°C)	T_s-T_g
C	58.5	56.5
D	56	56
E	54	56
F	50	56.5
G	49	56.5

Table III. Steady flow viscosity (poise).

Sample	log η(20°C)	Observed viscosity at elevated temperature log η(°C)	Calculated viscosity from Eq. (4) log η(°C)
C	13.15	4.88 (114)	4.64 (114)
D	12.70	4.44 (117)	4.53 (117)
E	12.10	4.02 (110)	4.48 (110)
F	10.45	3.75 (104)	3.65 (104)
G	9.69	3.60 (97)	3.31 (97)

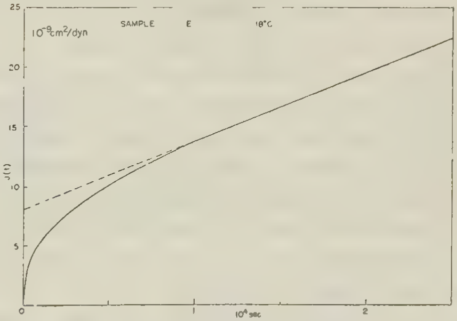

Fig. 11. Master creep compliance for sample E reduced to 18°C plotted in linear time scale.

$$\log \eta(T)=\log \eta(T_s)-\frac{8.86(T-T_s)}{101.6+(T-T_s)}$$
$$=\log \eta(20^\circ\mathrm{C})+\frac{8.86(20-T_s)}{101.6+(20-T_s)}$$
$$-\frac{8.86(T-T_s)}{101.6+(T-T_s)}. \qquad (4)$$

For many glass-forming substances, Eq. (3) has been found approximately valid up to 100 degrees above T_g.[7] This is also the case with asphalt. In Table III the viscosity at elevated temperature, observed by a capillary viscometer, is listed. In this experiment the rate of shear was so small that non-newtonian behaviors were not observed. This values are in fairly good agreement with the calculated ones (see the fourth column in Table 3) from $\eta(20^\circ\mathrm{C})$ using Eq. (4). The agreement is rather surprising, considering that the calculated viscosity is extrapolated from that at 20°C which is higher than the former by the factor of $10^6 \sim 10^9$.

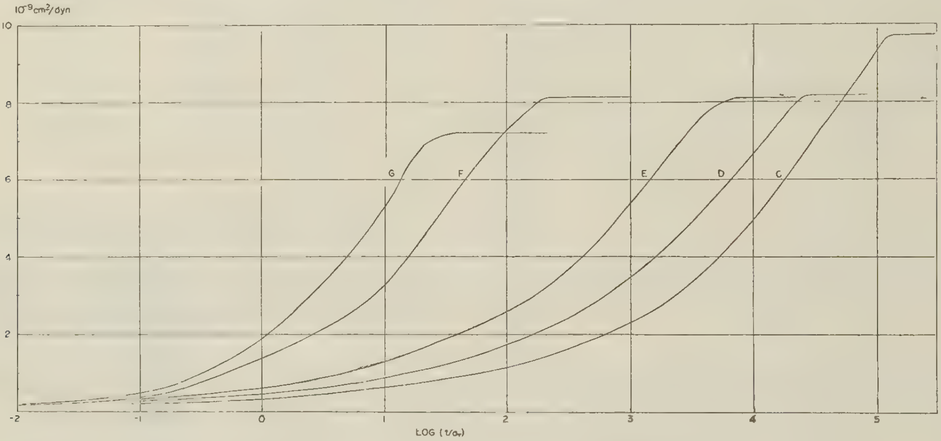

Fig. 12. Elastic compliance reduced to 20°C plotted against reduced time (sec).

§ 8. Retarded elasticity and distribution of retardation times

By substracting viscous flow (t/η) from creep compliance, elastic deformation can be separated out. Since instantaneous elastic compliance is estimated to be less than 10^{-10} cm²/dyn from the rigidity below T_g (see Fig. 3) and gives only a negligible contribution to the total compliance, the elastic part is nearly wholly ascribed to retarded elasticity. This was also experimentally verified by recovery test after creep.

The elastic compliance $J_e(t)$ reduced to 20°C is shown in Fig. 12 for the five samples. Equilibrium elastic compliance $J_e(\infty)$ is about 8×10^{-9} cm²/dyn. From the shape of the curves one sees that they can be expressed by not a single, but multiple retardation times. The distribution function of retardation times can be calculated in a first approximation by the following formula:[8]

$$L(\log \lambda)=0.434\left[\frac{d\,J_e(t)}{d\log t}\right]_{t=\lambda}. \qquad (5)$$

The function $L(\log \lambda)$ reduced to 20°C is illustrated in Fig. 13 in logarithmic scales.

As is readily seen, the function for all the samples is of a wedge shape, that is, log L linearly increases with log λ up to the maximum retardation time and suddenly falls off. The slope of wedge is 0.5 for F and G, and less for C, D and E. It must be noticed here that the distribution function of a wedge

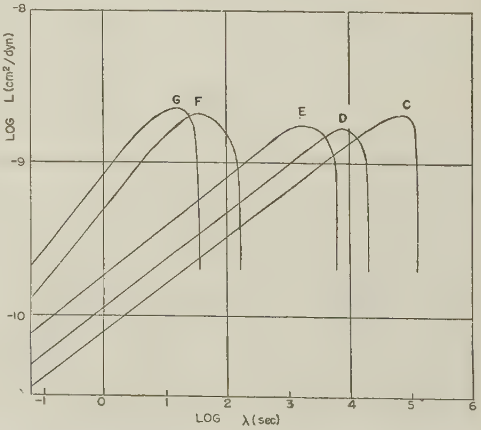

Fig. 13. Distribution function of retardation times reduced to 20°C.

shape is widely observed for linear amorphous polymers above glass transition temperature.[9]

§ 9. Discussions

Summarizing the results, it follows:

(1) Asphalt exhibits glass transition temperature T_g. T_g becomes higher with increase of asphaltene content X. The intensity of transition decreases with increase of X and the transition disappears for X more than 70%.

(2) Above T_g asphalt is viscoelastic. Dynamic loss peak is observed in this region. The temperature of maximum loss becomes higher with increase of X.

(3) The temperature dependence of steady flow viscosity as well as retardation times obeys Williams-Landel-Ferry's equation, when the standard temperature is taken 56° higher than T_g.

(4) The viscosity and maximum retardation time at a given temperature, say at 20°C, markedly increase with X.

(5) The equilibrium elastic compliance and peak intensity of distribution function of retardation times are rather insensitive to X, being about 8×10^{-9} cm²/dyn and 2×10^{-9} cm²/dyn respectively.

(6) The distribution function of retardation times are, when plotted in logarithmic scales, of a wedge shape, the slope being 0.5 for the samples of low X, but less for high X.

From all of these experimental facts, we may deduce some conclusions about the molecular structures of asphalt. From the above facts we can safely conclude that linear hydrocarbons, the major component of maltenes, play the chief role in the glass transition and the mechanical dispersion phenomena accompanied with it, whereas cyclic molecules in asphaltenes perhaps may have rather hindering effect on the brownian motion of linear molecules.

A recent theory of Rouse[10] for the viscoelastic properties of isolated chain molecules predicts that the distribution function of retardation times should be of a wedge shape with the slope of 0.5. The same slope is predicted for a network chain structure from the extension of this theory.[11] In fact, all the amorphous linear polymers have the distribution function of this type above T_g. Since the same behavior is observed in the present case, it may be reasonably said that linear molecules in asphalt form a network structure and the retarded elasticity may be ascribed to microbrownian motions of chain segments between temporary crosslinking points.

A remark, however, must be here noted. Strictly speaking, since the average molecular weight of asphalt is several hundreds[3], molecules in asphalt can only approximately form such a network assumed in the Rouse theory, in which a chain is considered to consist of many submolecules, portions of polymer chain long enough for the separation of their ends to approximate a Gaussian probability distribution. But it may not be unreasonable, as a first step of approach, to assume a network structure in asphalt.

Cyclic molecules may get in the space among the network and disturb its thermal motion. It is not impossible to assume, according to many colloid-chemical studies of asphalt,[3] that cyclic molecules may be in an associated state. Of course, some of the cyclic molecules may form the network together with linear molecules and increase the stiffness of chain.

According to the statistical theory[12] of a network structure, equilibrium elastic compliance $J_e(\infty)$ is written as

$$J_e(\infty)=\frac{M}{\rho RT}\,, \tag{6}$$

where M is the molecular weight of a chain segment between two crosslinks, ρ the density of segment, R the gas constant, T the absolute temperature. Using the observed value of $J_e(\infty)=8\times10^{-9}$ cm²/dyn and assuming $\rho=0.5$ g/cc (ρ is not the density of asphalt as a whole, but of network-forming components only), we get $M=100$. This value is very reasonable compared with the average molecular weight of asphalt.

In conclusion, it is to be hoped that a knowledge of not only viscoelastic properties, but also dielectric dispersion, nuclear magnetic resonance etc. might allow a more precise picture of molecular behaviors in asphalt.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 10, OCTOBER, 1960

On the Flow of An Electrically Conducting Fluid Near An Accelerated Plate in the Presence of a Magnetic Field

By A. S. GUPTA

Department of Applied Mathematics, Indian Institute of Technology, Kharagpur, India.

(Received May 17, 1960)

The flow of an electrically conducting viscous incompressible fluid due to uniformly accelerated motion of an infinite flat plate is discussed. A uniform magnetic field fixed relative to the fluid is supposed to be present. It is found that when the induced field is negligible compared to the imposed field, velocity at any point and at any instant decreases with the increase in the magnetic field strength. It is further shown that the increase in magnetic field results in an increase in the drag suffered by the plate.

§ 1. Introduction

The magnetohydrodynamics of the flow of a viscous, incompressible and electrically conducting fluid in the presence of an external magnetic field due to the impulsive motion of an infinite flat plate has been discussed by Rossow[1)]. Recently Ong and Nicholls[2)] have extended the problem to cover the case of the flow near an infinite wall which executes simple harmonic motion parallel to itself. In both the problems, however, the induced magnetic field produced by the current has been neglected. Kakutani[3)] has included this induced field while considering the flow of a hydromagnetic fluid in the presence of an oscillating flat plate.

In this paper the flow of an electrically conducting viscous incompressible fluid due to the accelerated motion of an infinite flat plate in the presence of a uniform magnetic field is discussed. The induced magnetic field is neglected as in the case of previous workers. The velocity profile is found in the case when the magnetic lines of force are fixed relative to the fluid and finally the skin friction is calculated.

§ 2. Basic Equations and their Solutions.

Let x denote the coordinate parallel to the direction of motion of the plate and y the coordinate perpendicular to it. At time $t<0$, the fluid and the plate are assumed to be at rest. The plate starts moving at $t=0$. A uniform magnetic field B_0 fixed relative to the fluid is acting along y-axis. The equations of hydromagnetics are:

a) Maxwell's equations (neglecting displacement current)

$$\text{Curl}\,\vec{H}=4\pi\vec{j} \qquad (1)$$

$$\text{Curl}\,\vec{E}=-\frac{\partial\vec{B}}{\partial t} \qquad (2)$$

$$\text{div}\,\vec{B}=0 \qquad (3)$$

$$\vec{B}=\mu_e\vec{H} \qquad (4)$$

b) Ohm's law:

$$\vec{B}=\mu_e\vec{H} \qquad (5)$$

c) The equation of continuity for the fluid:

$$\text{div}\,\vec{q}=0 \qquad (6)$$

d) The modified Navier-Stokes equation:

$$\frac{\partial\vec{q}}{\partial t}+(\vec{q}\cdot\text{grad})\vec{q}=-\frac{1}{\rho}\,\text{grad}\,\rho+\nu\nabla^2\vec{q}+\frac{1}{\rho}\,\vec{j}\times\vec{B} \qquad (7)$$

Where $\vec{E}$ is the electric field, $\vec{B}$ the electromagnetic induction, $\vec{H}$ the magnetic field, μ_e the magnetic permeability, σ the electrical conductivity, $\vec{q}$ the velocity of the fluid. All electromagnetic quantities are measured in electromagnetic units.

In the present problem it is assumed following Meyer[4)] that no applied or polarization voltages exist. i.e., $\vec{E}=0$. This then corresponds to the case where no energy is being added or extracted from the fluid by the electrical means. The magnetic effects are confined to retarding the flow and dissipating energy of motion into heat. Since the plate is infinite, the physical variables will depend on y (the distance from the plate) and t only. Hence if $\vec{q}\equiv(u, v)$ eqn. (6) gives $\partial v/\partial y=0$. This by virtue of the fact that $v=0$ at the plate, gives

$$v=0 \qquad (8)$$

everywhere.

In general, the electrical current flowing in the fluid gives rise to an induced magnetic field which distorts the applied magnetic field, which would exist if the fluid were an electrical insulator. However, since the viscous boundary layer is thin and thermally ionized air is at best a poor electrical conductor it is permissible to neglect the induced field compared to the applied field acting along y-axis. This permits the following simplification for $\vec{B}\equiv(B_x, B_y)$:

$$B_x=0;\quad B_y=\text{Constant}=B_0 \qquad (9)$$

These clearly satisfy eqn. (3). Using eqn. (5) (with $\vec{E}=0$), (8) and (9), the ponderomotive force $\vec{F}=\vec{j}\times\vec{B}/\rho$ in (7) will have the following components

$$F_x=\frac{-\sigma B_0{}^2u}{\rho};\quad F_y=0 \qquad (10)$$

Eqn. (7) now gives with $\vec{q}=(u(y,t), 0)$,

$$\frac{\partial u}{\partial t}=\nu\frac{\partial^2u}{\partial y^2}-\frac{\sigma B_0{}^2u}{\rho} \qquad (11)$$

$$0=-\frac{1}{\rho}\frac{\partial p}{\partial y} \qquad (12)$$

Eqn. (12) gives

$$p=\text{constant} \qquad (13)$$

Eqn. (11) is to be solved subject to the following conditions:

$$u=0 \text{ everywhere for } t<0 \qquad (14)$$

$$\left.\begin{array}{l} u=At^n \text{ at } y=0,\quad t>0 \\ u=0 \text{ or finite at } y=\infty,\quad t>0 \end{array}\right\} \qquad (15)$$

The Laplace transform of (11) with respect to t together with eqn. (14), gives

$$\nu\frac{d^2\bar{u}}{dy^2}-(p+m)\bar{u}=0 \qquad (16)$$

where

$$\bar{u}=\int_0^\infty u(y_1t)e^{-pt}dt,\quad (p>0);\quad m=\frac{\sigma B_0{}^2}{\rho}. \qquad (17)$$

The solution of (16) is

$$\bar{u}=C_1\exp\left[-y\{(p+m)/\nu\}^{1/2}\right]+C_2\exp\left[y\{(p+m)/\nu\}^{1/2}\right] \qquad (18)$$

Eqn. (15) gives

$$\bar{u}=\frac{A\Gamma(n+1)}{p^{n+1}} \text{ at } y=0$$

and $u=0$ or finite at $y=\infty$

Using these conditions, eqn. (18) gives

$$\bar{u}=\frac{A\Gamma(n+1)}{p^{n+1}}\exp\left[-y\{(p+m)/\nu\}^{1/2}\right] \tag{19}$$

Hence

$$u(y,t)=\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}e^{pt}\,\bar{u}(y,p)dp$$

$$=\frac{A\Gamma(n+1)}{2\pi i}\int_{c-i\infty}^{c+i\infty}\frac{e^{pt}}{p^{n+1}}\cdot\exp\left[-y\{(p+m)/\nu\}^{1/2}\right]dp \tag{20}$$

For a uniformly accelerated plate $n=1$, so that eqn. (20) gives

$$u(y,t)=\frac{A}{2\pi i}\int_{c-i\infty}^{c+i\infty}\frac{e^{pt-b\sqrt{p+a^2}}}{p^2}dp \tag{21}$$

where

$$b=\frac{y}{\sqrt{\nu}};\quad a^2=m \tag{22}$$

Putting $p+a^2=v^2$, eqn. (21) gives

$$u(y,t)=\frac{Ae^{-a^2t}}{\pi i}\int_{Br_3}\frac{e^{v^2t-bv}}{(v^2-a^2)^2}v\,dv$$

$$=\frac{Ae^{-a^2t}}{\pi i}\,\frac{1}{4a}\int_{Br_3}e^{v^2t-bv}\left[\frac{1}{(v-a)^2}-\frac{1}{(v+a)^2}\right]dv, \tag{23}$$

where Br_3 is the Bromwich path defined in McLachlahn[5].

Integrating along Br_3, we have

$$\frac{1}{\pi i}\int_{Br_3}\frac{e^{v^2t-bv}}{v-a}dv=e^{a^2t-ab}\,.\ \operatorname{erfc}\frac{b-2at}{2\sqrt{t}} \tag{24}$$

and

$$\frac{1}{\pi i}\int_{Br_3}\frac{e^{v^2t-bv}}{v+a}dv=e^{a^2t+ab}\,.\ \operatorname{erfc}\frac{b+2at}{2\sqrt{t}}. \tag{25}$$

Differentiating equns. (24) and (25) with respect to a under integral sign and substituting in (23), we get

$$u(y,t)=\frac{A}{4a}\Bigg[e^{-ab}\left\{(2at-b)\operatorname{erfc}\frac{b-2at}{2\sqrt{t}}+2\sqrt{\frac{t}{\pi}}\,.\ e^{-\frac{(b-2at)^2}{4t}}\right\}$$
$$+e^{ab}\left\{(2at+b)\operatorname{erfc}\frac{b+2at}{2\sqrt{t}}-2\sqrt{\frac{t}{\pi}}.\ e^{-\frac{(b+2at)^2}{4t}}\right\}\Bigg] \tag{26}$$

which gives the velocity distribution.

For $n=2$,

$$u(y,t)=\frac{A}{2\pi i}\int_{C-i\infty}^{C+i\infty}\frac{e^{pt-b\sqrt{p+a^2}}}{p^3}dp$$

This gives on putting $p+a^2=v^2$ as before,

$$u(y,t)=\frac{Ae^{-a^2t}}{\pi i}\int_{Br_3}\frac{e^{(v^2t-bv)}v}{(v^2-a^2)^2}dv$$

$$=\frac{Ae^{-a^2t}}{8a^2\cdot\pi i}\int\!\!\int_{Br_3}\left[\frac{1}{(v-a)^3}+\frac{1}{(v+a)^3}+\frac{1}{2a}\cdot\frac{1}{(v+a)^2}-\frac{1}{2a}\cdot\frac{1}{(v-a)^2}\right]dv \tag{27}$$

Differentiating eqn. (24) and (25) twice with respect to a under integral sign and substituting in eqn. (27), we get after a lengthy calculation,

$$u(y,t)=\frac{A}{16a^3}\Bigg[e^{-ab}\Big\{(3a^3t^2-4a^2bt+ab^2+b)\operatorname{erfc}\frac{b-2at}{2\sqrt{t}}+\sqrt{\frac{t}{\pi}}\cdot(4a^2t-2ab-2)$$
$$e^{-\frac{(b-2at)^2}{4t}}+e^{ab}\Big\{(4a^3t^2+4a^2bt+ab^2-b)$$
$$\operatorname{erfc}\frac{b+2at}{2\sqrt{t}}-\sqrt{\frac{t}{\pi}}(4a^2t+2ab-2).\ e^{-\frac{(b+2at)^2}{4t}}\Big\}\Bigg] \tag{28}$$

This method can be generalised to calculate $u(y,t)$ from (20) for any positive integral value of n.

Substituting the values of b and a from eqn. (22) in eqn. (26), we get

$$u(y,t)=\frac{A}{4a}\Bigg[e^{-y\sqrt{\frac{m}{\nu}}}\left\{\left(2\sqrt{m}t-\frac{y}{\sqrt{\nu}}\right)\operatorname{erfc}\frac{\frac{y}{\sqrt{\nu}}-2\sqrt{m}t}{2\sqrt{t}}+2\sqrt{\frac{t}{\pi}}e^{-\left(\frac{y}{\sqrt{\nu}}-2\sqrt{m}t\right)^2\Big/4t}\right\}$$
$$+e^{y\sqrt{\frac{m}{\nu}}}\left\{\left((2\sqrt{m}t+\frac{y}{\sqrt{\nu}}\right)\operatorname{erfc}\frac{\frac{y}{\sqrt{\nu}}+2\sqrt{m}t}{2\sqrt{t}}-2\sqrt{\frac{t}{\pi}}e^{-\frac{\left(\frac{y}{\sqrt{\nu}}+2\sqrt{m}t\right)^2}{4t}}\right\}\Bigg] \tag{29}$$

Introducing the non-dimensional variables

$$\Phi(\eta,a_0)=\frac{4u(y,t)}{At};\quad \eta=\frac{y}{\sqrt{\nu t}};\quad a_0=\sqrt{m}t \tag{30}$$

eqn. (29) can be written as

$$\Phi(\eta,a_0)=\frac{1}{a_0}\Bigg[e^{-a_0\eta}\left\{(2a_0-\eta)\operatorname{erfc}\frac{\eta-2a_0}{2}+\frac{2}{\sqrt{\pi}}e^{\frac{-(\eta-2\alpha_0)^2}{4}}\right\}$$
$$+e^{a_0\eta}\left\{(2a_0+\eta)\operatorname{erfc}\frac{\eta+2a_0}{2}-\frac{2}{\sqrt{\pi}}e^{\frac{-(\eta+2\alpha_0)^2}{4}}\right\}\Bigg] \tag{31}$$

It may be noted that $a_0=\sqrt{t\sigma B_0^2/\rho}$ may be looked upon as the non-dimensional Hartman's number in the unsteady motion. A graph is drawn showing the variation of $\Phi(\eta, a_0)$ with η for different values of a_0. It follows from the graph that for a fixed t, velocity at any point in the fluid decreases with increase in a_0 i.e. the magnetic field strength. This is to be expected physically for the effect of magnetic field is to bring about a certain amount of "stiffness" in the fluid resulting in a consequent decrease in the velocity of the fluid.

§ 3. Determination of the skin Friction.

Skin-friction is given by

$$\tau_\omega=-\mu\left(\frac{\partial u}{\partial y}\right)_{y=0}$$

$$=\mu\cdot\frac{At}{4a_0}\cdot\frac{d}{d\eta}\left[e^{-a_0\eta}\cdot\left\{(2a_0-\eta)\,erfc\,\frac{\eta-2a_0}{2}+\frac{2}{\sqrt{\pi}}e^{\frac{-(\eta-2\alpha_0)^2}{4}}\right\}+e^{a_0\eta}\left\{(2a_0+\eta)\,erfc\,\frac{\eta+2a_0}{2}-\frac{2}{\sqrt{\pi}}a_0e^{-a_0^2}\right]$$

This gives after using $\eta=y/\sqrt{\nu t}$

$$\tau_\omega=\frac{\mu A\sqrt{t}}{2a_0}\cdot\left[(2a_0^2+1)erfc\;a_0+\frac{2}{\sqrt{\pi}}a_0e^{-a_0^2}\right] \tag{32}$$

Introducing the drag-coefficient τ_ω^* defined by

$$\tau_\omega^*=\frac{2\tau_\omega}{\mu A}\sqrt{\frac{\nu}{t}}\,, \tag{33}$$

$$\tau_\omega^*=\left(2a_0+\frac{1}{a_0}\right)erfc\;a_0+\frac{2}{\sqrt{\pi}}e^{-a_0^2} \tag{34}$$

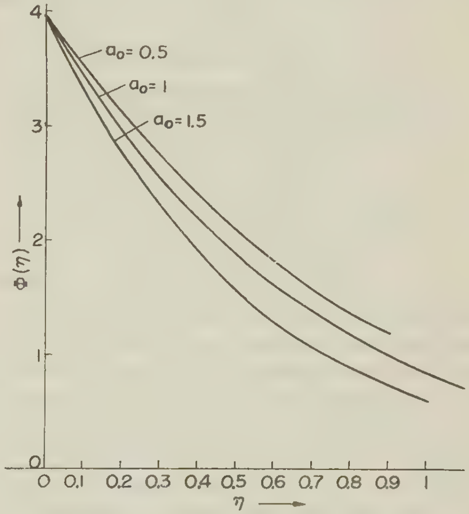
The following table shows the variation of τ_ω^* for different values of a_0.

a_0	τ_ω^*	a_0	τ_ω^*
.1	2.259	.7	2.606
.2	2.288	.8	2.710
.3	2.325	.9	2.821
.4	2.374	1.0	2.944
.5	2.438	1.5	3 661
.6	2.519	2.0	4.499

§ 4. Discussion.

The fact that the drag increases with the increase in the magnetic field is due to the following physical considerations.

Because of the motion of the fluid in the magnetic field, an associated electrical field is produced, which according to Ohm's law, sets up electrical currents in the fluid if the latter be a conductor. The interaction of these currents with the magnetic field then produces a body force which must be included in the Navier-Stokes equations for the motion of the fluid. The effect of this body force is to inhibit the motion of the fluid across the lines of force. The natural tendency of the fluid to move along the plate is opposed resulting in an increase in drag.



I thank Dr. G. Bandyopadhyay for some helpful suggestions in the preparation of this paper.

Time Decrease of Permeability of Substitutional Ferromagnetic Alloys

By Chinji KURODA

Electrical Communication Laboratory
Nippon Telegraph and Telephone Public Corporation
1551, Kichijoji, Musashino-shi, Tokyo, Japan

(Received July 8, 1960)

Decrease of permeability with time after the demagnetization by alternating current is known under the name of disaccommodation (D.A.). It has been proved that D.A. of α-iron is caused by the diffusion of C or N atoms in the interstitial sites. On the other hand, when the substitutional ferromagnetic alloys, which are constituted of Fe, Co, Ni and others, are heat-treated in magnetic field, their magnetic properties are changed more or less. This is well explained by the formation of directional order which can be realized by the diffusion of the elements[1]. Then we can expect that these substitutional alloys also exhibit a magnetic aftereffect at elevated temperatures.[2] Conversely, we can investigate the kinetics of directional ordering by means of the measurements on magnetic aftereffects of permeability.

From this point of view, D.A. of Ni-Co alloys was observed. The specimens whose dimension is 0.2 m/m×7 m/m×300 m/m were obtained by melting the electrolytic Ni and Co in vacuum and cold-rolling. D.A. was measured with a sinusoidal magnetic field of 160 c/s whose amplitude was 0.039 œ. The induced voltages in the secondary coil, after amplified and rectified, were recorded as the permeability. Prior to the measurement of D.A., the specimen was heated to 900°C and maintained for one hour at that temperature, then cooled in magnetic fields of 30 œ to the temperature, at which we could make the measurement, and again maintained for about one hour. The heat-treatments and measurements were done all in dry hydrogen atmospheres. Because of the cooling in a magnetic field, the change of directional order after demagnetization may be supposed to occur almost in 180°-walls.

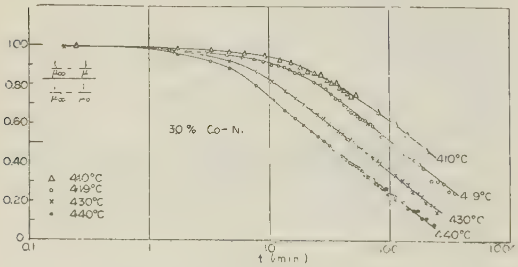

Fig. 1. D.A. of 30% Co-Ni alloy after cooling to the measuring temperature in 30 œrsteds. Ordinate represents $(1/\mu_\infty - 1/\mu)/(1/\mu_\infty - 1/\mu_0)$.

Fig. 1, where ordinate corresponds to $(-1/\mu)$, shows the D.A. at various temperatures. These curves cannot be explained in terms of single relaxation time but present the distinct linear part with $\log t$. According to the representation due to Néel's calculation[3], in which the logarithmic distribution of the relaxation time, τ, was assumed, the ratio of $\tau_{\max}$ to $\tau_{\min}$ could be obtained as about 135 from the linear part for all temperatures of the measurements. Also, activation energy, ca. 2.5 e.v., was obtained from the dependency on temperature of relaxation times. This value agrees with the activation energy obtained by Yamamoto et al.[4] in the case of induced anisotropy energy measured at room temperature after cooling in magnetic field for the alloy of same composition.

From these experimental results, we find out that also for the substitutional alloys in which the number of diffusable atoms is great, the magnetic aftereffect may be described on the assumption of logarithmic distribution of relaxation time. However, the width of distribution in these cases is much broader than in the case of α-iron, in which the ratio is ca. 30[5], although the magnetic structures are simpler due to the cooling in a field. In order to explain this width, it may be necessary to take in the interactions of atoms that migrate under various situations.

We also investigated this alloy with the Co contents from 40% to 70%. Detailed results will be reported later.

The Effect of Cation Vacancies on the Magnetic Annealing of $Co_xFe_{3-x}O_4$

By Tohru INOUE, Hiroshi MIZUTA* and Shūichi IIDA

Department of Physics, Faculty of Science, University of Tokyo

(Received June 3, 1960)

It has been shown experimentally by Iida et al[1] that, in iron cobalt ferrites, the magnitudes of the unixial anisotropy induced by the cooling in a magnetic field depend essentially on the degree of oxidation of the specimens. A postulate has also been presented by them that directional configuration among Co^{++}, Fe^{++}, Fe^{+++} and cation vacancies might play an essential rôle in this phenomenon. On the other hand, Bickford et al[2] have obtained a series of remarkable results for the cobalt poor specimens in highly oxidized states, which can be explained by assuming that the induced anisotropy in these specimens comes from the preferential occupation of Co^{++} ions among four different sites of 16*d* lattice points. Based upon this result they have suggested that, the role of cation vacancies might be only to make the movement of cations easy at high temperatures. In contrast with this suggestion, however, the further experiment made by them[3] for reduced specimens rather shows that the magnitude depends upon the vacancy concentration. Therefore it has become uncertain whether the amount of cation vacancies influences the final equilibrium magnitude of the uniaxial anisotropy or not.

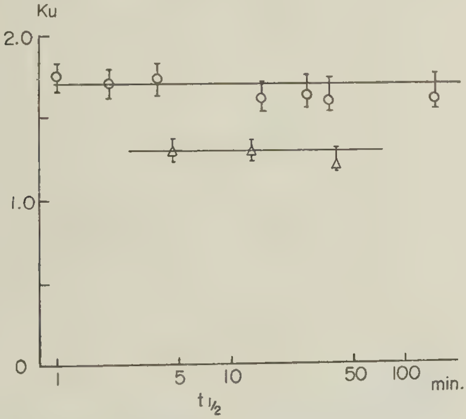

Fig. 1. Relation between final magnitude of anneal induced anisotropy Ku and relaxation time $t_{1/2}$. It should be noticed that the range of permissible errors is not equal for plus and minus side. This is due to the experimental condition of each measurement.
○: $Ku\times10^{-4}$ erg/gr $x=0.063$ $T=100°C$
△: $Ku\times10^{-5}$ erg/gr $x=0.5$ $T=143°C$

Polycrystalline $Co_xFe_{3-x}O_4$ specimens containing cation vacancies in various concentrations were made and the final magnitude of the anneal-induced anisotropy Ku and the relaxation time $t_{1/2}$ (the time at which Ku becomes one half of the initial value) were measured at high temperatures by a torque meter[1]. Special care was taken in order to control and homogenize the concentration of cation vacancies. Adequate reduction of the specimen was made by heat treating each specimen sealed in a small quartz container with a little amount of metallic iron as a reducer. Magnetic measurements were also made with the specimen in the sealed state. It should be emphasized that before measurements each specimen was always annealed at 600~800°C for about two days.

The results for two typical compositions are shown in Fig. 1. As is shown clearly, the final magnitudes of the unixial anisotropy do not depend on the change of the relaxation time of the specimens. Although analysis of the cation vacancy content of each specimen has not yet been performed, the relaxation time observed is considered to be inversely proportional to the density of vacancies in a certain range of the density (this is inferred from a recent stochastic and the statistical thermodynamical analysis)[4],[5]. Therefore, it can be concluded that although the amount of cation vacancies present influences the rate of cation migration very much, it does not affect the final magnitudes of the induced anisotropy, in accordance with the suggestion made by Bickford et al. We believe that this conclusion is hold for the entire range of $Co_xFe_{3-x}O_4$.

From this result it is presumed that, in the case of Bickford et al, the homogeneity of specimens has not been enough. It should be remarked that in our case of $x=0.063$, the homogeneity of the specimens is guaranteed further by the single relaxation time character of all relaxation curves observed.

Observations were also made with specimens which had been reduced severely. The relaxation time increases very much and the measurements could only be made at high temperatures (400~550°C). Moreover, the activation energies calculated are quite different from that of oxidized specimens. It is suggested that the cation migration in this case is taking place by a different diffusion mechanism (interstitialcy diffusion).

Colour Center and Gaseous Ions Produced in High Frequency Spark between the Electrodes of Semi-metals, Metal Elements, and Ionic-crystals

By Toshiyoshi Yuasa

Department of Chemistry, School of General Studies, Kyoto University, Kyoto

(Received May 17, 1960)

A double focusing Mattauch-type mass spectrometer with a high-frequency spark ion source was used here. Hintenberger[1], by using the same kinds of apparatus as the author's, has already found the lines of C molecule ions from C_2^+ to C_{28}^+ in the spark between graphite electrodes. However, the mechanism of production of molecular ions is not clear yet. To find out what kinds of electrode elements are capable of producing such molecular ions, experiments were performed by the author in the following way. The material to be examined was prepared in the form of rods. Two such rods were required for each sample and were mounted in the spark ionization source with their tips apart and directly. The source was evacuated and, when the pressure has fallen to about 2×10^{-6} mmHg, a spark voltage was applied to the sample rods. The mass spectrum was recorded on a Ilford Q-II photographic plate.

The experimental results obtained were as shown in Table I. Table I shows that their singly-charged poly-atomic molecular ions are produced for only the semi-metallic samples. When the samples of alkali-halide single crystal were taken out from spark source after examination, it was observed that the crystals were held in their shape and moreover colour centers were formed finely; yellow for NaCl, yellowish brown for LiF, and cobalt blue for KBr. More detailed studies will be reported later.

Magnetic Transition in $TiCl_3$

By Shinji Ogawa

Research Institute of Applied Electricity,
Hokkaido University, Sapporo

(Received July 8, 1960)

The nature of the magnetic transition in oxides of titanium and vanadium has been recently discussed by Carr and Foner[1], and Goodenough[2] has pointed out an importance of a direct cation-cation interaction in the ionic crystals which contain the transition metal ions having less-than-half d electrons.

A magnetic transition of similar nature has been observed in $TiCl_3$. Two different results of the magnetic susceptibility of polycrystalline $TiCl_3$ have been reported by Starr, Bitter and Kaufmann[3] and by Klemm and Krose[4]. Our measurement shown in Fig. 1 is in good agreement with the latter's.

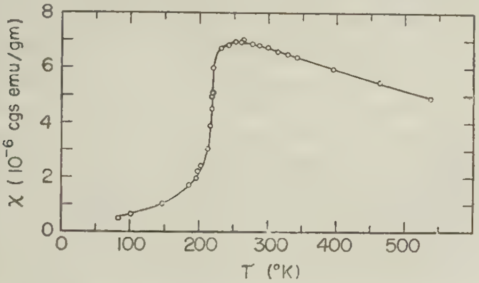

Fig. 1. The magnetic susceptibility of polycrystalline $TiCl_3$.

It was tried to measure the magnetic torque of a small single crystal of hexagonal plate-like shape which had grown up in preparing $TiCl_3$ by the method of reducing $TiCl_4$ with H_2 gas[4], but the amplitude of torque was so small that it could not be measured with the torque magnetometer used. However, the difference between $\chi_{\parallel}$ and $\chi_{\perp}$, the magnetic susceptibilities parallel and perpendicular to the c-axis*, has been estimated to be less than 3×10^{-7} cgs emu/gm in the range of temperature from 77° to 370°K. Combining both results, it is concluded that both $\chi_{\parallel}$ and $\chi_{\perp}$ decreases abruptly at the transition temperature, $T_t=217°\pm2°K$, in contrast to normal antiferromagnetic substances. This anomalous transition suggests a possibility of a lattice distortion at T_t[5]. An X-ray measurement was therefore made. Powder patterns were recorded on a Norelco diffractometer using a copper radiation. The room temperature pattern is in good agreement with that in literature[6], except a slight difference in lattice constants. At T_t, a change in lattice symmetry was not found, although its possibility was not denied because of the broadening of diffraction lines below T_t. However, the lattice spacings changed rather abruptly at T_t. The lattice constants a and c determined from the (30.0) and (00.12) lines respectively are plotted against temperature in Fig. 2. At T_t, the lattice contraction in the plane perpendicular to the c-axis is so large that the expansion in the c-direction cannot prevent a volume contraction.

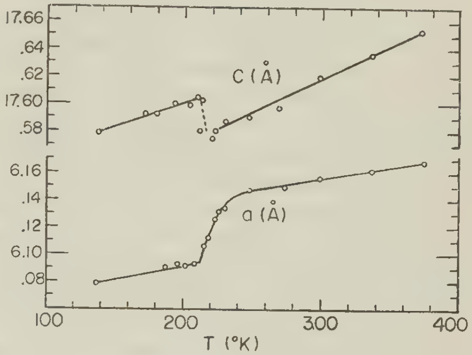

Fig. 2. The temperature dependence of lattice constants a and c.

Ti^{3+} ions in $TiCl_3$ crystal form a honeycomb lattice in the plane perpendicular to the c-axis and each lattice plane is separated from the next plane with intervening two hexagonal lattice planes of Cl^- ions. The observed lattice distortion suggests a formation of the bonding among Ti^{3+} ions in the plane perpendicular to the c-axis below T_t, favoring the model proposed by Goodenough[2]. A long-range antiferromagnetic ordering below T_t is doubtful. An examination by means of neutron diffraction is desired.

The author would like to thank Professor Y. Yokozawa for his continuous interest.

On "Screened Impurity Potentials in Metals"

by Ralph J. HARRISON and Arthur PASKIN

Materials Research Laboratory, Ordnance Materials Research Office, Watertown, Massachusetts, U.S.A.

(Received July 6, 1960)

Takimoto[1] has recently derived an expression for the Fourier transform of the screened impurity potential in a cloud of conduction electrons. This expression agrees with that obtained by Silverman and Weiss[2], Langer and Vosko[3] and Izuyama[4]. McIrvine[5] has made an examination of the spatial form of the screened potential obtained by integration of Takimoto's expression for the Fourier transform. McIrvine showed that for one limiting range of values of the screening parameter the integrand has poles on the imaginary axis which contribute an exponentially screened term of the customary Thomas-Fermi (T-F) form. For another range of values of the screening parameter there are complex poles which give rise to an exponentially damped oscillatory term. McIrvine did not consider, however, the contribution to the integral arising from the logarithmic singularity of the integrand in the region $\kappa=2k_0$, where κ is the magnitude of the wave vector in transform space and k_0 is the absolute value of the Fermi wave vector. The importance of this region was pointed out by Langer and Vosko[3]. The second derivative of the integrand has a real pole here which gives rise to an undamped oscillatory term which would becme dominant at large distances for all values of the screening parameter. Langer and Vosko have derived an experession for the change density asymptotically valid at large distances and has also presented results of numerical integration vaild to small distances.

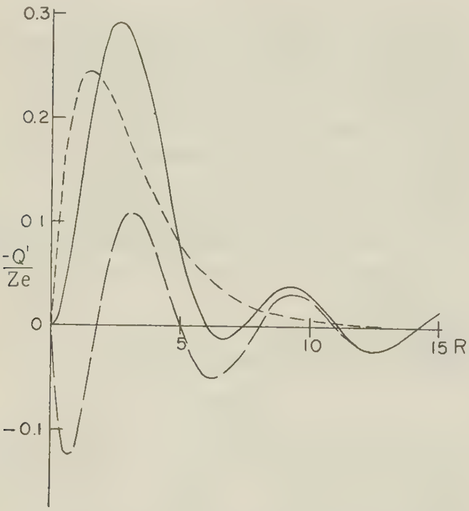

Fig. 1. Radial charge density about an impurity in Cu as function of distance from impurity. $Q'=dQ/dR$.

—— From numerical integration of Takimoto potential.

...... From customary T-F expression.

— — — Difference

In Fig. 1 we present results* obtained from a similar numerical integration of Takimoto's expression using the value of the screening parameter for copper, assuming the free electron value of Fermi energy. For convenience, the quantity plotted as the solid curve is radial charge density, dQ/dR, where dQ is the charge contained in the spherical shell defined by spheres of radius $R+dR$, and where $R\equiv 2k_0r$, with r the distance in real space. For comparison, the customary T-F radial charge density is also plotted in Fig. 1, as well as the difference between it and the Takimoto radial charge density. It is noteworthy that the difference curve is quite close to the values given by the asymptotic expression from large values of R down to about half the nearest neighbor distance, i.e. between $R=3.5$ and ∞, dQ/dR is quite closely given by

$$dQ/dR=(-Ze)\,[\alpha^2R\exp(-\alpha R)-\alpha^2(1+\tfrac{1}{2}\alpha^2)^{-2}R^{-1}\cos R],$$

where Ze=assumed charge on impurity, q=T-F screening parameter, $\alpha=q/2k_0$ and $\alpha R=qr$. In the example illustrated, $\alpha\sim 2/3$. It is possible that for much smaller values of α, a representation as the sum of a damped oscillatory term of the type suggested by McIrvine and the Langer-Vosko asymptotic form would prove useful.

Electrical Properties of Heavily Doped N-type Germanium

By Yoshitaka FURUKAWA

The Electrical Communication Laboratory, Musashinoshi, Tokyo

(Received August 4, 1960)

It has been reported that[1] for the same electron density, mobility in Sb-doped germanium is higher than that in As-doped germanium, and that[2] phonon assisted tunneling is observed in Sb-doped junctions of germanium but not in P- and As-doped junctions. Therefore, the effect of simultaneous doping of these impurities on the electrical properties of germanium may be an interesting problem.

For this purpose, four crystals containing both As and Sb have been prepared. Rough estimation for As concentration at the top (seed side) of the crystals and at the portion where single crystal breaks is given in Table I.

Table I.

Crystal	As (cm^{-3}) top	n (cm^{-3}) top	As (cm^{-3}) tail	n (cm^{-3}) tail
No. 1	$\sim 2\times 10^{18}$	4.8×10^{18}	$\sim 10^{19}$	1.6×10^{19}
No. 2	$\sim 5\times 10^{17}$	3.0×10^{18}	$\sim 3\times 10^{18}$	8.7×10^{18}
No. 3	$\sim 10^{17}$	1.7×10^{18}	$\sim 10^{18}$	5.2×10^{18}
No. 4	$\sim 2\times 10^{17}$	2.3×10^{18}	$\sim 6\times 10^{17}$	4.7×10^{18}

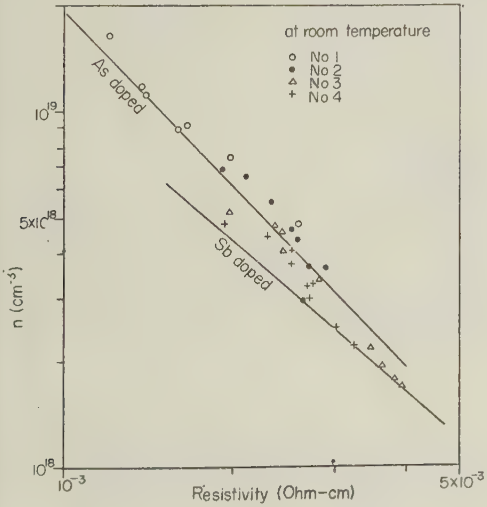

Fig. 1. *n versus* ρ relation.

Fig. 1 shows electron concentration (n) *versus* resistivity (ρ) relation. Solid lines[1] in this figure correspond to As- and Sb-doped germanium. As will be seen from this figure, measured points for samples with small r (r=As concentration/total donor concentration) lie on Sb-doped line, while measured points for samples with large r lie on As-doped line. It has been estimated that the transition of measured points from Sb-doped line to As-doped one occurs at $r \approx 0.2$.

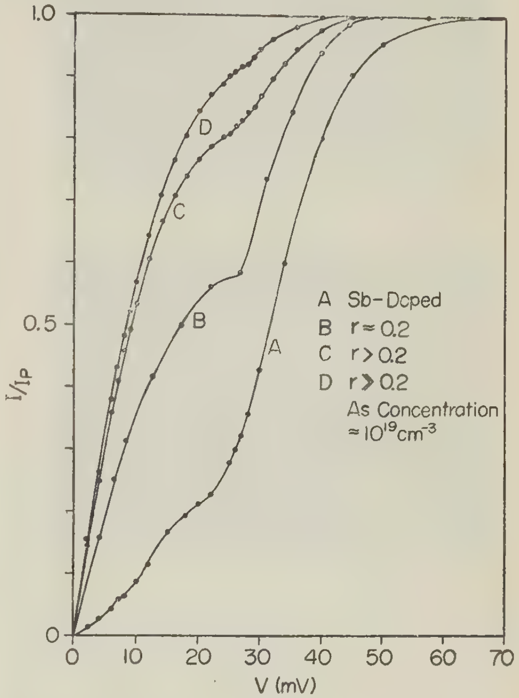

Fig. 2. V-1 characteristic of Sb- and (As+Sb)-Doped Junctions at 4.2°K.

At first, it was expected that indirect tunneling would not be observed in diodes made of (As+Sb)-doped germanium in which $r>0.2$ and n lies on As-doped line shown in Fig. 1. However, the experimental results did not agree with this expectation. Fig. 2 shows a typical example of current-voltage characteristics of Esaki-diodes made of Sb- and (As+Sb)-doped germanium at 4.2°K. Indirect tunneling[2] associated with longitudinal acoustic phonon has been observed even for the samples in which $r \gg 0.2$ and As concentration is about 10^{19} cm^{-3}. However, tunneling associated with transverse acoustic phonon is quite ambiguous for all samples measured in present experiment (except Sb-doped diodes).

Two different interpretations have been given for the difference of tunneling processes (direct and indirect) in As- and Sb-doped junctions. One[2] is based on modification of conduction band edge form, and another[3] is based on the difference of impurity scattering. To explain the present experimental results, the latter interpretation seems to be preferable.

Details will be reported in the near future.

The author thanks Mr. Z. Kiyasu, Associate

Director, and Dr. T. Niimi heartily for the guidance in this work.

Radiation of Plasma Oscillation

Shoji KOJIMA and Shigeo HAGIWARA
Tokyo University of Education,
Otsuka, Tokyo

(Received August 1, 1960)

In a previous paper we reported that a radiation having the frequency of the electron plasma oscillation was found with a Yagi antenna in a frequency region of about 700 Mc[1]. Further studies on this radiation have been carried out in microwave region. The discharge tube used was a mercury filled hot cathode tube having a pair of probes and two grids which were first introduced by Takayama to eliminate low frequency oscillations of the discharge[2]. The geometry of the tube is shown in Fig. 1. The radiation was detected with a electromagnetic horn and a superheterodyne receiver whose intermediate frequency was 70 Mc with a band width of 2 Mc.

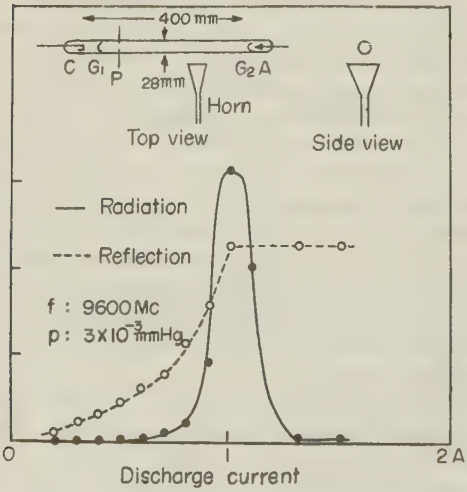

Fig. 1. Resonance curve of radiation.
Full line shows power of radiation in arbitrary scale.
Dotted line shows reflection ratio.

In order to determine the electron concentration of plasma, an experiment on microwave reflection was also carried out by using a klystron signal source. Reflection ratios were measured with a standing wave ratio meter.

Since the electron concentration varies as the discharge current was changed, the power of radiation was measured as a function of discharge current at a fixed frequency of the receiver. A result at a frequency of 9600 Mc is reproduced in Fig. 1 with a full curve. The reflection ratios which were measured at nearly same condition are also shown in the figure with a dotted curve. The radiation shows a predominant resonance at the current where the reflection reaches a saturation. Since at this current the frequency of plasma oscillation becomes 9600 Mc, the radiation seems to originate from the plasma oscillation.

The power of radiation at the resonance peak was roughly estimated to be a order of 10 $\mu\mu$w. The thermal noise of plasma in the above case was very small. The apparent half width of the resonance curve corresponds to about 200 Mc in frequency scale. The true width, however, may be smaller than 60 Mc, because the superheterodyne apparatus receives a image frequency besides the desired frequency. The hight of the resonance was almost constant for the whole region of positive column. In the vicinity of the cathode, the first grid or the probe, however, the radiation was very strong. This fact seems to agree with the previous conclusions that the plasma oscillation is strongly excited in front of the cathode and that the transformation of plasma oscillation into radiation takes place markedly at inhomogenious plasma.

When the pressure of tube increased, the height of resonance decreased and at about 10^{-2} mmHg the resonance sank below the noise level of the apparatus.

Such resonance was not observed in usual fluorescent lamp of 10 watts. However, long tubes of 20 watts or more showed a broad hump at the current which gives rise to the plasma oscillation having the frequency equal to that of the receiver. Above this current the well known noise radiation was observed.

The Effect of θ' Phase on the Plastic Deformation of an Age-Hardenable Al-Cu 4% Alloy

By Keisuke MATSUURA and Shigeyasu KODA
The Research Institute for Iron,
Steel and Other Metals,
Tohoku University, Sendai

(Received August 4, 1960)

In the previous short note[1], the effect of G-P aggregates on the plastic deformation was discussed. In the present study, to consider the effect of θ' phase on the plastic deformation, polycrystalline specimens (their grain size was 1/10~1/20 mm, but sometimes a few c.m.) were aged for various times at 240°C after air-cooling from 530°C. The air-cooled state is a supersaturated one with solute atoms, and the heat treatment mentioned above harden the specimens with θ' phase. Wires of 1 mm diameter for tensile testing, and strips of 1 mm thickness for the observation of slip patterns were extended at room temperature and -196°C. Some of the results are shown in Fig. 1 and Photo. 1. The following characteristics were observed.

(1) The initial rate of strain-hardening of aged specimens up to a stress δ_c increases appreciably compared with that of an air-cooled one. The curves are nearly linear, and the slope is $d\delta/d\varepsilon = 5.1\times10^2$ kg/mm^2. Moreover it is insensible to the grain size and the deformation temperature. However, δ_c becomes smaller as the deformation temperature becomes higher. When the applied stress increases over δ_c, the rate of strain-hardening begins to decrease and eventually becomes smaller than that of an air-cooled one.

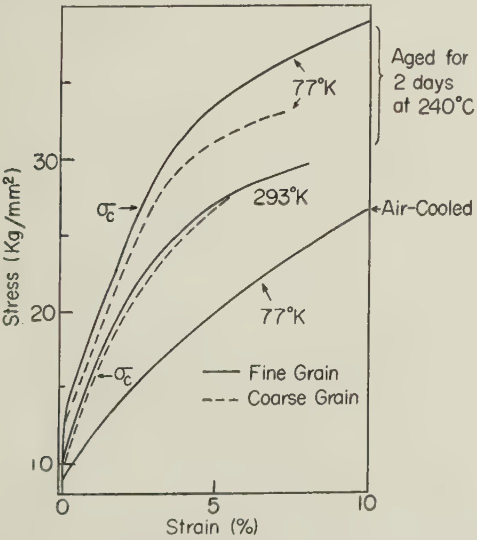

Fig. 1. Stress-strain curves of specimens aged for 2 days at 240°C and the air-cooled one at room temperature and -196°C.

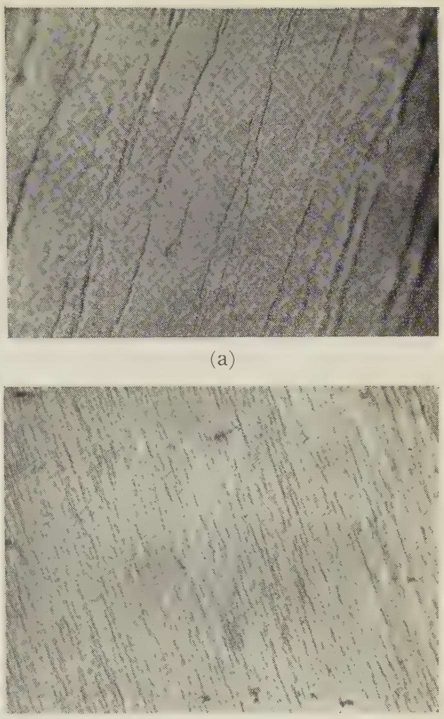

(a)

(b)

Photo. 1. Slip lines of specimens aged for 2 days at 240°C. (a) At the vicinity of fracture by extension at room temperature. (b) After 4.5 % extension at -196°C.

(2) The slip lines are not observed up to a plastic strain ε_c. It may be due to the fact that the slip lines are too fine and wavy to be observed as lines by means of an optical microscope. When the ageing proceeds from 2 hr. to 2 days, the value of ε_c at room temperature deformation varies from 2 % to the fracture strain and the slip lines observed above ε_c become from fine to coarse.

For the room temperature deformation of one aged for 2 days, sharp and coarse slip lines which are frequently connected with cross slip are observed only at the fractured grain, but at -196°C deformation faint and short slip lines connected with cross slip are observed at $\varepsilon_c \sim 5$ %. These facts may be explained as follows. In the specimens, for example the ones aged for 2 days, which θ' phase develops sufficiently, most of dislocations in motion pile up against the precipitates or pass through between them leaving loops around them. Such a process may cause to operate multiple slip as shown by disappearance of slip lines. The increase of strain-hardening is expected because of the interaction of dislocations by the piling up on the precipitates[2] and the operation of multiple slip[3].

Also it is expected that the strain hardening is insensible of the crystal orientation. The same rate of strain-hardening in the fine- and coarse-grained crystals suggests that it is not sensible of the crystal orientation. When the applied stress reaches to δ_c, the piled-up dislocations slip away by cross slip[4] or slip through the precipitates due to the stress concentration in front of the piled up dislocations. If the appearance of slip lines is associated with the slip of precipitates, it follows that, if the deformation temperature is high enough or the precipitates develop sufficiently the cross slip is dominent factor of the decrease in the rate of strain-hardening and if not so the slip of the precipitates is the factor.

Magnetic Properties of $MgMn_2O_4$

By Kiyoshi MURAMORI and Syohei MIYAHARA

Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received July 1, 1960)

Crystallographical properties of $MgMn_2O_4$ have been studied by Sinha et al.[1] and it has been found that they exhibit an approximate normal spinel structure with a tetragonal deformation at room temperature and most manganese ions are located on octahedral sites. Therefore it is likely that $MgMn_2O_4$ has the same antiferromagnetic properties as the zinc ferrite. However, Jacobs[2] has shown recently that $MgMn_2O_4$ has a spontaneous magnetization of about $0.2\mu\beta$ at 4.2°K which increases linearly with magnetic field at high intensities. In order to clarify the magnetic properties of $MgMn_2O_4$, the crystallographical properties were studied in detail by X-ray diffraction experiments and the susceptibilities of a powdered specimen were measured.

The specimen was prepared from powders of MgO and Mn_2O_3 which were made by calcining the salts. The mixtures were fired for a few hours in air at 1200°C, annealed for a day in air at 900°C in order to complete the conversion of divalent manganese ions to trivalent ones, and cooled slowly to room temperature at the rate of 0.5°C/min. X-ray diffraction patterns of the specimen show a tetragonal spinel-like structure with $c/a=1.15$, which is in agreement with the value determined by Sinha et al.. The cation distribution of the specimen that was determined by the X-ray diffraction intensity ratios of (202)/(004) and (422)/(004) differ about 15% from that of the completely normal spinel structure and is independent of thermal treatments of the specimen within the experimental errors.

Table I. u, x, T_a and C_{mol} mean oxygen positional parameter, fraction of Mg ions located on A-sites, asymptotic Curie temperature and Curie constant.

u	x	T_a	C_{mol}
0.385	0.85	500°K	5.75

Magnetic susceptibility was measured by a Sucksmith's ring balance. From the liquid nitrogen temperature, where the specimen shows no intrinsic magnetic moment, to 550°C, the inverse of the magnetic susceptibility changes linearly with temperature, showing the asymptotic Curie temperature to be −500°K. According to Lotgering[3] the asymptotic Curie temperature of a magnetic spinel is represented by

$$T_a=-(C_A n\alpha/6+C_B n\beta+4nC_AC_B/3)/C_{at}\,, \qquad (1)$$

where C_A and C_B are the Curie constants per mole of tetrahedral (A) and octahedral (B) sites ions respectively, $C_{at}=(C_A+2C_B)/3$; and n, $n\alpha$ and $n\beta$ are the molecular field constants between A-B, A-A and B-B site-ions respectively. It is evident that the first term of the formula (1) has little contribution to T_a. On the other hand, assuming the triangular arrangement of the magnetic moments of cations at B-sites as proposed by Yafet and Kittel[4], the resultant magnetic moment M_0 is expressed

$$M_0=\pm M_A(1-1/\beta)\,, \qquad (2)$$

where + or − sigh is taken for $M_B>M_A$ or $M_A>M_B$ respectively.

Using the relations (1) and (2) and the observed value of T_a (=500°K) and estimated value of M_0 ($=0.2\mu\beta$) by Jacobs, the values of n and $n\beta$ are obtained. For the case $M_B>M_A$ or $M_A>M_B$, $n\beta$ is 100 or 114 respectively. The above values of $n\beta$ are approximately in agreement with that of $n\beta=82\pm12$ obtained from linear increase of magnetic moment by Jacobs[2]. Therefore the magnetic properties of $MgMn_2O_4$ are thought to be consistent with the triangular ferrimagnetic model.

Decay of Potassium 44

By Kazusuke SUGIYAMA, Tsutomu TŌHEI, Masumi SUGAWARA
Department of Physics, Faculty of Science, Tohoku University, Sendai
Tsunekichi DAZAI and Yukinori KANDA
Tokyo Institute of Technology, Tokyo

(Received June 6, 1960)

An investigation of the decay scheme of K^{44} has been made with anthracene- and 5″×5″ NaI(Tl)-scintillation counters, and coincidence techniques. In addition to the 4.91-, 3.55- and 2.63-MeV beta rays, the following gamma rays has been assigned to Ca^{44}: 0.48-, 0.63-, 0.74-, 0.90-, 1.06-, 1.16-, 1.5-, 1.74-, 2.08-, 2.17-, 3.4-, 4.4-, 4.6- and 5.0-MeV. A decay scheme is proposed.

§1. Introduction

It is interesting to get an information about the level structure of Ca^{44} which situates between double magic nuclei Ca^{40} and Ca^{48}. Hitherto this has been investigated by the negatron decay of K^{44} and the positron decay of Sc^{44}. B. L. Cohen[1] has reported the 1.13-, 2.07- and 2.48-MeV gamma rays in his study of K^{44} and suggested that there was 1.5-MeV beta ray to higher level, though no comment on the level structure was offered. J. W. Blue and E. Bleuler[2] have reported the presence of 1.16- and 2.54-MeV gamma rays in their study on the Sc^{44} decay.

According to the beta ray energy systematics[3], the K^{44}–Ca^{44} energy difference is about 6.1-MeV and is higher than the Sc^{44}–Ca^{44} energy difference of 3.6-MeV, then one may have more information in the higher levels of Ca^{44} from the study of K^{44}.

§2. Experimental Procedure and Results

a) *Source sample*

Natural Calcium ($CaCO_3$) was irradiated with 18-MeV deuteron-carbon neutrons by the 160-cm cyclotron of the Institute of Nuclear Study, University of Tokyo. Irradiated samples were dissolved in a solution of HCl, and chemically separated by means of a method using tetraphenyl-boron-soda. Gamma ray spectra were measured at each stage of chemical process to confirm that Calcium (Ca–49) and Argon (A–41) were removed.

Decay life of the chemically separated sample was measured by a G–M counter and an anthracene scintillation counter which was used for the beta ray spectrum in the high energy portion. The decay curve measured by a G–M counter is shown in Fig. 1. Half life of K^{44} then assigned as 22.3-min., though it had measured 18-min.[4], 20-min.[5] and 22-min.[1] so far.

b) *Beta rays*

Beta ray spectra were obtained using a 1-in. dia. 1-in. long anthracene crystal with a multichannel pulse height analyser. The anthracene scintillation counter was calibrated with the Cs^{137} conversion line, Zn^{65}, Na^{22}, Na^{24}, Co^{60} gamma ray Compton edges and the Sr^{90} beta ray spectrum. The Fermi-Kurie plot is shown in Fig. 2. The maximum energies of beta rays were obtained as the 4.91-, 3.55- and 2.63-MeV from the Fermi-Kurie plot. Lower energy beta rays were covered by gamma ray background. Though the 3.55-MeV beta ray has been found in the decay of K^{42}, it may exist in the decay of K^{44} also.

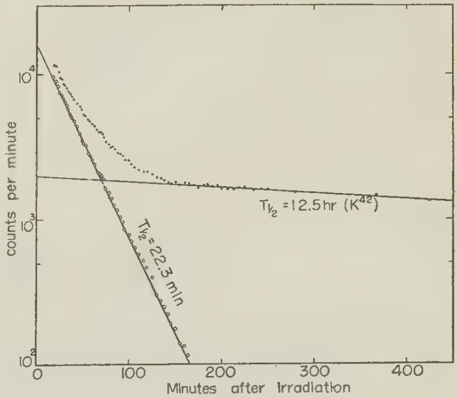

Fig. 1. Decay of K^{44}. ● shows the experimental count, and ○ shows the value that subtracted the K-42 (12.5-hr) from the experimental count.

c) *Gamma rays*

Gamma ray spectrum study was made using 5-in. dia. 5-in. long NaI(Tl) crystal. A lead collimating slit (see Fig. 3) was used for the sum peak measurement. Extreme cases of the measurement are shown in Fig. 3.

Though B. L. Cohen has suggested that the 3.6-MeV peak is the sum peak, it was confirmed as a single peak in our spectrum. Furthermore higher energy gamma rays could be observed, as the large 5-in. dia. 5-in. long NaI(Tl) crystal was used. The gamma ray spectrum was measured at 14-min., 34-min. and 56-min. after irradiation, and each peaks showed 22-min. decay life except the 1.5-MeV peak. The 1.5-MeV peak was found to be mixed gamma rays of Ca^{44} and Ca^{42}, since this peak had two decay components of 22-min. and a longer one in the decay life measurement. The gamma ray spectrum in lower energy portion is shown in Fig. 4.

d)· *Gamma-gamma coincidence measurements*

Gamma-gamma coincidences were studied with 5-in. dia. 5-in. long and 3-in. dia. 3-in.

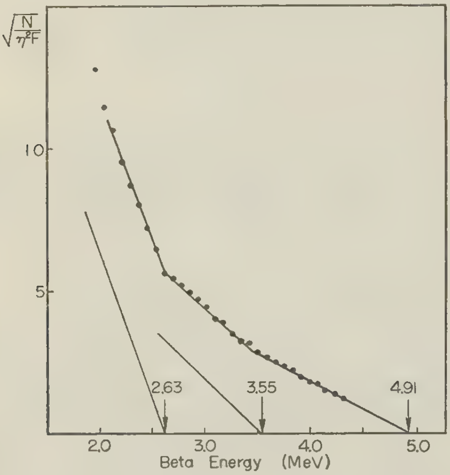

Fig. 2. Fermi-Kurie plot of the beta spectrum of K^{44}.

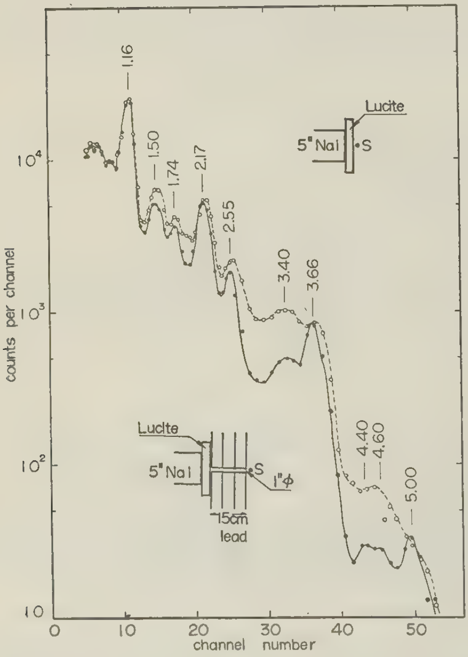

Fig. 3. Gamma ray spectra in K^{44}. Arrangements for sum peak measurements are also shown in this figure.

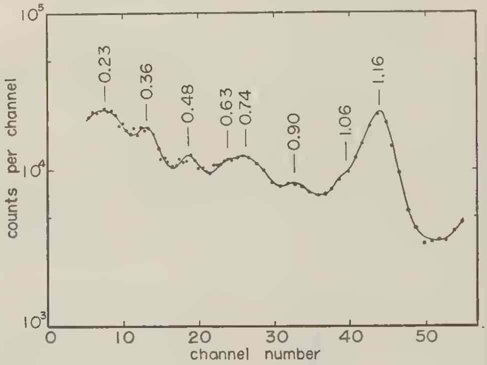

Fig. 4. The gamma ray spectrum in lower energy portion of K^{44}.

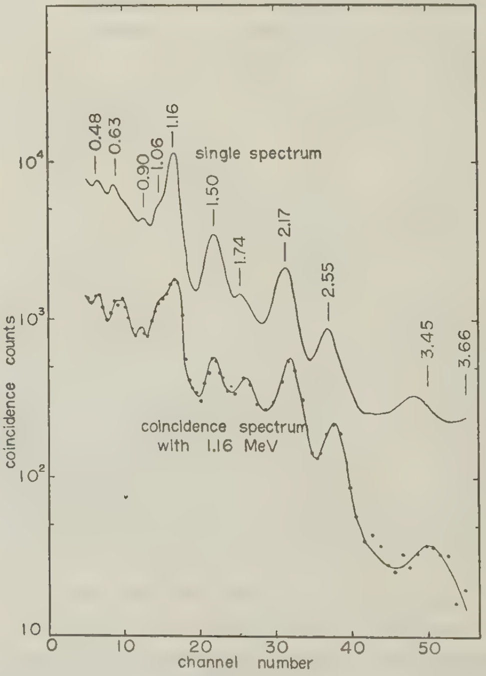

Fig. 5. Coincidence spectrum with the 1.16-MeV Gamma ray peak.

long NaI(Tl) crystals. The 1.16-, 1.5-, 2.1- and 2.5-MeV peaks were employed as gates. In each coincidence experiment the chance coincidence spectrum was subtracted from the observed coincidence spectrum using the gate counts as the source intensity normalization. The net coincidence spectra are shown in Fig. 5 and Fig. 6. It was found that the 2.1-MeV peak was a superposition of the 2.08- and 2.17-MeV and the 2.55-MeV line was also a doublet. These results are tabulated in Table I.

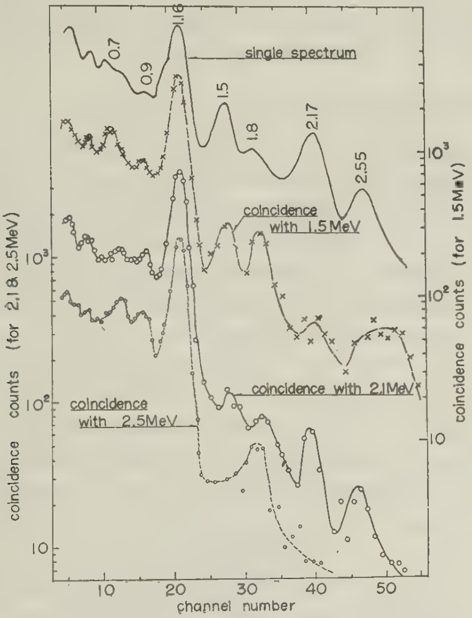

Fig. 6. Coincidence spectra with the 1.5-MeV Gamma ray peak (---×---), the 2.1-MeV Gamma ray peak (——○——) and the 2.5-MeV Gamma ray peak (----●----).

§ 3. Conclusion and Discussion

a) *Results*

At the result of above measurements, gamma rays belonging to Ca^{44} were assigned, and they are tabulated in Table II with their relative intensities. The relative intensities of lower energy gamma rays could not be determined since they suffered from disturbances due to higher energy gamma-rays. For the determination of the relative intensity, the efficiency of 5-in. dia. 5-in. long NaI(Tl) crystal with the lead slit was determined experimentally using several gamma rays of Cs^{137}, Na^{22}, Na^{24}, and Co^{60}, the efficiency in our source position (see Fig. 2) being found to be lower than the calculation[6] for parallel beam.

Table II. Energy and relative intensity of gamma radiations in K^{44}.

γ-ray energy	relative intensity
0.48-MeV	—
0.63	—
0.74	—
0.90	1
1.06	1

2.55	12
3.4	—
3.66	6.2
4.4	—
4.6	—
5.0	0.6

b) *Decay scheme*

There are reaction data on the levels of Ca^{44}, $K^{41}(d, p)Ca^{44}$ by J. P. Schiffer[7] and $Ca^{44}(p, p')Ca^{44}$ by C. M. Braams[8]. These data were referred to our proposed level scheme shown in Fig. 7.

No measurement have been reported to far on the spin and parity assignment of the K^{44} ground state. Since this configuration is p: $(d\ 3/2)^3$ and n: $(f\ 7/2)^5$, according to Nordheim rule it might be 2^-. Although K^{40} and K^{42} have the same configuration with K^{44}, however, there are measurements[3] in which K^{40} has 4^- and K^{42} has 2^- and K^{40} is an exception of the Nordheim's rule. According to the beta energy systematics, the K^{44}–Ca^{44} transition energy is expected to be about 6.1-MeV. Since our measurement has shown that the highest energy of the beta ray is 4.91-MeV and it is known that the first excited state of Ca^{44} is at 1.16-MeV the 4.91-MeV beta ray therefore may correspond the transition to the 1.16-MeV 2^+ state. The branching ratio of this transition is about ten percent and so $\log ft=8.0$ which is rather lower than the value for the first unique forbidden transition.

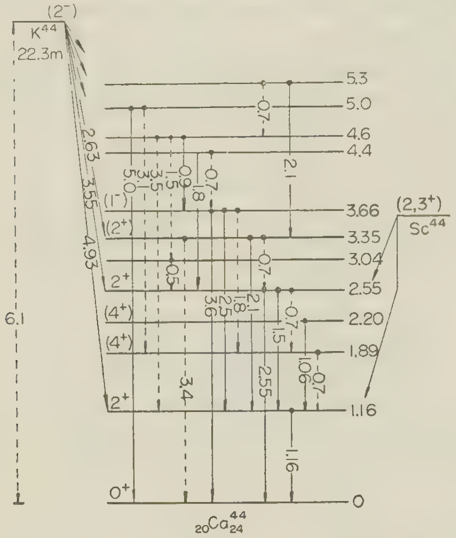

Fig. 7. Proposed decay scheme of K^{44}. The decay scheme of Sc^{44} proposed by J. W. Blue and E. Bleuler is also shown in this figure.

So, it may be expected that the spin and the parity of the ground state of K^{44} is 2^-. We could not find the 6.1-MeV beta ray within the intensity limit of one percent. This transition would be the first unique forbidden because $\log f_0t=7.4$ and $\log ft>9.5$. It is therefore reasonable that K^{44} ground state is 2^-. The 1.89-MeV second excited state and the 2.2-MeV third excited state may be 0^+ or 4^+, since we could find neither the cross over gamma rays to the ground state nor beta rays to these states. However, it would be 0^+ if the ground state of K^{44} is 4^-. As to this problem, it is interesting that the second excited state of Ca^{42} is recently measured as 0^{+} [9),10)].

The 2.55-MeV state is expected to be 2^+ because of the presence of the 2.55-MeV gamma ray to the ground state, the 3.55-MeV beta transition ($\log f_0t=6.1$) and the K-Capture transition from the Sc^{44} ground state (2^+ or 3^+)[2)].

The 2.63-MeV beta transition ($\log f_0t=5.7$) was assigned as the transition to the 3.35-MeV state which was assigned as 2^+.

Although we could not assign the spins of the higher energy levels from our data, the 3.66-MeV state may be the lowest odd spin state and probably 1^- according to the odd spin state systematics, found by H. Morinaga.

§ 4. Acknowledgement

The authors would like to thank Dr. H. Morinaga who suggested the present work and showed his unpublished data studied at Purdue University. They are also indebted to Professor M. Kimura for his continual encouragements throughout this work. It is a pleasure to acknowledge their indebtedness to Dr. S. Iwata who suggested the method of the chemical treatment. Further, they are greatly indebted to the beta group, the chemist group and the cyclotron crew in the Institute of Nuclear Study, Tokyo University.

Absolute Cross Section of the Reaction $Cu^{63}(\gamma, n)Cu^{62}$ for Lithium Gamma Rays

By Shinjiro YASUMI, Minoru YATA*, Kunio TAKAMATSU,
Akira MASAIKE and Yoshiko MASUDA**

Department of Physics, Faculty of Science, Kyoto University, Kyoto

(Received July 13, 1960)

The cross section of the reaction $Cu^{63}(\gamma, n)Cu^{62}$ for Li gamma rays was measured in order to discover some causes of the existing discrepancy between values measured by bremsstrahlungs and by nuclear gamma rays. Experimental procedures used in this experiment were much improved as compared with those used in previous measurements performed in our laboratory for the same purpose.

The present results were as follows:

$$\sigma_{\mathrm{Li}-\gamma}=62\pm4 \text{ mb for Li gamma rays,}$$

and

$$\sigma_{17.6}=76\pm5 \text{ mb for 17.6 Mev } \gamma\text{-rays.}$$

This value is about 30 per cent lower than the average cross section value determined by the photon difference method in several bremsstrahlungs' experiments. Therefore, we suggest that the modified spectrum method proposed by Penfold and Leiss might eliminate not only the above-mentioned discrepancy but also the discrepancy between theoretical and experimental values in the form $\sigma_{-2}\equiv\int\sigma E^{-2}dE$, as pointed out by Levinger.

§1. Introduction

It is a very interesting problem to study the interactions between electromagnetic waves and various nuclei by comparing experimental values with theoretical predictions on total photoreaction cross sections. Usually, for this purpose, experimental cross sections determined by using electron bremsstrahlungs are compared with the various sum rules in such forms as $\int\sigma dE$, $\int\frac{\sigma}{E}dE$, $\int\frac{\sigma}{E^2}dE$, etc.

In a previous paper¹⁾, using lithium gamma rays, we determined a value for the cross section of $Cu^{63}(\gamma, n)Cu^{62}$ reaction, which has been frequently used as the standard for photoreaction cross sections; and we compared this value with other experimental values hitherto published by several authors at $E_\gamma=17.6$ Mev. Then we found that the values measured by various investigators did not agree with one another, and they can be roughly divided into two groups, one of which averages about 100 mb and the other about 50 mb. Moreover, it appears generally that the former group contains mainly bremsstrahlungs' data and the latter mainly Li gamma rays' ones.

These facts seem to be very important for the above-mentioned problem, and further we found that our previous experiment¹⁾ included the following defects: (1) There are comparatively large statistical errors in the absolute measurement of the γ-flux; (2) We had used the values determined by another experiment as the correction factors for the absolute β counting, instead of determining these factors directly, and the geometries of the two β countings were found to be not identical with each other. Therefore, the correction factors used in the previous work seem to be inappropriate. (3) When we converted the cross section for cross section for Li gamma rays into the one for 17.6 Mev gamma rays, the most suitable values were not necessarily used. In order to discover the causes for such discrepancies among the measured values, we tried to improve the experimental procedures to obtain a more accurate value on the $Cu^{63}(\gamma, n)Cu^{62}$ cross section. Refinements performed in this study are as follows: (1)

---

* Present address: Sumitomo Electric Industries Co. Ltd.

** Radiation Center of Osaka Prefecture.

Hough's method[2),3)] in the absolute determination of the γ-ray flux was improved by using a transparent 4π Geiger counter specially designed at our laboratory; (2) As another calibration of the γ-ray intensity, a large NaI ($5''\phi \times 4''$) scintillation counter was used, whose detection efficiency for gamma rays was calculated by Wolicki *et al.*;[4)] (3) The absolute β counting method by which we obtained a true specific activity from counting rates measured for samples with finite thickness, was also improved not only by using 4π β counter whose construction was designed to be almost the same as that of the transparent 4π Geiger counter, but also by using very intense Cu^{62} thin samples activated by T-d 14 Mev neutrons at the same irradiation geometry as γ-rays' one; (4) The γ-ray source was more sharply defined than in the previous experiment.

§ 2. Experimental Procedures and Results

The γ-rays were produced by the $Li^7(p, \gamma)Be^8$ reaction: Li metal of about 0.5 mm in thickness, attached firmly* on molybdenum plates sufficiently cooled with water from behind, was bombarded with magnetically analysed protons ($\sim$50 μA) which were accelerated to about 450 kev by a Cockcroft generator. Sample discs made of natural copper, which were 20 mm in diameter and 0.9 mm in thickness, were irradiated by these γ-rays, and (γ, n) cross sections were determined by the activation method.

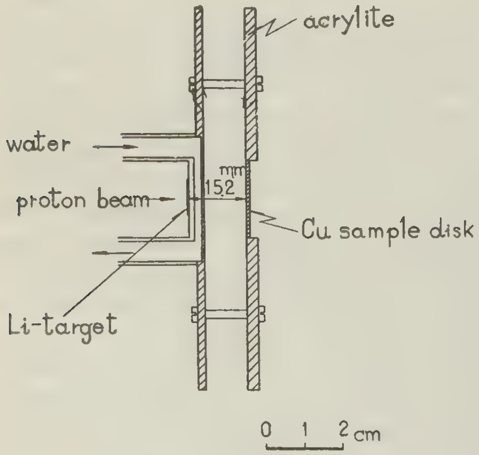

Fig. 1. Schematic drawing of the γ-ray irradiation geometry.

The size of the proton beam spot was well-defined to about 5 mm×4 mm by a slit of 4 mmϕ and the γ-irradiation geometry used in this work was the same as for the previous experiment[1)], as shown in Fig. 1.

Measurement of γ-quanta

The γ-ray intensities were measured by using an end-window Geiger counter enclosed with thick lead walls, as indicated in Fig. 2, which we shall call the "γ-monitor" hereafter; and its detection efficiency for Li-p γ-ray was calibrated by the improved Hough's method of which we will give an account subsequently.

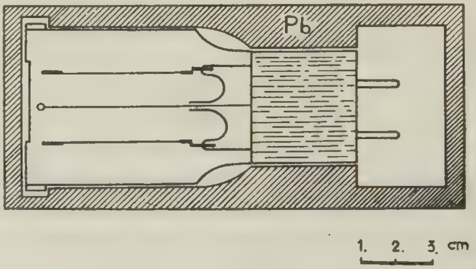

Fig. 2. An end-window Geiger counter enclosed with thick lead walls, which we call the "γ-monitor" in this paper.

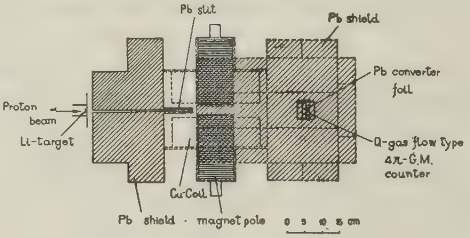

Fig. 3. Hough's arrangement for determining the γ-ray flux used in this experiment. A detailed construction of the Q-gas flow type 4π-Geiger counter represented in this figure is shown in Fig. 4.

Hough's arrangement for determining the γ-ray flux used in this experiment is schematically represented in Fig. 3. The counter which we used to count secondary electrons emitted from a converter foil by γ-rays has the construction as shown in Fig. 4. This is a 4π Geiger counter of Q-gas** flow type and is made transparent along the γ-rays' passage by the use of two windows consisting of mylar and wire gauze. A converter attached to a converter holder by "cello-tape" can be put in the centre of this counter.

---

* Lithium metal was melted on a molybdenum plate in a vacuum chamber.

** Q-gas consists of helium (99%) and isobutane (1%), and it was purchased from Takachiho Shoji Co. Ltd.

As converters, lead foil discs 8 mm in diameter were used, their dimension being carefully determined, taking account of the dimensions of the Pb-slits and the windows of the counter.

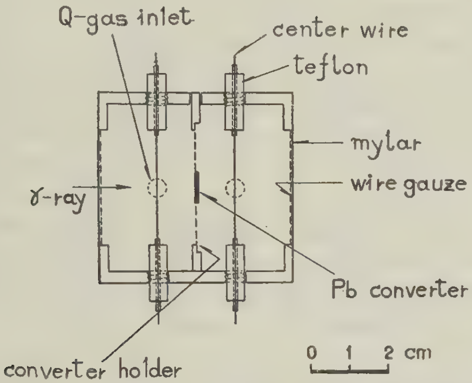

Fig. 4. Construction of the Q-gas flow type 4π-Geiger counter used in Hough's arrangement.

We can expect from the arrangement shown in Fig. 3 that the counter will be able to count all secondary electrons produced from a Pb converter disc if the latter is sufficiently thin.

In this case, the count of the converter counter is given by

$$N_c(w)=N_{c0}+n_\gamma\frac{N_0}{M}w\bar{\sigma}_e\ , \qquad (1)$$

where

$N_c(w)$: counts of the counter with a Pb converter of w weight,
N_{c0}: counts of the counter without a Pb converter,
n_γ: number of γ-quanta per cm² at the position of a Pb converter,
$\bar{\sigma}_e$: electronic absorption cross section of lead for Li-p γ-rays (averaged over 17.6 Mev and 14.8 Mev γ-rays),
w: weight of lead converter discs,
N_0: Avogadro's number,
M: Molecular weight of lead.

The γ-monitor (Fig. 2) to be calibrated was in operation together with the 4π counter, and we measured the ratio of $N_c(w)$ to the count of the γ-monitor N_M for various weights of converters. Then, Eq. (1) becomes,

$$\frac{N_c(w)}{N_M}=\frac{N_{c0}}{N_M}+\frac{n_\gamma N_0}{M\cdot N_M}\cdot w\bar{\sigma}_e\ . \qquad (2)$$

The ratio N_{c0}/N_M should be as small as possible to ensure the accuracy of measurements. For this purpose, special care was taken with the arrangements in Fig. 3: (1) The dimensions of the Pb-slit were so chosen that the γ-ray flux through it sufficiently covered the converter disc (8 mmϕ) and never collided with the thick walls of the 4π counter; (2) No lead shields were placed behind the counter; (3) The magnetic field of an electromagnet was used to remove secondary electrons from the forward direction.

In this experiment, it is obvious that the correct alignment of the γ-source—slit—counter—converter foil-system is very essential, and the transparency of the converter counter was found to be very helpful in aligning it exactly and easily.

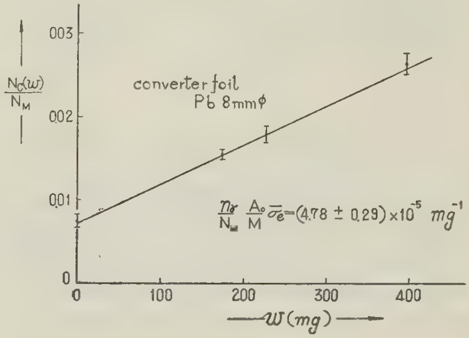

Fig. 5. Plot of $N_c(w)/N_M$ *versus* w, the thickness of converter foils. The solid straight line is the best fit by least square calculation. From the slope of this straight line, we obtain, $(n_\gamma/N_M)(N_0/M)=(4.78\pm0.29)\times10^{-5}\ \text{mg}^{-1}$.

The ratio $N_c(w)/N_M$[*] is plotted against various thicknesses ($w=0$, 172.0 mg, 225.3 mg, 397.3 mg) of the foil converter discs in Fig. 5, in which the solid straight line is the best fit by least square calculation. From the slope of this straight line, we obtain

$$\frac{n_\gamma N_0\bar{\sigma}_e}{N_M M}=(4.78\pm0.29)\times10^{-5}\ \text{mg}^{-1}\ . \qquad (3)$$

Then, if we use $\bar{\sigma}_e=(19.6\pm0.12)$ barns as the electronic absorption cross section of lead for

---

[*] For Li-p γ-rays, as naturally expected, the counting rates of the forward-half counter was almost constant for changing thickness of foils. Therefore we adopted the counts by the backward-half counter only as $N_c(w)$.

Li-p γ-rays, averaged over 17.6 Mev and 14.8 Mev γ-rays, we get

$$\frac{n_\gamma}{N_M}=0.8331\,\mathrm{cm}^{-2}\,.$$

Consequently, if we assume that γ-rays are emitted isotropically[5], the total number of γ-quanta, N_γ, emitted from a target is given as follows for one count of the γ-monitor placed at a distance of 50.05 cm from the γ-source:

$$\frac{N_\gamma}{N_M}=\frac{n_\gamma}{N_M}4\pi R^2=(4.09\pm0.25)\times10^4\,. \qquad (4)_1$$

This value agrees very well with the previous measurement[3] performed by us, which however has less accuracy than the present work.

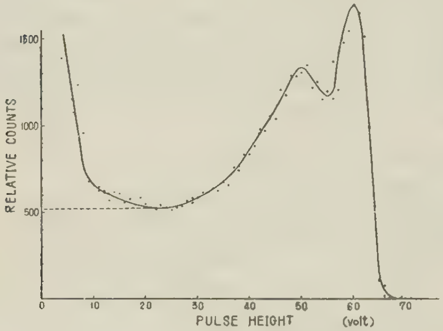

Fig. 6. Pulse-height distribution from an NaI crystal ($5''\phi\times4''$) irradiated by Li-p gamma rays. The shape of pulse-height distribution at low energy range is assumed to be represented by a dotted straight line parallel to the abscissa.

Another calibration of the γ-monitor was performed using an NaI (Tl) crystal ($5''\phi\times4''$) scintillation counter, which was operated together with the γ-monitor during the irradiations of γ-rays. Pulse-height distributions from the NaI counter were obtained with a 10 channel pulse-height analyser, and these are shown in Fig. 6. If the shape of pulse-height distribution at lower energy ranges is assumed to be represented by a dotted straight line parallel to the abscissa as shown in Fig. 6, the following value is obtained from the detection efficiencies of the NaI (Tl) scintillator for γ-rays calculated by Wolicki *et al.*[4], and from the geometries of arrangements:

$$\frac{N_\gamma}{N_M}=(4.41\pm0.44)\times10^4\,. \qquad (4)_2$$

This value agrees fairly well with the value $(4)_1$ obtained by Hough's method, taking into account the absorption by target materials.

Thus, we adopted the value determined by Hough's method as the detection efficiency of the γ-monitor, namely: For the case where the γ-monitor is placed at a distance of 50.05 cm from the γ-source,

$$\frac{N_\gamma}{N_M}=\frac{4\pi}{\omega\cdot\mathcal{E}}=(4.095\pm0.25)\times10^4\,, \qquad (5)$$

where ω is the solid angle which the γ-monitor subtends at the γ-ray source and $\mathcal{E}$ is the detection efficiency of the γ-monitor.

Determination of the Cross Section

The cross section of $\mathrm{Cu}^{63}(\gamma, n)\mathrm{Cu}^{62}$ reaction was determined by the activation method.

γ-ray intensities were measured by the γ-monitor for every one minute interval throughout irradiations, and we can regard γ-ray intensities as almost constant in each interval. After irradiations, produced activities on sample discs of 20 mm in diameter and 0.9 mm in thickness were measured by an end-window Geiger counter for about ten minutes.

Then, the cross section σ was determined by the following equation:

$$\sigma=\frac{M\left[N\Big/\sum_{i=1}^{T}N_{Mi}\exp\{-(T-i+t_0)\lambda\}\right]\cdot S'\cdot C_k}{N_0\eta\Omega A[(1-e^{-\lambda})(1-e^{-t'\lambda})/\lambda)]\cdot(4\pi/\omega\cdot\mathcal{E})}\,, \qquad (6)$$

where

N_0: Avogadro's number
M: molecular weight of the sample
η: isotopic abundance
S': $=S\cdot C_G=\lim\limits_{w\to0}\dfrac{N_s}{N\cdot w}$ where S is a correction factor related to the self-absorption and the self-scattering of the sample; C_G is a geometrical correction factor for the β-counting concerning the solid angle, the absorption by air and a mica window of an end-window Geiger counter, and the back scattering; N_s is the β count on thin samples, and N is the β count for the same time interval on samples of 0.9 mm in thickness, after neutron irradiations.
Ω: solid angle of the sample under irradiation; it is equal to $(1/4)\log\{(R^2+a^2)/a^2\}$, where R is the radius of the sample and a is the distance between the γ-source and the front surface of the sample disc.
A: correction factor concerning the finite

dimension of the γ-source.

N_{Mi}: γ-counts by the γ-monitor for one minute of the i-th interval

T: time of irradiation

t_0: time elapsed from the end of irradiation to the beginning of the β counting

i: number of the order of each time interval during irradiation (integer)

t': time interval of β-counting on the sample after irradiation

N: β-counts per t' minute on the sample of 0.9 mm in thickness

C_k: correction factor concerning the branching ratio between the positron emission and the orbital electron capture

ω: solid angle which the γ-monitor subtends at the γ-ray source

$\mathcal{E}$: detection efficiency of the γ-monitor, where $4\pi/\omega\mathcal{E}=4.095\times10^4$ by Eq. (5)

λ: decay constant of the isotope Cu^{62}

S' can be defined to be the product of S factor by C_G-factor, the former being the correction factor related to the self-absorption and self-scattering of the the sample, and the latter being the geometrical correction factor concerning the solid angle, the absorption by air and mica window of an end-window Geiger counter, and the back scattering of the sample and the other materials.

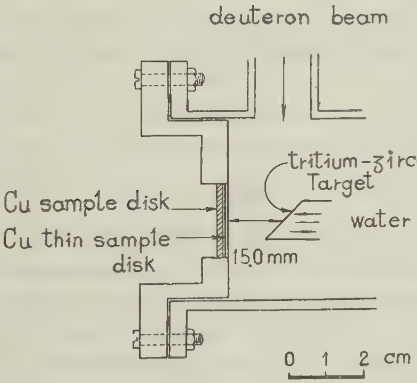

Fig. 7. Schematic drawing of the neutron irradiation geometory.

In order to obtain the S'-value, thin copper discs of various thickness with the same diameter as the sample disc were irradiated with T-d neutrons in juxtaposition with it, as indicated in Fig. 7. After irradiations, produced activities on the former (thin sample) were counted by a 4π-Geiger counter of Q-gas flow type whose construction is shown in Fig. 8 and on the latter (so-called sample disc) by an end-window Geiger counter for the same time interval.

When the ratio $N_s/(N\cdot w)$ is plotted against w, we obtain a curve as shown in Fig. 9. If this curve is extrapolated to zero thickness, then the limiting value $\lim_{w\to0}\{N_s/(N\cdot w)\}\equiv S'$ can be obtained, which may be taken as the value proportional to the product of the "true" specific activity by the geometrical correction factor.

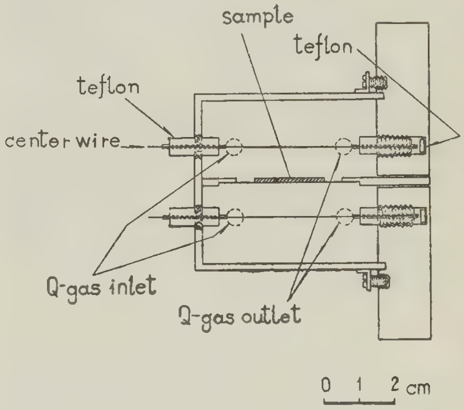

Fig. 8. Construction of a 4π-Geiger counter of Q-gas flow type used in the activation measurement.

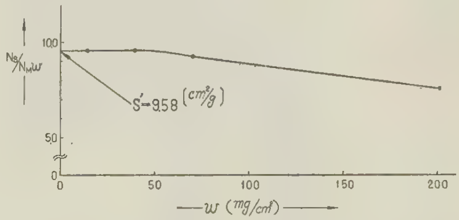

Fig. 9. Plot of $\{N_s(w)\}/(N\cdot w)$ *versus* the thickness of thin samples. Extrapolating this curve to zero thickness, the limiting value $\lim_{w\to0}(N_s)/(N\cdot w)=S'=9.58\ \mathrm{cm^2/g}$ can be obtained.

The result is as follows:

$$S'=9.58\ (\mathrm{cm^2/g})\ . \qquad (7)$$

We measured the decay curve at each run in the above-mentioned measurement, and it was verified that the same residual activity on samples irradiated by T-d neutrons was measured as in the case of Li-gamma rays.

The half-life of Cu^{62} was determined as 9.79 ± 0.13 min. in our previous work[1] and then the decay constant λ becomes:

$$\lambda=0.0708\,\mathrm{min}^{-1}\,. \tag{8}$$

Thus, substituting (5), (7), (8) into Eq. (6), the cross section of $Cu^{63}(\gamma, n)Cu^{62}$ for lithium gamma rays was obtained as follows:

$$\sigma_{\mathrm{Li}\text{-}\gamma}=62\pm4\ \mathrm{mb}\,. \tag{9}$$

The uncertainty indicated above is the overall error which results from the measurements for the following values, namely: S', $\omega\mathcal{E}$, N, λ, and N_{Mi}.

§ 3. Conclusions and Discussions

Lithium gamma rays, as is well known, consist of 17.6 Mev lines with a half-width of 12 kev and 14.8 Mev lines with a half-width of about 1.9 Mev[6]. When we want to convert the cross section value for Li gamma rays to that for 17.6 Mev gamma rays, it is necessary for us to know the intensity ratio between the above two γ-rays and the ratio of (γ, n) cross sections of Cu^{63} for these two γ-rays.

By simple calculations, the relation between $\sigma_{17.6}$ and $\sigma_{\mathrm{Li}\text{-}\gamma}$ is given by

$$\frac{\sigma_{17.6}}{\sigma_{\mathrm{Li}\text{-}\gamma}}=\frac{1+R}{(1/r)+R}\,, \tag{10}$$

where $I_{17.6}/I_{14.8}=R$ (intensity ratio) and $\sigma_{17.6}/\sigma_{14.8}=r$ (cross section ratio). For the intensity ratio R, the value determined by Stearns and McDaniel[7] is widely used, and we also adopted this value, namely $R=1.7\pm0.2$.

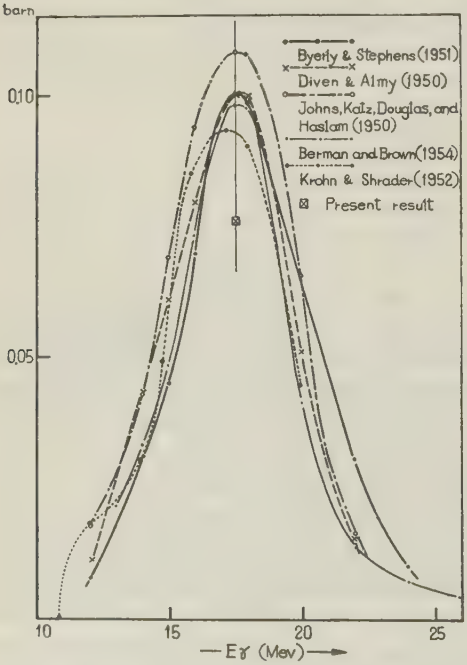

Fig. 10[8]. Excitation curves of the reaction $Cu^{63}(\gamma, n)Cu^{62}$ obtained by various authors. A point represents the value for 17.6 Mev γ-ray determined in the present experiment.

For the cross section ratio r, excitation curves determined by many authors give somewhat different values as indicated in Fig. 10. If we adopt the average value of these measurements for r, namely $r=2.0$, the cross section for 17.6 Mev γ-ray can be obtained by (10):

$$\sigma_{17.6}=76\pm5\ \mathrm{mb}\,.$$

This value is about 30 per cent lower than the average value of cross section values determined with bremsstrahlungs as is shown in Fig. 10.

Recently, Penfold and Leiss[9] proposed the "modified spectrum method" instead of the "photon difference method" originated by Katz and Cameron[10]. In the reaction $Ni^{58}(\gamma, n)Ni^{57}$, Roalsvig *et al.*[11] found that the absolute value of $\sigma_{\max}$ obtained by using the modified spectrum method was about 40 per cent lower than the value obtained by the photon difference method. If we assume a similar situation in the case of $Cu^{63}(\gamma, n)Cu^{62}$ as in the case of nickel, it seems very probable that $\sigma_{17.6}$ obtained by the present experiment will agree nicely with bremsstrahlung's data obtained by the modified spectrum method, since all bremsstrahlungs' data reproduced in Fig. 10 were obtained by the photon difference method.

Moreover, it was pointed out by Levinger[12] that the sum rule calculation in the form of $\sigma_{-2}\equiv\int\sigma E^{-2}dE$ by Migdal[13] gave $2.25\,A^{5/3}$ μb/Mev, while the experimental data for seven nuclei from Al to U agree with the equation of the same form but with a larger coefficient, namely, $\sigma_{-2}=3.5\,A^{5/3}$ μb/Mev. Considering* the fact that the above experimental data were all based on the $Cu^{63}(\gamma, n)Cu^{62}$ reaction cross section obtained from bremsstrahlungs' data by the photon difference method, it seems likely to us that the modified spectrum method for measurements with bremsstrahlungs might eliminate the above discrepancy between the theoretical and the experimental equations about σ_{-2}, as well as the discrepancy between the cross section value obtained by bremsstrahlungs and that obtained by lithium gamma rays.

---

* For these discussions we are greatly indebted to Dr. K. Okamoto.

Acknowledgements

The authors wish to express their sincere gratitude to Prof. K. Kimura for his encouragement throughout this experiment.

They are deeply indebted to Drs. K. Okamoto, T. Nakamura, I. Kumabe, and Prof. M. Kimura of Tohoku University for their valuable discussions. They wish also to express their sincere thanks to Mr. K. Okano for his kind help in γ-ray flux measurement by a scintillation counter. The authors' thanks are also due to Professor S. Tomotika and Mr. H. Hackett jr. for their kind inspection of the manuscript. The work was partly supported by a grant-in-aid for scientific research from the Ministry of Education.

Multipole Interaction Stabilizing Cubic Molecular Crystals

By Taro KIHARA

Department of Physics, Faculty of Science, University of Tokyo

(Received July 1, 1960)

The stability of several cubic molecular crystals is investigated on the basis of multipole interaction between the molecules. The stability of the cubic close-packed structure of heavy rare-gas crystals is due to the repulsion between electrical octapoles induced in atoms in the hexagonal close-packed structure. The face-centered cubic structures of carbon dioxide and cyclohexane-hexahalides and the body-centered cubic structures of silicon-tetrafluoride and hexamethylene-tetramine are configurations with the maximum electrostatic attraction between permanent charge distributions in the molecules. Pingpong balls containing two or four pieces of magnet represent these molecules with permanent multipoles; and it is demonstrated that a proper "crystal" of such balls (suspended in water) is stable.

§1. Introduction

Spherically symmetric molecules crystallize into a close-packed structure. Thus neon, argon, krypton, xenon, and also methane CH_4 and adamantan (sym-tricyclodecane) $(CH_2)_6(CH)_4$ crystallize into the face-centered cubic lattice. There have been several attempts to explain the stability of the cubic close packing for rare-gas atoms over the hexagonal close packing (except helium for which quantum effect is predominant), but the problem has not been settled. A purpose of the present paper is to answer from a very simple and presumably correct point of view.

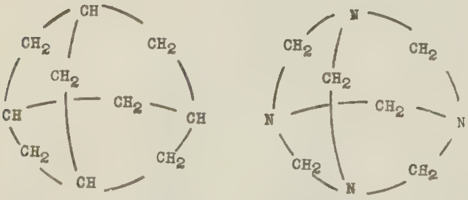

Fig. 1. Two nearly spherical molecules, adamantan and hexamethylene-tetramine, for which crystal structures are different.

Silicon-tetrafluoride SiF_4 and hexamethylene-tetramine $(CH_2)_6N_4$ are both nearly spherical like methane and adamantan (Fig. 1). They crystallize, however, not into a close-packed structure, but into the body-centered cubic lattice keeping the molecular orientations parallel (Fig. 2). On the other hand crystals of carbon-dioxide CO_2, cyclohexane-hexachloride $C_6H_6Cl_6$ and cyclohexane-hexabromide $C_6H_6Br_6$ have face-centered cubic structures. The molecular axes are then distributed equally in four orientations $(1,1,1)$, $(1,1,-1)$, $(1,-1,1)$, and $(-1,1,1)$; and the structures are not close packing for these prolate and oblate molecules (Fig. 3). All these molecules have strong electric multipoles; and another purpose of the present paper is to explain, by use of artificial molecules, the stability of these structures from the multipole interaction between molecules.

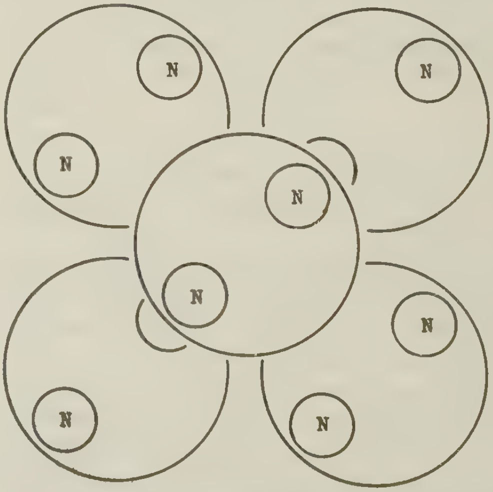

Fig. 2. Molecular orientation in the body-centered cubic crystal of hexamethylene-tetramine.

§2. Crystals of Heavy Rare-Gas Atoms

Much of the empirical research in molecular physics has been based on a two-body potential function such as

$$U(r)=\frac{U_0}{s-6}\left[6\left(\frac{r_0}{r}\right)^s-s\left(\frac{r_0}{r}\right)^6\right] \qquad (1)$$

or

$$U(r)=\frac{U_0}{\sigma-6}\left[6\exp\frac{\sigma(r_0-r)}{r}-\sigma\left(\frac{r_0}{r}\right)^6\right], \qquad (2)$$

where r is the intermolecular distance, and U_0 and r_0 are potential parameters. If the potential is assumed to be additive and if only the first-neighbor interaction in a crystal is considered, then the cubic and hexagonal close-packed structures have equal cohesive energies, because in both cases an atom has equal number (twelve) of first neighbors.

Interactions between second and farther neighbors were calculated in detail by Kihara and Koba[1]. It was shown, however, that the stability of the cubic close-packed lattice does not follow from the additive potential (1) for any value of s greater than 6 nor from the potential (2) for $\sigma > 8.675$. For these potentials the hexagonal close-packed lattice is more stable, although it is favored over the cubic by only 0.01 percent of the cohesive energy. The cubic close-packed lattice becomes more stable than the hexagonal for σ less than 8.675. But the potential (2) with $\sigma < 8.765$ has too wide a bowl to be accepted as a very accurate two-body intermolecular potential. This work was supplemented and confirmed by Jansen and Dawson[2], who took account of the zero-point energy.

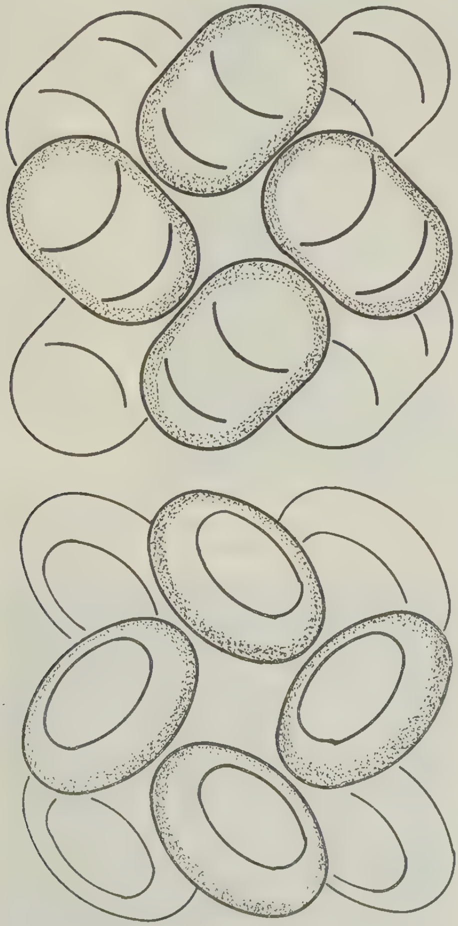

Fig. 3. Molecular orientations in the face-centered cubic crystals of carbon-dioxide (top) and cyclohexane-hexahalides.

Explanation of the stability of the cubic crystals on the basis of a two-body potential function was thus unsuccessful. As a next step three-body interactions were considered by several authors. Axilrod[3] summed the triple-dipole interaction, a nonadditive part of the van der Waals attraction, in both the cubic and hexagonal close packings. He concluded: " The difference in the triple-dipole interaction for the cubic and hexagonal close-packed lattice, although favoring the former structure, is less than 0.01 percent of the cohesive energy and hence cannot account for the structure of these rare-gas solids ".

The second and third virial coefficients in the equation of state of rare gases calculated by use of the potential (1) with $s=12$ agree with observed values when the nonadditivity of the intermolecular potential is taken into account[4]. If we assume the potential additivity, on the other hand, then we must use an effective intermolecular potential with a wider bowl in order to explain the temperature dependence of the third virial coefficient[5]. In other words, the influence of nonadditivity of the intermolecular potential can, to some extent, be eliminated by using an effective (additive) intermolecular potential with a wider bowl. An appropriate choice may be not far from the potential (2) with $\sigma=8.675$, for which two structures of close packing have exactly equal cohesive energies.

Thus we have seen that no essential difference exists between cubic and hexagonal cohesive energies so far as a central force is assumed between molecules. An alternative approach is therefore needed; non-central forces must be considered, as it was pointed out by Prins et al.[6] and Barron and Domb[7].

A rare-gas atom is spherically symmetric in free space, but not in a crystal because of the compression by surrounding atoms. An atom in a close-packed lattice has twelve nearest neighbors and has six "windows" facing the second neighbors (Fig. 4). At these windows the electron density should be different from other parts, and hence the atom has an electrical multipole. It is easily seen that, in a hexagonal close-packed lattice, this multipole is an octapole and the octapole interaction between first neighbors is repulsive.

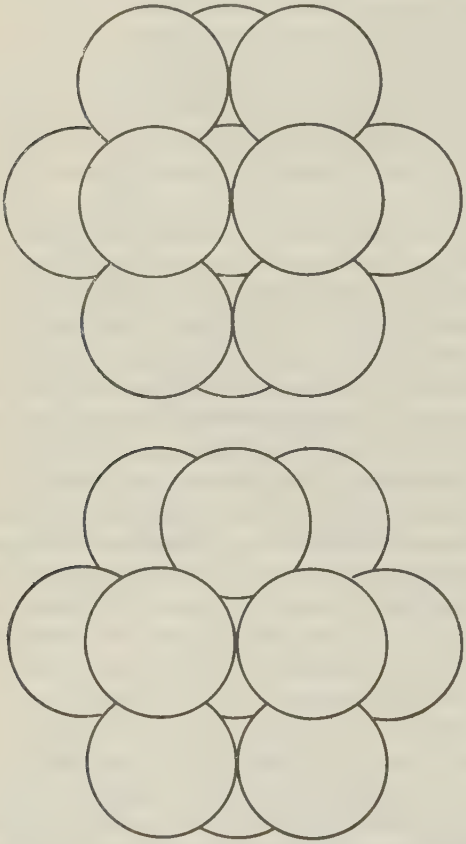

Fig. 4. First neighbor configurations for hexagonal (top) and cubic close packings.

In a cubic close-packed lattice, on the other hand, an atom has a higher symmetry, the lowest-order non-vanishing multipole being hexadecapole. Although this hexadecapole interaction is also repulsive, the effect is definitely smaller than the octapole repulsion in the hexagonal case.

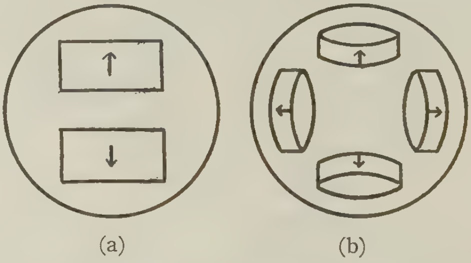
Thus we reach the following conclusion: *The stability of the cubic close-packed structure of heavy rare-gas crystals is due to the repulsion between electrical octapoles induced in atoms in the hexagonal case.*

§ 3. Cubic Crystals of Molecules with Permanent Multipoles

In a previous paper Kihara and Koba[8] discussed the cohesive energy of the face-centered cubic crystal of carbon-dioxide, and showed that 20 percent of the cohesive energy is the quadrupolar attraction between the molecules. If the carbon-dioxide crystallized into a close-packed lattice, keeping the molecular axes parallel, then the quadrupolar interaction, which is repulsive in this case, would reduce its total cohesive energy.

The crystal structures of cyclohexane-hexahalides can be understood in a similar way. It should be noted, however, that quadrupoles of these molecules are not point quadrupoles but the molecules have their nonvanishing sizes of charge distribution.

The electric charge distribution in a carbon-dioxide or cyclohexane-hexahalide molecule can be represented by a "magnetic charge distribution" in a convex body, a sphere, say. A system of these models of molecules will then crystallize into the corresponding cubic lattice, if the stability of the real crystal is due to this orientation-sensitive interaction.



(a) (b)

Fig. 5. Pingpong balls containing pieces of magnetized barium-ferrite, which are our molecular models for carbon-dioxide and for hexamethylene-tetramine.

In order to make this type of artificial molecule, place appropriately two pieces of magnet inside a pingpong ball (Fig. 5a); let the ball have unit density and be suspended in water. A "crystal" of such balls in the configuration of carbon-dioxide or cyclohexane-hexahalide (Fig. 6) is in fact satisfactorily stable against disturbances.

A system of pingpong balls, each containing four smaller pieces of magnet in configuration of a tetrahedral symmetry (Fig. 5b), can "crystallize" in a body-centered cubic lattice which is characteristic of silicon-tetrafluoride

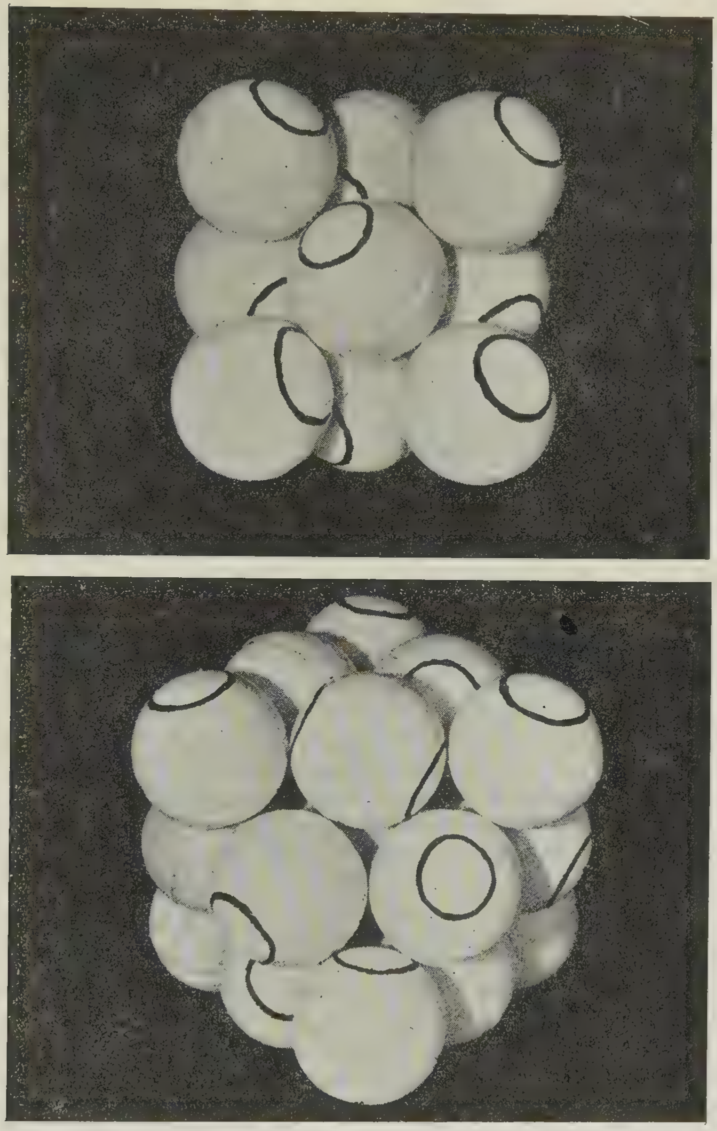


Fig. 6. Face-centered cubic crystals of the magnetized balls for carbon-dioxide or cyclohexane-hexahalide. Circles on the spherical surface indicate the positions of the magnets.

or hexamethylene-tetramine, the position of a piece of magnet corresponding to the position of a fluorine or nitrogen atom. (Fig. 7).

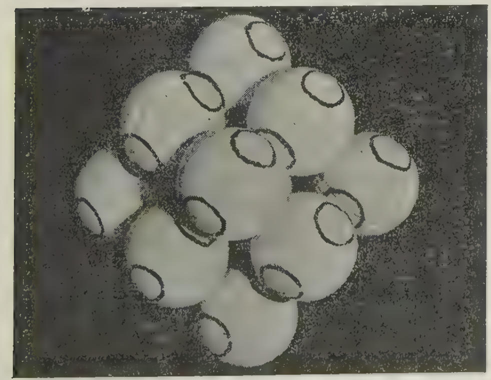

Fig. 7. Body-centered cubic crystal of the magnetized balls for silicon-tetrafluoride or hexamethylene-tetramine.

Thus we reach the following conclusion: *The face-centered cubic structures of carbon dioxide and cyclohexane-hexahalides and the body-centered cubic structures of silicon-tetrafluoride and hexamethylene-tetramine are configurations with the maximum electrostatic attraction between permanent charge distributions in the molecules.*

This work was partly done at the University of Wisconsin, Theoretical Chemistry Laboratory, in February and March, 1960.

Anisotropic Hall Coefficients in n-Type Germanium

Hisao MIYAZAWA and Hajime MAEDA

Matsuda Research Laboratory, Tokyo-Shibaura Electric Co.,
Komukai-Toshiba-cho, Kawasaki

(Received July 13, 1960)

Precise measurements of Hall effect have been made at 77°K, 90°K, 195°K, and 298°K up to 11,000 gauss on oriented single crystals of n-type germanium containing 5×10^{14} antimony per cm^3 as donor centers. The results should principally indicate the variations of μ_H/μ with the magnetic field and with the temperature, since the carrier concentration may be practically constant under the present conditions.

Absolute values of μ_H/μ have been deduced from R_∞ and R_0. R_∞ for which μ_H/μ always equals unity is fortunately obtained by extraporating $R_H^{\langle001\rangle}$(77°K) vs $1/H^2$ data. Then $R_H^{\langle001\rangle}/R_\infty$ will straightway give $\mu_H/\mu \cdot \langle001\rangle_H$. On the other hand, μ_H/μ for other orientations may be indirectly estimated from their extraporated R_0 for which μ_H/μ is independent of the orientation and should be equal to $R_0^{\langle001\rangle}/R_\infty$ at respective temperatures, neglecting the effect due to slightly different impurity concentration between specimens.

Values of μ_H/μ thus determined are always smaller than unity, while those of $\langle001\rangle_H$ approach to unity most rapidly with increasing field and those of $\langle110\rangle_H$ most slowly. They are of course temperature dependent and the zero magnetic field values are equal to 0.83 at 77°K, 0.84 at 90°K, 0.90 at 195°K and 0.92 at 298°K respectively.

Numerical evaluation of the Boltzmann's equation taking account of ellipsoid model and mixed scatterings can give the observed values fairly well. It appears, however, preferable to introduce some correction term, e.g., reasonable amount of optical phonon scattering for the best agreement.

§1. Introduction

Hall measurements are the most popular and fundamental techniques to obtain many information about electronic properties in semiconductor physics. In most cases thus far, however, little attention has been paid to μ_H/μ appearing in the Hall coefficient, sometimes assuming it equals unity while sometimes equating it to $3\pi/8$ without considering scattering mechanisms in detail.

According to theoretical calculations, on the other hand, it is generally predicted that μ_H/μ is more or less dependent on the applied magnetic field and not a unique constant unless free carriers are perfectly degenerated. Usually, the behavior is rather complicated even if the semiconductor material is isotropic. For instance, Johnson and Whitesell[1] have indicated interesting results in which magnetic field dependence of μ_H/μ is considerably influenced by mixing a small amount of ionized impurity scattering into the acoustic phonon scattering in the case of isotropic semiconductor, although no experimental verifications have been given because of the lack of proper isotropic materials. Theoretical analysis of anisotropic Hall coefficients in n-type germanium has been briefly dealt with by Abeles and Meiboom[2] and also by Shibuya[3] who have aimed to explain anisotropic magnetoresistance data[4] by assuming ellipsoid band model and isotropic thermal scattering. Putting the effective mass ratio at 20, they obtained 0.93 for the values of μ_H/μ at zero magnetic field. As compared with the calculations by Johnson et al, the only regreatful point in their analysis is the neglection of slight impurity scattering in the real crystals, which may considerably affect the field dependence of Hall coefficient.

As for the experimental examinations of μ_H/μ, there have been little works chiefly because of the requirements for accurate instrumentations detecting rather small effects. It is noteworthy that anisotropic variations of relative μ_H/μ values with magnetic field strengths were first observed in n-type germanium at room temperatures by Mason, Hewitt and Wick[5] and ingeniously analysed on the phenomenolygical basis of cubic symmetry only. Though their beautiful results can elucidate the relation between crystal direction and Hall coefficient, absolute values of μ_H/μ and its temperature effect have not been given and remained obscure. A drastic determination of μ_H/μ in germanium was reported by Morin[6] who compared the conductivity mobility, which was calibrated by the drift mobility of minority carriers injected in p- or n-type specimens at 300°K, with the Hall mobility of respective type. He has quoted an experimental value of 1.05 for n-type independent of temperature between 25 and 300°K. In his case, however, despite of epoch-making method, observed data were too dispresed to discuss the agreement with theory and moreover no anisotropic characteristics were considered. His brilliant success was a disclosure of extraordinary behavior of μ_H/μ in *p*-type germanium which will not be referred here.

Since the ellipsoid model for n-type germanium has been well established by cyclotron resonance experiments[7], theoretical investigations of transport phenomena thereafter have been pointed to the anisotropy in the relaxation time. General aspect on such a basis has been discussed by Herring and Vogt[8]. Under these circumstances, reexamination of the Hall effect as well as other transport phenomena taking account of crystal orientation and scattering anisotropy was a desirable subject for many valley semiconductors. Bullis and Krag[9] have reported a timely work on n-type germanium specimens of highly symmetric orientations, in which they have shown that observed data for μ_H/μ at 77°K agree reasonably well with calculations using ellipsoid model and constant mean free time hypothesis, especially the agreement is good when the magnetic field is in $\langle 001\rangle$ direction and exceeds several kilo-gauss. In the second paper[10], Bullis has extended his measurements including other galvanomagnetic effects to another temperature of 300°K in addition to 77°K in order to evaluate the anisotropy factor principally due to the relaxation, where he has quoted the behaviors of Hall coefficients could not be quantitatively explained. Though these investigations have almost clarified qualitative features of μ_H/μ, there is some further information yet to be desired for better understandings.

The authors have carried out similar measurements on specimens of several selected crystal orientations at four different temperatures in the exhaustion region, and obtained the explicit variations of anisotropic μ_H/μ with temperatures and magnetic field strengths making an attempt at the highest accuracy. The present paper will describe those experimental results and the theoretical calculations aiming more quantitative approach without neglecting anisotropic factors both in effective mass and in mixed scatterings.

§2. Experimental Procedures

The techniques used here are almost similar to those by Bullis and Krag[9] and will be described briefly. Highly uniform and stable magnetic field up to 11,000 gauss was produced by an electromagnet for high resolution nuclear magnetic resonance of which pole face diameter was 30 cm and gap was 4.5 cm. The field strengths were determined within

0.01% errors by measuring proton resonance frequencies with a heterodyne frequency meter. The measurements of Hall voltage and sample current were carried out by a YEW Type P–7 potentiometer, where the observed values were reproducible at most within ±0.1%. Therefore, the whole accuracy was limited only by potential measurements.

Four measuring temperatures chosen here were 77°, 90°, 195°, and 298°K which were respectively provided by liquid nitrogen, liquid oxygen, mixture of dry ice and ethyl ether, and air-conditioned room temperature. In all cases the sample mounted on a holder was directly immersed in a Dewar vessel containing each refrigerant or no refrigerant.

The specimens were zone-leveled n-type germanium single crystals of about 3 ohm-cm containing nearly 5×10^{14} antimony per unit volume. Since these crystals are so well controlled that the concentrations of uncontrolled centers less than 10^{13} may be easily realizable, one may suppose an essential condition for the present purpose that the carrier concentrations are practically constant irrespective of temperatures even in the worst case. After the crystals were oriented by X-ray analysis, the specimens were cut out of the crystals in the shape as shown in Fig. 1 by a supersonic dice. The selected orientations are also indicated in Fig. 1. Angle θ varying from 0° to 90° was chosen as a parameter. In the following, a notation $R_H^{\langle\theta\rangle}(T°\mathrm{K})$ will represent the Hall coefficient at magnetic field strength of H gauss and at temperature of T°K in a specimen for which magnetic field is applied in the direction of angle θ. In place of θ, Miller indices will be used in the case of high symmetry orientations, for example, $\langle 0° \rangle$ will be represented bv $\langle 001 \rangle$ and so on. As either sample current or Hall voltage is in $\langle 1\bar{1}0 \rangle$ direction in the present case and both are permutable each other[4], indication of the direction is omitted in the notation. Although no cross magneto-resistance effect[4] appears in these orientations, Hall coefficient is determined according to the usual way by reversing the magnetic field and the sample current and averaging the observed Hall voltages. It was found in our case that the reversal of current had no important effect upon the results. First of all, the vital point for precise experiments was to

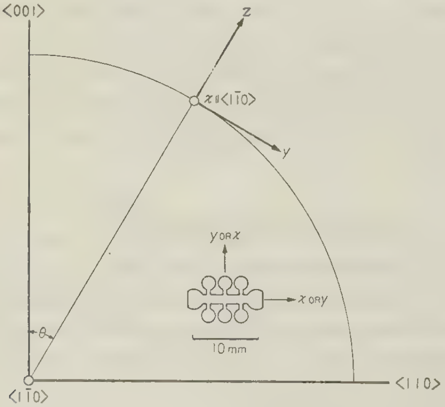

Fig. 1. Geometry of specimen and direction of magnetic field $\boldsymbol{H}$, sample current $\boldsymbol{I}$ and Hall voltage $\boldsymbol{V_H}$. θ is chosen as a parameter.

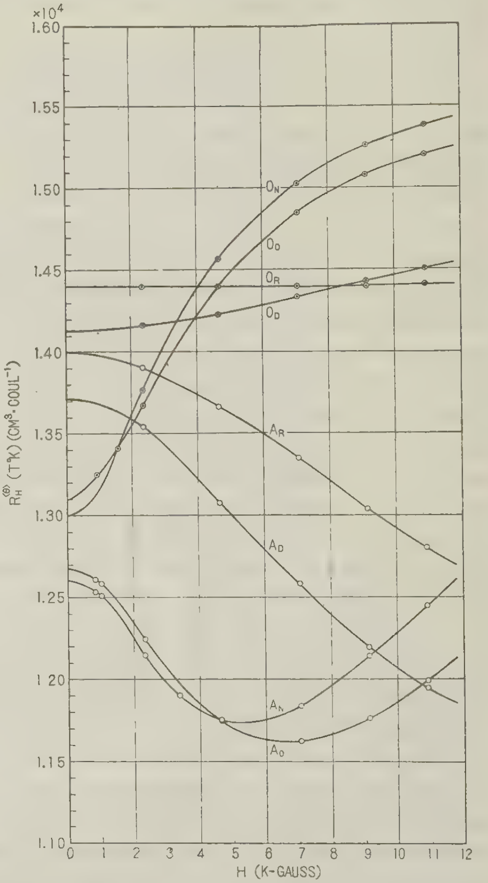

Fig. 2. $R_H^{\langle001\rangle}(T°\mathrm{K})$ and $R_H^{\langle110\rangle}(T°\mathrm{K})$ plotted against H. ⟨001⟩ sample is designated as " O ", and ⟨110⟩ as " A ". Subscripts R, D, etc. represent specified temperatures: i.e., R≡room temperature (298°K), D≡dry ice (195°K), O≡liquid oxygen (90°K), and N≡liquid nitrogen (77°K).

obtain low-resistance contacts for the specimens. In order to realize good ohmic contacts, electrode- and probe-arms were electroplated with rhodium or alloyed with tin-antimony alloy so as to be more n-type before soldering. There was no difference at room temperature between both treatments, where the contacts were always satisfactory, while at low temperatures the latter showed better results in contrast with facts that the former sometimes cracked or frequently made potentiometer balance insensible with slight contact resistance. Hence the alloying contacts were used in most specimens, though they required somewhat elaborate processes.

§ 3. Experimental Results

A. $R_H^{\langle\theta\rangle}$ vs H at several specified temperatures

Several curves of Hall coefficients for two typical high symmetry orientations are shown in Fig. 2. The following facts are notable here;

(1) that both $R_0^{\langle 001\rangle}(T°\mathrm{K})$ and $R_0^{\langle 110\rangle}(T°\mathrm{K})$ increase with increasing temperatures in the same proportion, and

(2) that $R_H^{\langle 001\rangle}(298°\mathrm{K})$ is strikingly field insensitive while other R_H's in both orientations vary in quite different manners.

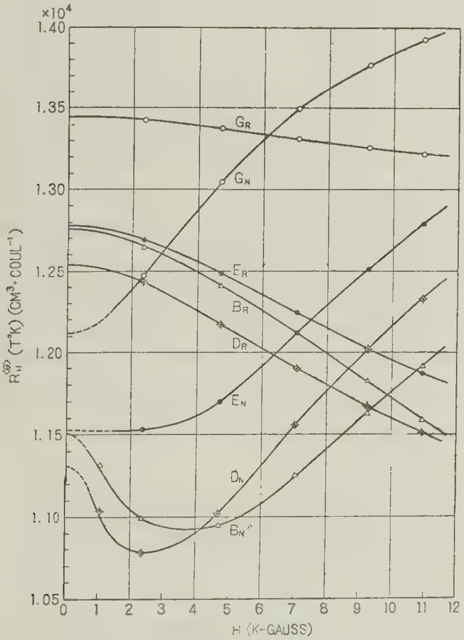

Fig. 3. $R_H^{\langle\theta\rangle}(T°\mathrm{K})$ vs H for several orientations. $\langle\theta\rangle=\langle 75°\rangle$ for sample B, $\langle 111\rangle$ for D, $\langle 112\rangle$ for E, and $\langle 15°\rangle$ for G. Subscripts are the same to Fig. 2.

Since carrier concentrations never decrease with increasing temperatures or hardly depend upon magnetic field strengths and directions, it is evident that behaviors of these curves should be ascribed to relative changes in μ_H/μ.

Fig. 3 shows several sets of Hall coefficients for specimens of other orientations.

B. Determination of $R_\infty^{\langle 001\rangle}(77°\mathrm{K})$ and $\mu_H/\mu\cdot\langle 001\rangle_H$

At high magnetic field and low temperatures a constant mean free time approximation for $R_H^{\langle 001\rangle}$ is very good as demonstrated by Bullis et al[9], and the Hall coefficient for an inifinite magnetic field, $R_\infty^{\langle 001\rangle}(77°\mathrm{K})$, is determined by plotting $R_H^{\langle 001\rangle}(77°\mathrm{K})$ as a function of $1/H^2$ and extraporating linearly to the value of $H=\infty$ as shown in Fig. 4. Since μ_H/μ at infinite magnetic field always equals unity irrespective of the crystal orientations, the mass ratio and the scattering mechanism as discussed in the theory. $R_H^{\langle 001\rangle}(T°\mathrm{K})/R_\infty^{\langle 001\rangle}\cdot(77°\mathrm{K})$ in the specimen should straightway give the absolute values of $\mu_H/\mu\langle 001\rangle_H$ provided the carrier concentration is constant. The constancy of the carrier will be discussed in the later section.

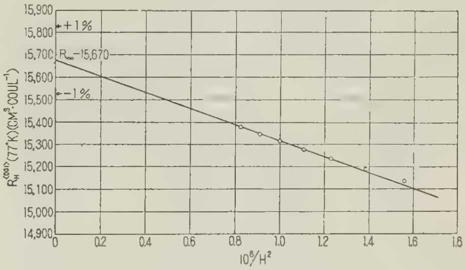

Fig. 4. $R_H^{\langle 001\rangle}(77°\mathrm{K})$ vs $1/H^2$. Determination of R_∞.

C. Evaluation of $\mu_H/\mu\langle\theta\rangle_H$

Since $R_\infty^{\langle\theta\rangle}(77°\mathrm{K})$ cannot be determined by simple extraporation method, $\mu_H/\mu\langle\theta\rangle_H$ must be indirectly evaluated in some other way. This is possible by noting a fact that the Hall coefficient for zero field is also independent of the crystal orientations, that is to say, $R_0^{\langle\theta\rangle}(T°\mathrm{K})ne$ should be equal to $R_0^{\langle 001\rangle}(T°\mathrm{K})n'e$ where n and n' are carrier concentrations of respective specimens and e is electronic charge. In the ideal case n and n' should be equal, but actually slight difference is inevitable because of the fluctuation in impurity concentration, even if the specimens are cut from the same ingot. Fortunately, $\mu_H/\mu(T°\mathrm{K})$ is a rather slowly varying function of the impurity concentration. Therefore, the effect of the difference in n on μ_H/μ will be neglected here, regarding it as insignificant. Fig. 5 shows the values of $\mu_H/\mu\langle\theta\rangle_H$ determined in these manners.

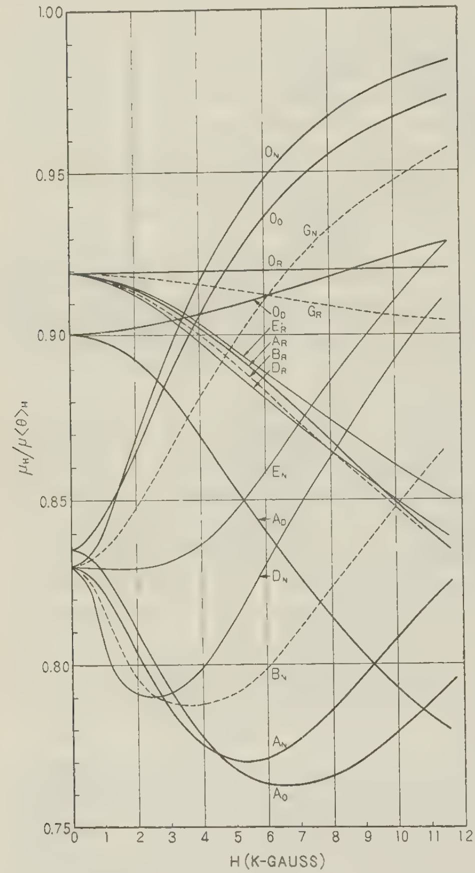

Fig. 5. Variations of $\mu_H/\mu\langle\theta\rangle_H$ at four temperatures with H.

In addition to the fact that considerably anisotropic features observed by Mason et al[5] and also by Bullis[9],[10] were reproduced here, it was explicitly examined for the first time that the values of μ_H/μ at usual magnetic field strengths and at usual exhaustion temperatures pass through a region fairly lower than unity in contrast with Morin's data[6].

As for the room temperature data, low field expansion formula,

$$R_H^{\langle\theta\rangle}=R_0(1+\xi^{\langle\theta\rangle}H^2+\eta^{\langle\theta\rangle}H^4+\zeta^{\langle\theta\rangle}H^6) \quad (3.1)$$

is valid in the whole range of measured magnetic field, and empirical values of coefficients, $\xi^{\langle\theta\rangle}$, $\eta^{\langle\theta\rangle}$ and $\zeta^{\langle\theta\rangle}$, are summarized in Table I, which also gives R_0, ρ_0 and μ_H. Theoretically calculated $\xi_c^{\langle\theta\rangle}$'s are also listed in Table I, where agreement between $\xi^{\langle\theta\rangle}$ and $\xi_c^{\langle\theta\rangle}$ seems to be satisfactory.

D. Reproductibility of $\mu_H/\mu(T°\mathrm{K})$

It will be desirable to check whether the assumption of constant carrier concentration irrespective of temperature is allowable or not. Though any orthodox examination is not available since variations of carrier concentration and μ_H/μ with temperatures is inseparable in the experiments, it may be worth-while to examine the reproducibility of μ_H/μ on specimens cut from different ingots which may contain different concentrations of uncotrolled centers. These uncontrolled centers which capture electrons at low temperatures may be ionized in some degree at room temperature, resulting in the increase in conduction electrons which, in turn, may cause the decrease in Hall coefficients. If observed values of $R_H^{\langle\theta\rangle}(T°\mathrm{K})/R_\infty(77°\mathrm{K})$ in each specimen were too much random, reliable determination of $\mu_H/\mu(T°\mathrm{K})$ may be hopeless,

2-13-02	7,567	8,330	0.909

* $R_H^{<001>}(298°\text{K})$ is field independent, and the value at 2355 gauss is taken as $R_0(298°\text{K})$.

though larger values are favorable.

The check was carried out on several ⟨001⟩ specimens, of which results always showing fairly good reproducibility are given in Table II. From these results it may be concluded (1) that the carrier contribution from the uncontrolled centers is fortunately insignificant, or otherwise, (2) that the contribution, if any, is very similar for all ingots. If the latter were the case, the present deduction for $\mu_H/\mu(T°\text{K})$ will be confused, and further discussion will be done in the later section.

§ 4. Theoretical Analysis

A. Model for scattering mechanism

An empirical fact of strikingly field independent R_H (298°K) cannot be explained by Abeles-Meiboom's theory[2] and will suggest that slight impurity scattering is important[1] even at room temperature. In the present case, therefore, mixed scattering will be taken into account, where the relaxation time will be treated not as a power function of electron energy but as a combination of lattice and impurity scatterings. Following Herring-Vogt[8], consider an ellipsoid model for relaxation time similar to effective mass, and denote the principal value along longitudinal axis ⟨111⟩ of an energy ellipsoid as τ_l and that along transverse axis as τ_t. Then,

$$\begin{aligned} 1/\tau_t &= \sqrt{kT}/l\ (x^{1/2}+\delta^2 x^{-3/2}) \\ 1/\tau_l &= \sqrt{kT}/l(x^{1/2}+r\delta^2 x^{-3/2}) \qquad (4.1) \\ x &\equiv \mathcal{E}/kT \end{aligned}$$

where $\mathcal{E}$ is energy of electron, k Boltzmann's constant, l mean free path associated with acoustic phonon scattering, δ^2 a parameter indicating mixing rate of impurity scattering in the direction of transverse axis and r is an anisotropy parameter for pure ionized impurity scattering. It has been cleverly determined by Laff and Fan's magnetoresistance experiment[11] that r equals 1/12, while acoustic phonon scattering is isotropic. These results will be utilized here, too. According to deformation potential theory[12] and Conwell-Weisskopf's theory[13], temperature dependence of δ^2 will be approximately given by

$$\delta^2 \infty (kT)^{-3}\ . \qquad (4.2)$$

If the anisotropy of impurity scattering is neglected, δ^2 corresponds to β or $6\mu_L/\mu_I$ given by Johnson-Whitesell[1]. That is to say,

$$\delta^2 \simeq 6\mu_L/\mu_I\ . \qquad (4.2a)$$

B. Conductivity tensor and expression of Hall Coefficient

Now let us consider non-degenerate case and Boltzmann satistics will be assumed. From Boltzmann's equation, the conductivity tensor associated with principal axes of an ellipsoid will be given in the following form, when magnetic field $\boldsymbol{H}(H_1, H_2, H_3)$ is applied,

$$\begin{aligned} \sigma_{11} &= uK\alpha + uv^2K^2\gamma H_1^2 \\ \sigma_{22} &= uK\alpha + uv^2K^2\gamma H_2^2 \\ \sigma_{33} &= u\alpha^* + uv^2K^2\gamma H_3^2 \\ \sigma_{12} &= -uvK^2\beta H_3 + uv^2K^2\gamma H_1H_2 = \sigma_{21}(-\boldsymbol{H}) \\ \sigma_{23} &= -uvK\beta^* H_1 + uv^2K^2\gamma H_2H_3 = \sigma_{32}(-\boldsymbol{H}) \qquad (4.3) \\ \sigma_{31} &= -uvK\beta^* H_2 + uv^2K^2\gamma H_3H_1 = \sigma_{13}(-\boldsymbol{H}) \\ K &\equiv m_3/m_1 = m_3/m_2 \\ u &\equiv Ne^2(l/m_3)(kT)^{-1/2}4/3\sqrt{\pi} \\ v &\equiv (e/c)(l/m_3)(kT)^{-1/2} \end{aligned}$$

where suffix 3 corresponds to longitudinal one and 1, 2 transverse, m_1, m_2 and m_3 are principal values for respective axis of effective mass tensor, K anisotropy parameter for effective mass, N carrier concentration per valley, $-e$ electronic charge. $K=20$ will be used[7] in the present analysis.

α, β etc. are integrals as shown in the following:

$$\begin{aligned}
\alpha(\delta^2,\ p;\ s) &\equiv \int_0^\infty F^{-1}(x^2+\delta^2)(x^2+r\delta^2)x^3 e^{-x} dx \\
\alpha^*(\delta^2,\ p;\ s) &\equiv \int_0^\infty F^{-1}(x^2+\delta^2)^2 x^3 e^{-x} dx \\
\beta(\delta^2,\ p;\ s) &\equiv \int_0^\infty F^{-1}(x^2+r\delta^2)x^{9/2} e^{-x} dx \\
\beta^*(\delta^2,\ p;\ s) &\equiv \int_0^\infty F^{-1}(x^2+\delta^2)x^{9/2} e^{-x} dx \\
\gamma(\delta^2,\ p;\ s) &\equiv \int_0^\infty F^{-1} x^6 e^{-x} dx
\end{aligned} \tag{4.4}$$

where

$$\begin{aligned}
&F(x,\ \delta^2,\ p;\ s) \equiv (x^2+\delta^2)^2(x^2+r\delta^2)+p(x^5+s\delta^2x^3) \\
&p \equiv v^2(KH_1^2+KH_2^2+K^2H_3^2) \\
&s \equiv (KH_1^2+KH_2^2+rK^2H_3^2)/(KH_1^2+KH_2^2+K^2H_3^2).
\end{aligned}$$

Let $\{\Sigma\}$ be conductivity tensor viewed from the observing coordinate system as chosen in Fig. 1, where magnetic field $\boldsymbol{H}$ is in z direction, current $\boldsymbol{J}$ in x and Hall voltage V_H in y direction. Then, the Hall coefficient is given by

$$R_H^{\langle\theta\rangle} = \frac{1}{H} \frac{-\Sigma_{yx}}{\Sigma_{xx}\Sigma_{yy}-\Sigma_{yx}\Sigma_{xy}} . \tag{4.5}$$

Assuming four ellipsoid model possessing [111] longitudinal axes, transformation of $\{\sigma\}$ to the observing coordinate system can be performed in two steps just like Abeles-Meiboom's fashion[2]. (See Appendix.)

Several expressions interested in the present experiment will be given in the following.

(1) Isotropic quantities

Zero field Hall coefficient is independent of orientations and expressed by

$$R_0 = -\left(\frac{3\pi}{8}\right)\frac{1}{nec}\left\{\frac{2}{\sqrt{\pi}}\frac{3K(K\beta_0+2\beta_0^*)}{(2K\alpha_0+\alpha_0^*)^2}\right\} \tag{4.6}$$

where n is total carrier concentration and equal to $4N$. As for conductivity and Hall mobility,

$$\sigma_0 = (4/3)u(2K\alpha_0+\alpha_0^*) \tag{4.7}$$

$$\mu_H = |R_0\sigma_0| = |v| \frac{K(K\beta_0+2\beta_0^*)}{2K\alpha_0+\alpha_0^*} . \tag{4.8}$$

Here α_0, β_0, etc. are the values for $H=0$ or $p=0$, i.e.[14],

$$\begin{aligned}
\alpha_0 &= \int_0^\infty \frac{x^3 e^{-x} dx}{x^2+\delta^2} \equiv 3!\,\mathfrak{L}_3(\delta) \\
\alpha_0^* &= 3!\,\mathfrak{L}_3(\delta\sqrt{r}) \\
\beta_0 &= \int_0^\infty \frac{x^{9/2} e^{-x}\, dx}{(x^2+\delta^2)^2} \equiv (9/2)!\,\vartheta_{9/2}(\delta) \\
\beta_0^* &= \frac{1}{1-r}(9/2)!\,\frac{1}{\delta^2}\{\mathfrak{L}_{9/2}(\delta\sqrt{r})-\mathfrak{L}_{9/2}(\delta)\} .
\end{aligned} \tag{4.9}$$

Meanwhile, infinite field Hall coefficient is also isotropic and simply given by

$$R_\infty = -\frac{1}{nec}\ . \tag{4.10}$$

(2) Anisotropic quantities

$$\frac{R_H^{\langle 001\rangle}}{R_0} = \frac{\dfrac{K\beta+2\beta^*}{K\beta_0+2\beta_0^*}}{\left(\dfrac{2K\alpha+\alpha^*}{2K\alpha_0+\alpha_0^*}\right)^2 + \left(\dfrac{K\beta+2\beta^*}{K\beta_0+2\beta_0^*}\right)^2(\mu_H H)^2} \tag{4.11}$$

where

$$r=1/12\ ,$$
$$s=(rK+2)/(K+2)=1/6$$
$$p=(1/3)\frac{(K+2)}{K}\left(\frac{2K\alpha_0+\alpha_0^*}{K\beta_0+2\beta_0^*}\right)^2(\mu_H H)^2\ .$$

$$\frac{R_H^{\langle 111\rangle}}{R_0} = \frac{\dfrac{K(3\beta^{(1)}+\beta^{(2)})+8\beta^{*(2)}}{4(K\beta_0+2\beta_0^*)}}{\left\{\dfrac{3K\alpha^{(1)}+5K\alpha^{(2)}+4\alpha^{*(2)}}{4(2K\alpha_0+\alpha_0^*)}\right\}^2 + \left\{\dfrac{K(3\beta^{(1)}+\beta^{(2)})+8\beta^{*(2)}}{4(K\beta_0+2\beta_0^*)}\right\}^2(\mu_H H)^2} \tag{4.12}$$

where superscripts (1) or (2) indicate that the following p and s should be substituted into α or β.

$$p=\left(\frac{2K\alpha_0+\alpha_0^*}{K\beta_0+2\beta_0^*}\right)^2(\mu_H H)^2\ , \qquad s=r=1/12$$

for superscript (1), and

$$p=\left(\frac{K+8}{9K}\right)\left(\frac{2K\alpha_0+\alpha_0^*}{K\beta_0+2\beta_0^*}\right)^2(\mu_H H)^2\ , \qquad s=\frac{rK+8}{K+8}=29/84$$

for superscript (2).

C. Numerical values and comparison with experiments

(1) Weak field behavior of R_H

Low field Hall coefficients may be expanded in a series with even powers of $\mu_H H$, of which form is expected from Eqs. (4.4) and (4.8) to be

$$R_H^{\langle\theta\rangle} = R_0\{1+a^{\langle\theta\rangle}(\mu_H H)^2 + b^{\langle\theta\rangle}(\mu_H H)^4 - \cdots\}\ . \tag{4.13}$$

In order to determine the coefficients $a^{\langle\theta\rangle}$ and $b^{\langle\theta\rangle}$ for specific orientations, integrals in (4.11) and (4.12) should be expanded in power series of p.

$$\begin{aligned}
\alpha &= \sum_{n=0}^{\infty}(-1)^n\alpha_n p^n, & \alpha_n &= \int_0^\infty \frac{(x^5+s\delta^2x^3)^n x^3 e^{-x}}{(x^2+\delta^2)^{2n+1}(x^2+r\delta^2)^n}dx \\
\alpha^* &= \sum_{n=0}^{\infty}(-1)^n\alpha_n^* p^n, & \alpha_n^* &= \int_0^\infty \frac{(x^5+s\delta^2x^3)^n x^3 e^{-x}}{(x^2+\delta^2)^{2n}(x^2+r\delta^2)^{n+1}}dx \\
\beta &= \sum_{n=0}^{\infty}(-1)^n\beta_n p^n, & \beta_n &= \int_0^\infty \frac{(x^5+s\delta^2x^3)^n x^{9/2} e^{-x}}{(x^2+\delta^2)^{2n+2}(x^2+r\delta^2)^n}dx \\
\beta^* &= \sum_{n=0}^{\infty}(-1)^n\beta_n p^n, & \beta^*_n &= \int_0^\infty \frac{(x^5+s\delta^2x^3)^n x^{9/2} e^{-x}}{(x^2+\delta^2)^{2n+1}(x^2+r\delta^2)^{n+1}}dx\ .
\end{aligned} \tag{4.14}$$

Numerical values of several α_n's and β_n's are summarized in Table III. Substituting (4.14) in (4.11) and (4.12), $a^{\langle\theta\rangle}$ and $b^{\langle\theta\rangle}$ in (4.13) will be given by

Table III.

s &\equiv \frac{rK+8}{K+8}=\frac{29}{84} \qquad \text{for superscript (2)}
\end{aligned} \tag{4.17}$$

Fig. 6 indicates $a^{\langle\theta\rangle}(\delta)$ thus calculated.

It is a remarkable result that sign reversal of $a^{\langle 001\rangle}$ takes place at $\delta\sim0.1$. In view of the fact that $R_H^{\langle 001\rangle}$(298°K) is independent of field strength at weak field, it is believed that δ must be nearly 0.1 at room temperature in the present crystals. Another information about δ can be obtained from (4.2a) using Conwell's μ_I for $N_I=5\times10^{14}$ and μ_L at room temperature[13], resulting in $\delta\sim0.14$, which agrees fairly well with the value above mentioned.

In order to compare (4.13) with (3.1), $\xi_c^{\langle\theta\rangle}\equiv a^{\langle\theta\rangle}\mu_H{}^2$'s were calculated by assuming δ 0.1 at 298°K and by using $\mu_H\sim3{,}800$ together with the theoretical curves for $a^{\langle\theta\rangle}$ shown in Fig. 6. Cubic symmetry relations[5] were used to calculate $\xi_c^{\langle\theta\rangle}$ except $\xi_c^{\langle 001\rangle}$ and $\xi_c^{\langle 111\rangle}$. As indicated in Table I, satisfactory agreement between $\xi^{\langle\theta\rangle}$ and $\xi_c^{\langle\theta\rangle}$ was obtained. These features will predict weak field behaviors of Hall coefficients for crystals of any resistivity or at any temperature not actually measured, by sliding δ with the relations of (4.2) and (4,2a).

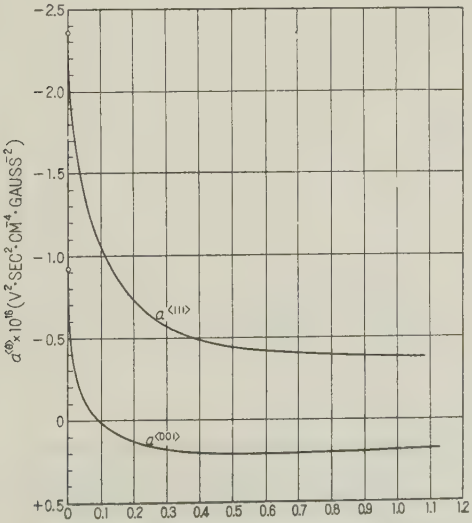

Fig. 6. Weak field expansion coefficient $a^{\langle\theta\rangle}(\delta)$.

(2) Temperature dependence of R_0/R_∞

From (4.6) and (4.10) R_0/R_∞ or μ_H/μ at zero field is easily obtained.

$$\begin{aligned}
\frac{R_0}{R_\infty} &= \frac{3\pi}{8}\frac{3K(K+2)}{(2K+1)^2}I(\delta) \\
I(\delta) &= \frac{2}{\sqrt{\pi}}\frac{(2K+1)^2}{K+2}\frac{(K\beta_0+2\beta_0{}^*)}{(2K\alpha_0+\alpha_0{}^*)^2}
\end{aligned} \tag{4.18}$$

Fig. 7 shows the behavior of $I(\delta)$, where solid curve is calculated with $K=20$ and $r=1/12$, while two broken curves correspond (1) to the one in which $K=15$ and $r=1/12$ are assumed, and (2) to the one in which $K=20$ and $r=1$, respectively. It is found that

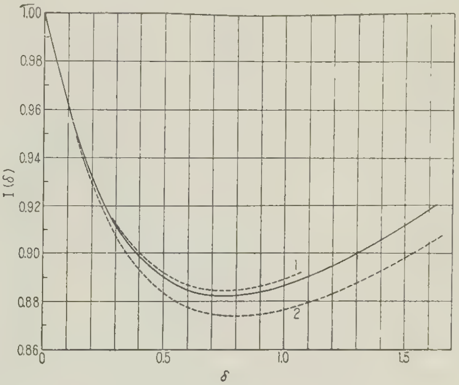

Fig. 7. $I(\delta)$ vs δ. Solid curve; $K=20$, $r=1/12$.
Broken curve 1; $K=15$, $r=1/12$.
Broken curve 2; $K=20$, $r=1$.

isotropic impurity scattering depresses the minimum of $I(\delta)$ to some extent, while mass ratio does not too much affect $I(\delta)$. When $\delta=0$, (4.18) coincides with Abeles-Meiboom or Shibuya's formula[2),3)].

For the purpose of comparison with experimental data, it will be convenient to draw the R_0/R_∞ curve not against δ but against temperature. From (4.2) and previous inference on δ, let us now assume

$$\delta(T)=0.1(300/T)^{3/2}\,. \tag{4.19}$$

Substituting (4.19) in (4.18), R_0/R_∞ will become a function of temperature. The resultant R_0/R_∞ vs T curve is illustrated in Fig. 8. It is seen that R_0/R_∞ has a minimum of 0.82 near liquid nitrogen temperature in the present case. Meanwhile, under constant mean free time assumption investigated by Bullis and Krag[9)] the minimum of R_0/R_∞ was 0.79. Of course, better agreement with experiments can be obtained in the present case, though exact experimental determination of R_0's is somewhat difficult at 77°K and 90°K. The discrepancy at zero field may be a fault of the constant mean free time approximation.

In Fig. 8 two other R_0/R_∞ vs T curves, in which (1) δ is chosen by Conwell-Weisskopf's formula or (2) isotropic impurity scattering is assumed, are also presented. It seems theoretical R_0/R_∞'s have qualitatively explained the behavior of experimental data. However, a tendency cannot be overlooked that the observed values deviate upwards from the theoretical curves, especially at higher temperatures, where no possibility depressing the observed points is expected. As will be discussed in the later section, this might suggest that some correction such as optical phonon scattering is necessary. Remarks on the curve 3 in Fig. 8 will be given in the next section.

§ 5. Discussions

A. Constancy of carriers

Applying Fermi satistics to a semiconductor containing 5×10^{14} donors, N_d, per cm^3 of which energy level, E_d, lies at 0.01 eV below the conduction band edge, the rate of exhaustion can be easily determined at any temperature. This is the ideal case in the pre-

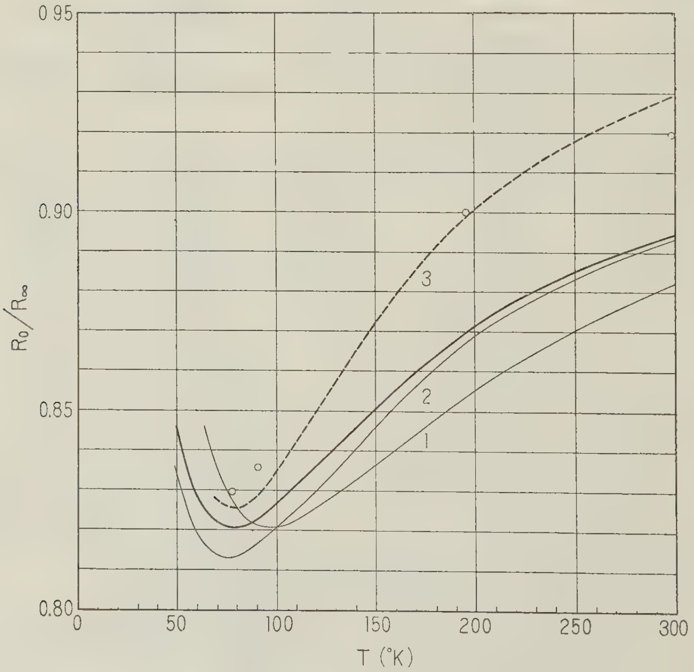

Fig. 8. R_0/R_∞ vs T. Open circles are experimental. Solid curve; calculated with $\delta=0.1\cdot(300/T)^{3/2}$, $K=20$, $r=1/12$. Thin curve 1; $\delta=0.14(300/T)^{3/2}$, derived from Conwell's μ_I is used instead of above δ. Thin curve 2; $r=1$ or isotropic impurity scattering is assumed, leaving δ and K unchanged. Broken curve 3; modified by optical phonon scattering.

Table IV. Rate of exhaustion and corresponding Fermi energy in a semiconductor, in which $N_d=5\times10^{14}$ cm^{-3}, $E_d=0.01$ eV and $(m^*/m)^{3/2}=0.4$.

	77°K	90°K	195°K	298°K
$N_d/n(T\,°\mathrm{K})$	1.0017	1.0011	1.0002	1.00006
$n(T\,°\mathrm{K})/n(77\,°\mathrm{K})$	1.0000	1.0006	1.0015	1.0016
$\zeta(T\,°\mathrm{K})$ eV	−0.052	−0.063	−0.156	−0.254

sent specimens. Table IV shows the ratio $N_d/n(T\,°\mathrm{K})$, $n(T\,°\mathrm{K})/n(77\,°\mathrm{K})$ and Fermi energy $\zeta(T\,°\mathrm{K})$. It is seen that the assumption of constant carriers is well assured in the ideal case.

However, actual specimens may naturally contain some uncontrolled imperfections, from which ionization is possible at higher temperatures. Then, let us consider the maximum concentration of these uncontrolled centers. One clue will be to measure the mean lifetime of injected minority carriers. In most crystals used here the lifetime by means of photoconductivity decay method was about 200 μsec at room temperature. According to Burton et al[15] the value of 200 μsec is their highest limit for 3 ohm-cm n-type germanium, where the concentration of the unknown recombination centers, N_x, may be estimated to be less than 1×10^{13} per cm^3. Though it is not clear what the sources of N_x are, probably they consist of crystal imperfections such as dislocations or vacancies and chemical impurities. As a matter of fact main centers concerned with the carrier contribution are those having energy levels near or between Fermi levels at liquid nitrogen and room temperatures. Therefore, dislocations, which have been proved to have an acceptor level about 0.2 eV below the conduction band[16], must be considered in the first place, since they are substantially empty at room temperature but can occupy electrons at low temperatures. According to the reciprocal law between lifetime and dislocation density[17], the lifetime of nearly 500 μsec, which is two or three times was large as the observed one, will be expected at room temperature using measured dislocation density of about 5×10^3 per cm^2 or less in our crystals. Thus it would appear that dislocations are an important factor among N_x concerned with the carrier contribution, even if Read's theory has concluded[18] that only relatively few of dislocation sites will be filled at low temperatures because of space charge effect. The remaining fraction of N_x might be due to chemical impurities, copper for example, and frozen-in vacancies, though their solubility[19] is rather small. These centers possess their energy levels near or below the middle of the gap[20] and do not much affect the number of carriers.

In consequence, the temperature effect of uncontrolled centers on number of carriers would be fortunately insignificant, and the resultant undesirable shift of $R_H(T\,°\mathrm{K})$ due to carrier change should be at most within 2 percent even in the worst case.

B. Thermomagnetic effect

Since the Ettinghausen effect cannot be excluded in the experiment, it will be necessary to confirm negligible contribution of the effect to Hall voltage. Ettinghausen effect, entirely the same with Hall effect, can be written in the form

$$\Delta T=PIH/d \tag{5.1}$$

where ΔT, P, I, and d are temperature difference across the specimen, Ettinghausen coefficient, total current and thickness of the specimen respectively. As for P, Mette et al[21] have obtained the value of nearly 10^{-6} deg. cm. amp.$^{-1}$ gauss^{-1} for 3 ohm-cm n-type germanium at 300°K. Using this result with the present experimental conditions of $I\sim0.5$ mA and $d\sim1$ mm, (5.1) gives $\Delta T\sim5\times10^{-5}$ deg. at $H=10^4$ gauss. Considering the Seebeck effect of which order is 1 mV per deg. carried out by Geballe and Hull,[22] the resultant electromotive force should be approximately equal to 0.05 μV. Consequently, this is quite negligible as compared with Hall voltage of about 10 mV at 10^4 gauss, and it may be concluded that even phonon-drag effect at low temperatures is out of the question.

C. Optical phenon scattering

Plotting the observed values of R_0/R_∞ against temperature, it seems that they are somewhat lager than the theoretical ones as already shown in Fig. 8. Furthermore, there may be a possibility that $R_0/R_\infty(298°\text{K})$ shifts within 2 per-cent toward higher value, in view of the doubt in carrier constancy. Though the discrepancy is not so definite that the theoretical analysis may be radically modified, it is yet suggested that some correction is desirable.

One resonable approach will be to consider the effect of optical phonon scattering, which has bee used to explain a fact that the temperature dependence of conduction electron mobility does not obey the exact $-3/2$ power law but rather follows -1.66 power law[6] in very pure crystals. In order to understand this behavior, Herring[23] has proposed to take account of intervalley scattering, while Weinreich et al[24] have insisted that the effect should be ascribed not to intervalley scattering but to optical phonon scattering with their experiments on acousto-electric effect.

Then, a trial calculation was carried out by adding a term $1/\tau_0$ due to optical phonon to Eq. (4.1). Here, $1/\tau_0$ is given by

$$1/\tau_0=\frac{\sqrt{kT}}{l}\begin{cases} C\dfrac{\gamma}{e^\gamma-1}\sqrt{x+\gamma}+C\dfrac{\gamma}{1-e^{-\gamma}}\sqrt{x-\gamma} & x>\gamma \\ C\dfrac{\gamma}{e^\gamma-1}\sqrt{x+\gamma} & x<\gamma. \end{cases} \tag{5.2}$$

where $\gamma\equiv\theta_0/T$. Using $\theta_0\sim432°\text{K}$ obtained by Brockhouse et al[25] by means of neutron diffraction, and by assuming $C=0.125$ which seems to be acceptable, broken curve 3 shown in Fig. 8 has been calculated, resulting in better agreement with the observed values.

§ 6. Conclusions and Acknowledgments

Anisotropic values of μ_H/μ appearing in Hall coefficients in n-type germanium have been precisely observed at four specifield temperatures and theoretically discussed under ellipsoid model and mixed scattering. Experimental results have elucidated the importance of slight impurity scattering. It has been also clarified that μ_H/μ's at usual magnetic field strengths are considerably anisotropic and almost always smaller than unity. These features are well explained by the theoretical analysis.

In case μ_H/μ is assumed to be $3\pi/8$ in ordinary Hall measurements, it is rather recommended that a value of 0.9, in place of $3\pi/8$, is used in non-degenerate n-type germanium. For further arguments, the following facts should be remembered even if number of carriers remains unchanged:

(1) R_0 decreases at first with decreasing temperature, reaches a minimum, and then begins to rise again.

(2) Unless θ is very small, $R_H^{\langle\theta\rangle}$ generally decreases at first with increasing field, reaches a minimum, and then increases toward its infinite field value.

(3) $R_H^{\langle 001\rangle}$ approaches its infinite field value in most straightforward way without initial decreasing.

Careful experiments of this kind may be utilized to detect the small mixing rate of ionized impurity scattering into lattice scattering or may be helpful to determine the symmetry property of energy band structure in a semiconductor. These knowledges will be also useful to apply the Hall effect to some devices.

Finally, the authors wish to acknowledg the support of Dr. H. Muraoka and Mr. T. Abe of Toshiba Transistor Plant who prepared and oriented the crystal. They are also greateful to Dr. M. Shibuya of the Electrotechnical Laboratory for many helpful suggestions and discussions. Mr. T. Kikuchi and Miss E. Komiyama assisted with many of the numerical calculations and the experimental measurements.

Appendix I. Transformation of $\{\sigma\}$ into $\{\Sigma\}$

(1) {S}, Conductivity tensor in respect to crystal axis system

The transformation must be performed in two steps. First, the components of $\{\sigma\}^{(i)}$, the conductivity tensor viewed from the i-th valley system (i), are transformed into the crystal axis system (c), while $\boldsymbol{H}^{(i)}$ in $\{\sigma\}^{(i)}$ are fixed as parameters. Here $\boldsymbol{H}^{(i)}$ is the set of the components of magnetic field $\boldsymbol{H}$ viewed from the i-th valley system. Let the transformation tensor be $\{\mathrm{A}\}^{(i)}$, defined for a vector $\boldsymbol{v}$ as

$$\boldsymbol{v}^{(i)}=\{\mathrm{A}\}^{(i)}\cdot\boldsymbol{v}^{(c)}\ . \tag{A.1}$$

Then we obtain

$$\{\mathrm{S}'\}=\sum_{i}\{\mathrm{A}\}^{(i)-1}\cdot\{\sigma(\boldsymbol{H}^{(i)})\}^{(i)}\cdot\{\mathrm{A}\}^{(i)}\ . \tag{A.2}$$

Secondly, $\boldsymbol{H}^{(i)}$'s in $\{\mathrm{S}'\}$ are replaced by the original magnetic field referred to the new system. This can be performed by substituting

$$\boldsymbol{H}^{(i)}=\{\mathrm{A}\}^{(i)}\cdot\boldsymbol{H}^{(c)} \tag{A.3}$$

in (A.2).

Table A—I.

$\{\mathrm{A}\}^{(1)}$ $\langle 111\rangle,\ \langle\bar{1}\bar{1}\bar{1}\rangle$	$\{\mathrm{A}\}^{(2)}$ $\langle 1\bar{1}1\rangle,\ \langle\bar{1}1\bar{1}\rangle$	$\{\mathrm{A}\}^{(3)}$ $\langle\bar{1}\bar{1}1\rangle,\ \langle 11\bar{1}\rangle$	$\{\mathrm{A}\}^{(4)}$ $\langle\bar{1}11\rangle,\ \langle 1\bar{1}\bar{1}\rangle$
$\begin{bmatrix}\frac{-1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0\\ \frac{-1}{\sqrt{6}} & \frac{-1}{\sqrt{6}} & \frac{2}{\sqrt{6}}\\ \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}}\end{bmatrix}$	$\begin{bmatrix}\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0\\ \frac{-1}{\sqrt{6}} & \frac{1}{\sqrt{6}} & \frac{2}{\sqrt{6}}\\ \frac{1}{\sqrt{3}} & \frac{-1}{\sqrt{3}} & \frac{1}{\sqrt{3}}\end{bmatrix}$	$\begin{bmatrix}\frac{1}{\sqrt{2}} & \frac{-1}{\sqrt{2}} & 0\\ \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{6}} & \frac{2}{\sqrt{6}}\\ \frac{-1}{\sqrt{3}} & \frac{-1}{\sqrt{3}} & \frac{1}{\sqrt{3}}\end{bmatrix}$	$\begin{bmatrix}\frac{-1}{\sqrt{2}} & \frac{-1}{\sqrt{2}} & 0\\ \frac{1}{\sqrt{6}} & \frac{-1}{\sqrt{6}} & \frac{2}{\sqrt{6}}\\ \frac{-1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}}\end{bmatrix}$

In n-type germanium, $\{\mathrm{A}\}^{(i)}$'s are given in Table A.I. Thus we obtain, denoting the field components referred to the crystal axis system as H_1, H_2, H_3,

$$\begin{aligned}
S_{11}&=u\sum_{i=1}^{4}[(1/3)\{2K\alpha(p^{(i)},\ s^{(i)})+\alpha^*(p^{(i)},\ s^{(i)})\}+v^2K^2H_1^2\gamma(p^{(i)},\ s^{(i)})\\
S_{12}&=u\sum_{i=1}^{4}[(-1)^i(1/3)\{K\alpha(p^{(i)},\ s^{(i)})-\alpha^*(p^{(i)},\ s^{(i)})\\
&\quad-(1/3)(vK\{Kq^{(i)}\beta(p^{(i)},\ s^{(i)})+q^{*(i)}\beta^*(p^{(i)},\ s^{(i)})+v^2K^2H_1H_2\gamma(p^{(i)},\ s^{(i)})\\
S_{12}(\boldsymbol{H})&=S_{21}(-\boldsymbol{H})\ .
\end{aligned} \tag{A.4}$$

Here we must substitute the following relations into $p^{(i)}$'s, $s^{(i)}$'s, $q^{(i)}$'s and $q^{*(i)}$'s according to Eq. (A.3).

$$\begin{aligned}
p_1&=(1/3)v^2K\{(K+2)(H_1^2+H_2^2+H_3^2)+2(K-1)(H_1H_2+H_2H_3+H_3H_1)\}\\
p_2&=(1/3)v^2K\{(K+2)(H_1^2+H_2^2+H_3^2)+2(K-1)(-H_1H_2-H_2H_3+H_3H_1)\}\\
p_3&=(1/3)v^2K\{(K+2)(H_1^2+H_2^2+H_3^2)+2(K-1)(H_1H_2-H_2H_3-H_3H_1)\}\\
p_4&=(1/3)v^2K\{(K+2)(H_1^2+H_2^2+H_3^2)+2(K-1)(-H_1H_2+H_2H_3-H_3H_1)\}\\
s_1p_1&=(1/3)v^2K\{(rK+2)(H_1^2+H_2^2+H_3^2)+2(rK-1)(H_1H_2+H_2H_3+H_3H_1)\}\\
s_2p_2&=(1/3)v^2K\{(rK+2)(H_1^2+H_2^2+H_3^2)+2(rK-1)(-H_1H_2-H_2H_3+H_3H_1)\}\\
s_3p_3&=(1/3)v^2K\{(rK+2)(H_1^2+H_2^2+H_3^2)+2(rK-1)(H_1H_2-H_2H_3-H_3H_1)\}\\
s_4P_4&=(1/3)v^2K\{(rK+2)(H_1^2+H_2^2+H_3^2)+2(rK-1)(-H_1H_2+H_2H_3-H_3H_1)\}
\end{aligned} \tag{A.5}$$

$$\begin{aligned}
q_1&=H_1+H_2+H_3 & q_1^*&=-H_1-H_2+2H_3\\
q_2&=H_1-H_2+H_3 & q_2^*&=-H_1+H_2+2H_3\\
q_3&=-H_1-H_2+H_3 & q_3^*&=H_1+H_2+2H_3\\
q_4&=-H_1+H_2+H_3 & q_4^*&=H_1-H_2+2H_3\ .
\end{aligned} \tag{A.6}$$

The other components of S_{jk} are obtained by cyclic permutation of indices of H_l in Eqs. (A.4), (A.5) and (A.6).

(2) $\{\Sigma\}$, Conductivity tensor in respect to observing system

The transformation can be performed in the same way as in (1). Now let us define the tensor {G} as follows

$$\boldsymbol{v}^{(o)}=\{\mathrm{G}\}\cdot\boldsymbol{v}^{(c)}\,, \tag{A.7}$$

or

$$\begin{aligned} &\boldsymbol{J}/\!/\langle G_{11},\ G_{12},\ G_{13}\rangle \\ &\boldsymbol{V_H}/\!/\langle G_{21},\ G_{22},\ G_{23}\rangle \\ &\boldsymbol{H}/\!/\langle G_{31},\ G_{32},\ G_{33}\rangle\,. \end{aligned} \tag{A.8}$$

Then we obtain

$$\{\Sigma'\}=\{\mathrm{G}\}\cdot\{\mathrm{S}\}\cdot\{\mathrm{G}\}^{-1}\,. \tag{A.9}$$

Subsequently, $\boldsymbol{H}$ in (A.9) must be replaced as

$$H_1=G_{31}H,\ H_2=G_{32}H,\ H_3=G_{33}H\,. \tag{A.10}$$

In the present experimental situation,

$$\{\mathrm{G}\}=\begin{bmatrix} -1/\sqrt{2} & 1/\sqrt{2} & 0 \\ -(1/\sqrt{2})\cos\theta & -(1/\sqrt{2})\cos\theta & \sin\theta \\ (1/\sqrt{2})\sin\theta & (1/\sqrt{2})\sin\theta & \cos\theta \end{bmatrix} \tag{A.11}$$

in accordance with Fig. 1.

For $\langle 001\rangle_H$ case, for instance, we obtain from (A.9), (A.10) and (A.11),

$$\begin{aligned} \Sigma_{11}&=(1/2)(S_{11}+S_{22}-S_{12}-S_{21}) \\ \Sigma_{22}&=(1/2)(S_{11}+S_{22}+S_{12}+S_{21}) \\ \Sigma_{12}&=(1/2)(S_{11}-S_{22}+S_{12}-S_{21}) \\ \Sigma_{21}&=(1/2)(S_{11}-S_{22}-S_{12}+S_{21})\,, \end{aligned} \tag{A.12}$$

where

$$\begin{aligned} S_{11}&=S_{22}=(4/3)u\{2K\alpha(p,\ s)+\alpha^*(p,\ s)\} \\ S_{12}&=-S_{21}=-(4/3)uvK\{K\beta(p,\ s)+2\beta^*(p,\ s)\}H\,. \end{aligned} \tag{A.13}$$

In this case, following parameters have been used which are derived from (A.5) and (A.6) together with (A.10) and (A.11).

$$\begin{aligned} p&\equiv p_1=\cdots=p_4=(1/3)v^2K(K+2)H^2 \\ s&\equiv s_1=\cdots=s_4=(rK+2)/(K+2) \\ q_1&=\cdots=q_4=H \\ q_1^*&=\cdots=q_4^*=2H\,. \end{aligned} \tag{A.14}$$

We obtain $R_H^{\langle 001\rangle}$ by substituting (A.12) and (A.13) into (4.5), and then R_0 by taking $p=0$, from which (4.11) can be derived. (4.12) is also obtained in the similar way.

Appendix II. Condition for weak field expansion

Expansion of α etc. in respect to p is performed by rewriting the denominator of integrand in the following form,

$$\frac{1}{(x^2+\delta^2)^2(x^2+r\delta^2)+px^3(x^2+s\delta^2)}=\frac{1}{(x^2+\delta^2)^2(x^2+r\delta^2)}\left[1-\sum_{n=1}^{\infty}\left\{\frac{x^3(x^2+s\delta^2)}{(x^2+\delta^2)^2(x^2+r\delta^2)}\right\}^n p^n\right]. \tag{A.15}$$

In the integration of every term the expansion is meaningless unless

$$\alpha_n p^n > \alpha_{n+1} p^{n+1}\ , \quad \text{etc.} \tag{A.16}$$

Therefore the condition will be sought here. Since $s<1$, the sufficient condition will be given by

$$\frac{px^3(x^2+s\delta^2)}{(x^2+\delta^2)^2(x^2+r\delta^2)} < \frac{px^3}{(x^2+\delta^2)(x^2+r\delta^2)} < 1 \qquad \text{for } 0 \leq x < \infty\ , \tag{A.17}$$

or

$$(x^2+\delta^2)(x^2+r\delta^2) - px^3 = \delta^4\{(\xi^2+1)(\xi^2+r) - \varphi\xi^3\} \equiv \delta^4 f(\xi) > 0\ , \tag{A.18}$$

where

$$\xi \equiv x/\delta\ , \qquad \varphi \equiv p/\delta\ .$$

From

$$f'(\xi) = \xi\{4\xi^2 - 3\varphi\xi + 2(1+r)\} = 0\ , \quad \text{and} \quad r = 1/12$$

the minimum value of $f(\xi)$ is given at

$$\xi_0 = (3\varphi + \sqrt{9\varphi^2 - (104/3)})/8\ . \tag{A.19}$$

Numerical evaluation of $f_{\min} > 0$ must result in the condition

$$\varphi \equiv p/\delta < 0.2\ . \tag{A.20}$$

On the Electrical and Optical Properties of p-type Cadmium Telluride Crystals

By Shôji YAMADA

Institute of Electronics, Fuculty of Engineering, Shizuoka University, Hamamatsu, Japan

(Received March 23, 1960)

The electrical and optical properties were measured with p-type synthetic CdTe single crystals. The Hell coefficients of the crystals increased by the heat treatment or the growth in the cadmium vapor. From the present measurements it will be shown that the intrinsic energy gap is about 1.43 e.v., the ionization energy of acceptors is about 0.20 e.v. and the Hall mobility of holes is about 80 cm^2/volt-sec. at room temperature. It seems that the data of Hall mobilities are in agreement with the theory of intercation with the optical mode of lattice vibrations.

§1. Introduction

CdTe is one of the II-VI compound semiconductors whose photoconductive, photovoltaic and luminescent properties have been investigated by many authors. CdTe surpasses any other II-VI compound in obtaining relatively large crystals from the melt and in preparing both n- and *p*-type crystals[1)2)3)].

Concerning CdTe crystals, relatively few papers have been published[4)5)] and only few properties have been clarified.

In this paper the method of the preparation of the single crystals and the treatment of them in Cd vapor will be reported. The measurements of optical absorption, reflection and refractive index, dielectric constant, photoconducting properties and Hall effects will also be described.

§2. Preparation of Samples

The crystals used in this experiment were synthetic single ones. For the purification the cadmium and tellurium were distilled in vacuum. The resulting materials were mixed in the proportion of atomic equivalents, and they were put into a fused silica tube crucible which had a capillary bottom in order to grow only one seed. Then the crucible was evacuated and sealed off. For the growth of the single crystal the double furnace of Stockbarger-type was used (Fig. 1). The crucible was heated at about 1150°C for 3 hours in the furnace, and it was gradually lowered down to the lower temperature region in the furnace. The speed of lowering was about 2 cm/hr. Thus the crystal was grown from the bottom of the crucible.

The crystals obtained were of cylindrical form of about 10 mm in diameter and 50 mm in length. The X-ray examination indicates that all these crystals had the lattice structure of zinc blende type, and that all the cleaved surfaces were (110) planes.

One of the crystals was first heated at the temperature of about 950°C, and then immediately immersed in water so as to be cooled down rapidly. This crystal also revealed an X-ray pattern of the cublic structure. The above result means that the transformation from cubic to hexagonal structure which was suggested by Miyasawa and Sugaike[4)6)7)] could not be observed at the temperature used.

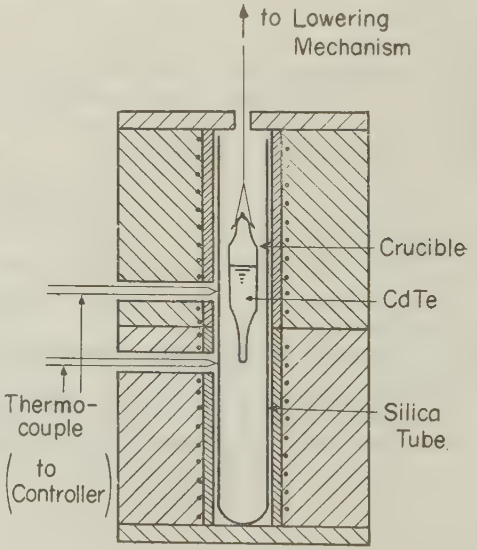

Fig. 1. Shematic diagram of the Stockbarger-type furnace.

All the crystals as grown showed *p*-type electrical conductivity, and the resistivies were of the order of $10^2 \sim 10^3\ \Omega$-cm. These crystals will be designated as *A*-type in this paper. The *p*-type crystals of high resistivity ($10^6 \sim 10^8\ \Omega$-cm) were obtained, however, by the crystal growth in the saturated vapor pressure of cadmium. These high resistivities were not altered both by the zone refining the elements and by the recrystallization of CdTe. These crystals will be called H-type. More doping of excess Cd could not change the crystals into *n*-tpye ones but made them porous.

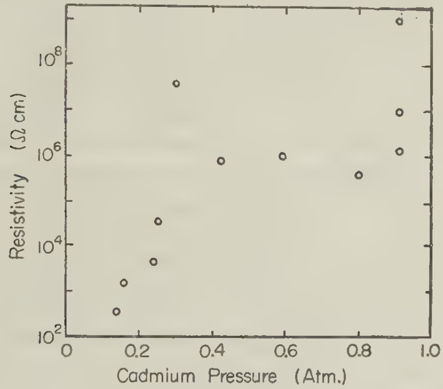

Fig. 2. The resistivity of samples as a function of Cd vapor pressure under the heat treatment. All the samples used were cut from the same A-type crystal and treated at 900°C for 5 hours.

Similar result were obtained under the heat treatment of samples in various cadmium vapor pressures. After the treatment the surfaces of about 0.1 mm in thickness of the samples (the dimension was about $9 \times 3 \times 2\ \mathrm{mm}^3$) were turned into *n*-type, but the bulk remained in *p*-type. This result was observed within the temperature range of 800∼950°C throughout the period of 3∼10 hours during which the treatment was conducted. Furthermore, it could not be altered when the rapid cooling was applied to the samples by means of immersion in water after the treatment. With the treated samples, the resistivity of the bulk was shown in Fig. 2. As the pressure increased, the resistivity of sample became higher, but under the pressure of more than 0.27 atmosphere the change of the resistivity with pressure was hardly observable. These samples will be designated as *C*-type.

By the addition of Ga into the melt, crystals obtained showed *n*-type condnction, but, so long as the amount of Ga was very small, the crystals remained *p*-type. These crystals will be called *G*-type.

§3. Experimental Results

1) *Optical Properties.* All the optical properties were measured at room temperature. Fig. 3 is the transmission data on the single crystals. It will be seen from the figure that there is the absorption edge at about 1.43 e.v. of the incident photon energy.

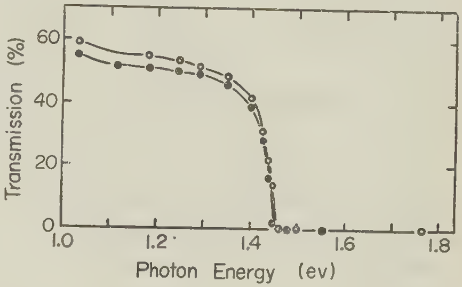

Fig. 3. Transmission measurements of CdTe single crystals.

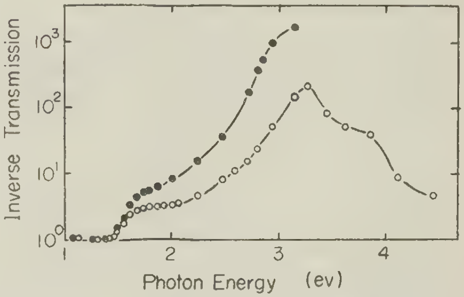

Fig. 4. Absorption spectra of thin films.

The absorption spectra of the evaporated thin films are shown in Fig. 4. There is also the absorption edge at about 1.43 e.v. Unless the correction is made relative to the reflection loss, the absorption coefficient is about $7 \times 10^4\ \mathrm{cm}^{-1}$ at 2 e.v. of the incident photon energy. From the fact the absorption edge is considered to be attributed to the fundamental absorption.

Fig. 5 shows the reflectivity of light on the cleaved surface of a single crystal, and the reflectivity spectrum seems to correspond well with the absorption ones.

The photoconducting phenomena could be observed on the crystals of high resistivity. The photoconducting spectra are shown in Fig. 6. With the *H*-type samples main peak is situated at about 1.42 e.v. According to the Hall measurements these crystals showed *p*-type conduction under illumination as well as in the dark. *G*-type crystals of *p*-type in the dark became *n*-type under illumination of light. There are three peaks of sensitivity at about 1.0, 1.37 and 1.43 e.v.

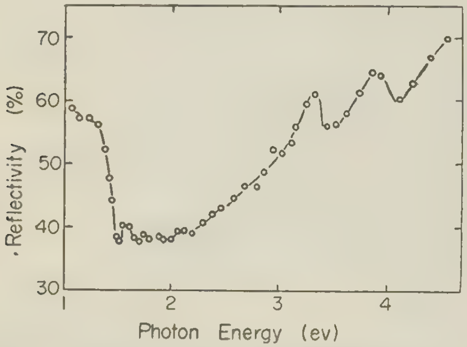

Fig. 5. Reflection on a cleaved surface of a crystal.

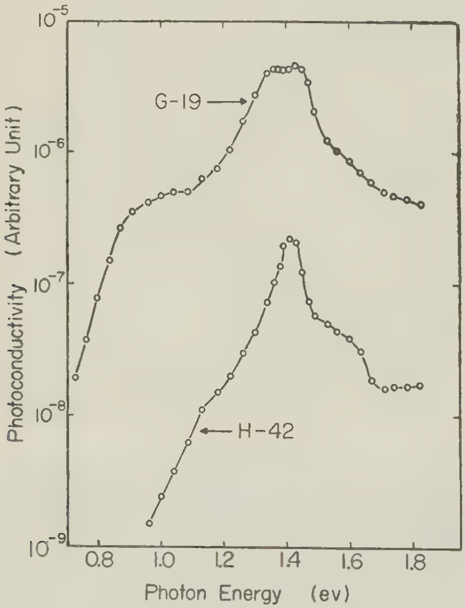

Fig. 6. Typical photoconducting spectra.

The refractive index *n* of the crystal was determined by the means of measurements of minimum deviation angle of light through the crystal cut into the prism. When the light of about 1 μ in wavelength was used, the value of *n* obtained was 2.83±0.03.

2) *Electrical Properties*. The Hall effects of the samples were measured with the ordinary d.c. method. The Hall coefficients of eight representative samples are shown in

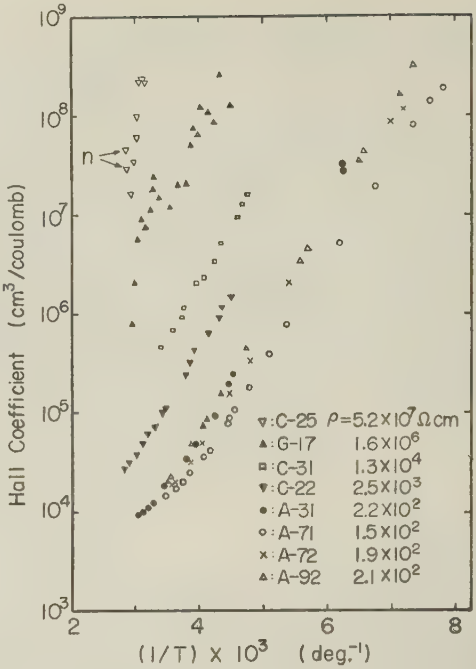

Fig. 7. Hall coefficients of eight samples as a function of inverse temperature. Hall coefficients observed in n-type are noted as n, and ρ is the resistivity of samples at room temperature.

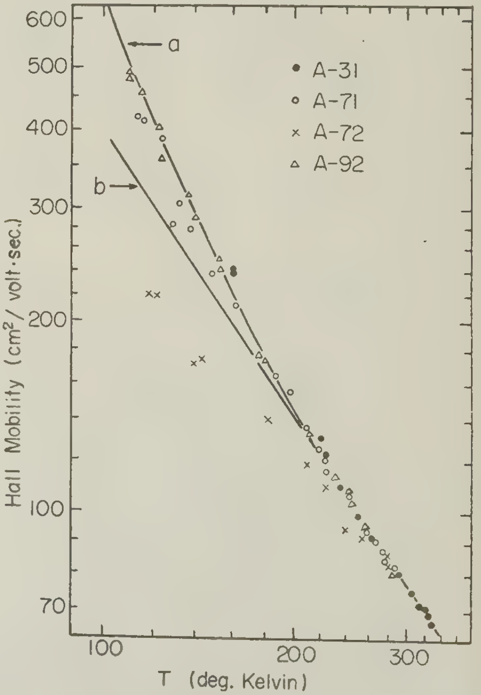

Fig. 8. Temperature dependence of the Hall mobilities with several A-type samples. Curve ***a*** and ***b*** are calculated from

$\mu_H=57\{\exp(252/T)-1\}$ and

$\mu_H=4\times10^5\,T^{-3/2}$ respectively.

Fig. 7. Except for the data on the samples of very high resistivity at high temperature range, all the coefficients obtained were of p-type, and the slopes of the curves are about the same. At temperatures higher than room one Hall coefficients of the samples of comparatively low resistivity have an inclination of saturation.

The Hall mobility of holes was determined from the data. The temperature dependence of Hall mobility μ_H for several A-type samples is shown in Fig. 8. The Hall mobility was about 80 cm²/volt-sec. at room temperature. With C-type samples the values were observed somewhat smaller than the above.

The dielectric constant $\mathcal{E}$ of the CdTe crystals was determined through the measurement of the capacities of condensers in which the CdTe plates were inserted as the dielectric media. When an osillator of 1 MC frequency was used, it was found that $\mathcal{E}$ is 10.3 ± 0.2 at room temperature.

§4. Discussions

It is known from the absorption and reflection data that the fundamental absorption edge is situated at about 1.43 e.v. This value coincides well with the main peak of photoconductivity. On the other hand, in the absorption and reflection spectra, some structures were also observed. Through the results may be interpreted with various possibilities, it is probable that the energy gap is about 1.43 e.v. unless the further informations are obtained.

Excess Te or Cd vacancies seem to be one of the most predominant impurity centers contained in the present crystals, since some amount of Cd is vaporized at the melting point of CdTe, and the resultant crystals grown from the mixture of atomic equivalent proportion may contain some excess Tellurium. In fact relatively low resistivities of p-type were observed in such crystals, and insulating crystals were grown in the saturated Cd vapor pressure. Simillarly, by the heat treatment in Cd vapor p-type samples of high resistivity could be obtained.

On the other hand, CdTe could hardly contain more than definite quantity of Cd excess impurity, becuse Cd added could not change carrier sign into n-type.

All the curves that represent the relation between the Hall coefficient and temperature data formed approximately the same slope in the case of p-type samples. Let $p=(3\pi/8)(1/Re)$ be the hole concentration, then we can obtain the concentration from the Hall coefficient R. In this case the hole concentration will be expressed as follows:

$$\frac{p(p+N_D)}{(N_A-N_D-p)N_V}=\left(\frac{m_d}{m_e}\right)^{3/2} D^{-1} \exp(-E_A/kT) \tag{1}$$

where N_A and N_D are the concentration of acceptors and donors included in the samples, and E_A and D the ionization energy and degeneracy of acceptor, respectively. Quantity m_d is the density-of-state mass of holes in the valence band, m_e is the free electron mass, and N_V is the density of state in the valence band with $m_d=m_e$.

If the logarithm of the left-hand side of Eq. (1) is plotted against the reciprocal of the absolute temperature, one should obtain a straight line whose slope gives E_A and whose intercept is $(m_d/m_e)^{3/2} D^{-1}$. In making such a plot the values of the parameters, N_A and N_D, must be chosen. Such plots of A-type samples were shown in Fig. 9. If we chose the other values of (N_A-N_D) or too small vales of N_D, the plots could not fit in with a straight line as shown in the figure. The intercept gives the value of $(m_d/m_e)^{3/2} D^{-1}$ as a reasonable value of about 0.5. If the value of N_D is too large, $(m_d/m_e)^{3/2} D^{-1}$ has an unreasonably large value. The slope of the line corresponds with $E_A=0.20$ e.v. Then it seems that in the A-type samples there are both acceptors and donors of $10^{15}\sim10^{16}$/cc and the ionization energy of acceptors will be about 0.20 e.v.

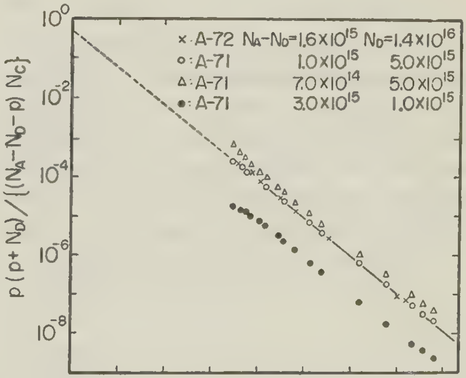

Fig. 9. Carrier concentration analysis of A-type samples.

In Fig. 8 curve ***b*** is drawn in accordance with the following equation:

$$\mu_H=4\times10^5\ T^{-3/2}\ \text{(practical unit)},$$

which is expected from the scattering by the acoustical mode of lattice vibrations. Our data show the larger values than the curve at low temperature and those data agree with neither the acoustical nor the impurity scattersng formulas.

Fröhlich and Mott[8] have studied the optical mode scattering in the weak coupling approximation, and Low and Pines[9] have developed the problem in the intermediated coupling range.

According to them the optical mode could be approximated with a single frequency ω. Then the following expression is given for the mobility μ below the Debye temperature $\Theta=\hbar\omega/k$:

$$\mu=\frac{1}{2\alpha\omega}\frac{e}{m}\left(\frac{m^*}{m}\right)^3 f(\alpha)\{\exp(\Theta/T)-1\}$$

$$\text{(electro-magnetic unit)}, \qquad (2)$$

where m and m^* are the effective mass of the electron and polaron respectively, α the strength of the interaction of the electron with the lattice, and $f(\alpha)$ a slowly varying function of α which is a little larger than unity at the low values of α. The quantities m and m^* are related as follows:

$$m^*=m(1+\alpha/6), \qquad (3)$$

and ω could be calculated from the *Reststrahl* wavelength λ_t as follows:

$$\omega=(\varepsilon/n^2)^{1/2}\ 2\pi c/\lambda_t \qquad (4)$$

and also α is given by

$$\alpha=\frac{e^2}{\hbar}\left(\frac{m}{2\hbar\omega}\right)^{1/2}\left(\frac{1}{n^2}-\frac{1}{\varepsilon}\right). \qquad (5)$$

Mitsuishi, Yoshinaga and Fujita[10] have observed the *Reststrahlen* of CdTe and found the wevelength to be about 66.7 μ. Using the values of dielectric constant and refractive index obtained, we cauld calculate the Debye temperature as 252°K.

In Fig. 8 curve ***a*** represents

$$\mu_H=57\{\exp(252/T)-1\}\ \text{(practical unit)}.$$

This expression seems to be better fitted to the experimental data and it may be considered that the deviation of the data from the curve ***a*** would be explained by the experimental errors and some contributions from the impurity and/or acoustical scattering.

If the Hall mobility μ_H meassured could be supposed to be the good approximation of true mobility μ, effective mass m, polaron effective mass m^* and coupling constant α could be calculated from the data. The values obtained for CdTe are as follows:

$$m=(0.63\pm0.06)m_e, \quad m^*=(0.69\pm0.07)m_e,$$

$$\alpha=0.57\pm0.08.$$

Assuming that $\mu_H=(3\pi/8)\,\mu$ we must enlarge the above values in about 9%.

§5. Acknowledgement

In conclusion, the author wishes to express his sincere thanks to Drs. K. Mizushima, O. Mikami and Y. Kamiya of Electrical Communication Laboratory for the instructions during the course of this work. The author is also indebted to Drs. T. Horii and S. Narita for their invaluable guidance and encouragements and to Messrs. A. Nakata and A. Takahashi for their laborious assistance.

Concentration Dependence of the Hall Coefficient in the Magnesium-Cadmium Alloys

By Seiichiro NOGUCHI and Takao SATO

Department of Physics, Faculty of Science, Tokyo Metropolitan University, Tokyo

(Received May 7, 1960)

The Hall coefficients of magnesium-cadmium alloys have been measured as a function of composition at both room temperature and 300°C with the magnetic field up to 6.5 KG. For all the compositions, the Hall coefficients are independent of magnetic field. An electronic structure of this system has been discussed with results of the lattice-spacing relations obtained by Hume-Rothery and Raynor. A relation between energy gap and concentration is discussed by comparing their results with the Hall coefficients measured by us. The present experimental results indicate that the energy gaps show a tendency to increase with the addition of cadmium to magnesium.

§1. Introduction

The Hall coefficients of magnesium and cadmium are negative and positive respectively. Both are divalent metals with the close-packed hexagonal structure. In pure magnesium or cadmium the number of overlapped electrons is equal to the number of holes in the first Brillouin zone. Thus a positive Hall coefficient means predominating hole mobility, while, if it is negative, an electron conduction must be more important.

Magnesium and cadmium make a continuous solid solution at higher temperatures, while at lower temperatures the existence of three ordered phases Mg_3Cd, MgCd and $MgCd_3$ has been confirmed by several investigators[1]. In the continuous solid solution region the axial ratio of the close-packed hexagonal lattice varies monotonically with concentration[2]. The electronic structure of the alloys should undergo a change with the variation of the axial ratio.

The purpose of the present paper is to obtain an information about the electronic structure of this system by means of the Hall effect measurements. The temperature at which a part of our measurements was performed is high enough for the existence of the continuous series of solid solutions. As it has been noted above, three ordered phases appear at room temperature, and correspond to three extreme values of the Hall coefficient.

§2. Experimental Procedure

Specimen preparation

The cadmium and magnesium used in this investigation have the purity of 99.9%. A series of 13 alloys is prepared to cover the whole concentration range. These alloys are melted under no flux, and cast into iron molds, so as to give plates 3 cm in length, 1 cm in width, and 0.2 cm in thickness, which are at once sealed in evacuated glass tubes, and annealed for 5 weeks at 300∼310°C. The tubes are then cooled in a blast of air, since quenching in water are responsible for the development of cracks as Hume-Rothery and Rayner had noted. After this treatment these alloys are polished to be 0.2∼0.3 mm in thickness as rapid as possible in order to prevent oxidization. They are sealed again in evacuated glass tubes, annealed for several days at 300°C, and then rapidly cooled to room temperature.

Measurement

All samples are approximately $25\times8\times0.3$ mm. The samples are joined by spot welding to annealed copper wires. A primary sample current of about 2A is supplied by batteries, and measured with a mirror-backed ammeter. The Hall voltage is measured with a DC amplifier[3] using a galvanometer which has a high sensitivity of about 7×10^{-9} V/div. and the technique has been developed in our laboratory. As mentioned by Hume-Rothery and Raynor, in quenched alloys the superlattice transformations took place on keeping the alloys at room temperatures, therefore, we measure the Hall coefficients at 300°C in an atmosphere of argon using an electric furnace which are put into the pole-pieces of electromagnet. The relatively shorter period fluctuations of the temperature of the specimen cause a variation of thermoelectric force at the probe-junctions, and therefore they disturb the measurement of Hall effect. The current of the furnace is supplied by a current stabilizer in order to eliminate fluctuations of a line voltage, because the Hall voltage to be measured in our work is less than 10^{-6} Volt and even a slight fluctuatians of the temperature difference between the probe-junctions can screen the Hall voltage.

§ 3. Results

The Hall coefficients of the magnesium-cadmium alloys at both room temperature and 300°C are given in Table I and Fig. 1.

Table I.

Composition (at. % Mg)	Hall Coefficient (m^3/A sec)	
	room temp.	300°C
0	6.0×10^{-11}	3.4×10^{-11}
10	10.0	3.3
20	16.9	3.3
25	17.8	3.3
30	17.0	3.2
40	11.9	0.3
50	6.0	0.0
60	10.4	− 0.4
70	15.9	− 0.5
75	14.0	− 0.7
80	7.7	− 1.6
90	5.8	− 4.7
100	−10.6	−10.6

(a) *The continuous solid solution*

The data at 300°C show that the Hall coefficients vary monotonically from a positive value for cadmium to a negative value for magnesium. The addition of cadmium to magnesium causes a rapid increase of the Hall coefficient, while the addition of magnesium to cadmium causes no changes. There is an abrupt change in the concentration-Hall coefficient diagram in the range of 60–70 at. % Cd.

(b) *The ordered phases*

The data at room temperature are given for the alloys which are annealed long enough to form ordered peases. In Fig. 1 the dependence of Hall coefficient on concentration has a minimum at 50 at. % and two maxima at 25 at. % and 75 at. % Cd correspoding to ordered alloys MgCd, Mg_3Cd and $MgCd_3$ respectively. Also included are the data of Salkovitz et al.[4] for magnesium-rich magnesium-cadmium alloys, and their results are in good agreement with our observations over the corresponding concentrations.

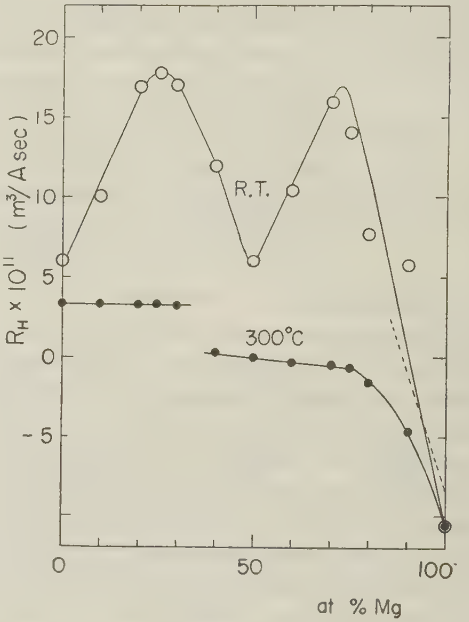

Fig. 1. The Hall coefficient at room temperature and 300°C as a function of concentration of cadmium. The dotted line shows the data of Salkovitz et al..

§ 4. Discussions

Many investigators have explained the peculiar variation of the lattice parameters of the metals with the close-packed hexagonal structure[5]. In 1940 Hume-Rothery and Raynor investigated the lattice parameters of magnesium-cadmium alloys at 310°C and made a discussion about onsets of electron overlaps across the faces of the Brillouin zone. They concluded that the observation was well interpreted with the Brillouin zone theory developed by Jones. A direct consequence of this theory is that a significant effect should be found on the Hall coefficient, when overlap occurs. Further, even if no new overlap occurs, the variation of concentration of the alloys should cause a distortion of Brillouin zone, i.e. a distortion of crystal structure on account of an interaction of Brillouin zone boundaries with Fermi surface[6].

The information of such a change of Fermi surface has come from X-ray data, but a more direct approach can be achieved by examining the concentration dependence of the Hall coefficient. The present measurements have shown that the Hall coefficients of the solid solutions of this system vary smoothly with composition except in the range of 60–70 at. % Cd.

Magnesium and cadmium have the same valency, i.e., divalent and almost the same volume, but have different axial ratios of their close-packed hexagonal structures. There is, however, much difference between the Hall coefficients of them, that is to say, the Hall coefficient of magnesium is -10.6×10^{-11}, and that of cadmium is 6.0×10^{-11} m^3/A sec. The Hall coefficient of magnesium does not vary with temperature, while that of cadmium shows a considerable decrease with the increase of the temperature in this temperature range. The Hall coefficient of cadmium is still positive, on the contrary, magnesium has a negative value in the temperature range of this measurements.

Since magnesium and cadmium are conductors of electricity, there must be an overlap into a second zone, the two band model might be adopted, and one can write

$$R_H=-\frac{1}{|e|}\left\{\frac{n_1\mu_1{}^2-n_2\mu_2{}^2}{(n_1\mu_1+n_2\mu_2)^2}\right\}\,, \qquad (1)$$

were R_H is the Hall coefficient, μ is the mobility, and n is the number of charge carriers per unit volume, and subscripts 1 and 2 refer to electrons and holes. Since both metals are divalent, each atom contributes two electrons in all the concentrations of these alloys. As the first Brillouin zone of close-packed hexagonal structure can contain two electrons per atom, the number of electrons which are effective as carriers is equal to the number of holes. Therefore, Eq. (1) can be written as follows,

$$R_H=-\frac{1}{n|e|}\left(\frac{\mu_1-\mu_2}{\mu_1+\mu_2}\right)\,, \qquad (2)$$

$$R_H\sigma=-(\mu_1-\mu_2)\,, \qquad (3)$$

were σ is the total conductivity. The values of $(\mu_1-\mu_2)$ for both the continuous solid solution and the ordered phases are calculated by using both the Hall coefficient obtained in our present work and the conductivity measured by Grube and Schiedt. The values for the ordered phases may be meaningless because the electron number n_1 may differ from the hole number n_2 due to the splitting of the Brillouin zone by a formation of new periodicity and a distortion of the structures. The variations of these $(\mu_1-\mu_2)$ with compositions are presented in Fig. 2. Also included are the data of Salkovitz et al. for the magnesium-rich region in magnesium-cadmium system. Their results are in good agreement with the present results in the corresponding compositions.

The first Brillouin zone of the close-packed hexagonal structure is shown in Fig. 3, and the energy of an electron varies continuously within this zone which is surrounded every-

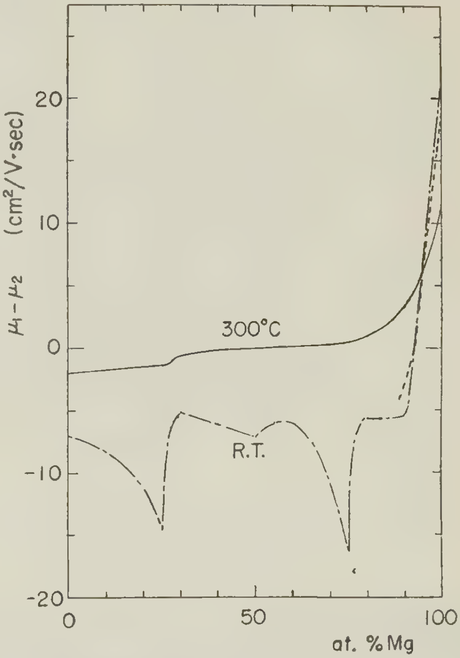

Fig. 2. The difference between electron and hole mobilities versus composition curves at room temperature and 300°C. The dotted line is the results obtained by Salkovitz et al..

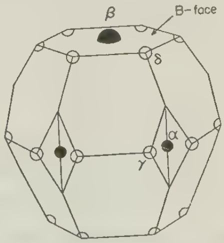

Fig. 3. The first Brillouin zone of the close-packed hexagonal structure.

where by an energy discontinuity, and contains exactly two electrons per atom. As mentioned above, magnesium and cadmium are conductors of electricity, then there must be an overlap into a second zone. In order to explain the present results, two types of electron overlaps and holes are employed. Mott and Jones have shown that the overlaps may occur either at β or at the re-entrant corners, point α, in Fig. 3. As it has been noted above, in magnesium-cadmium alloys at higher temperatures, there must be the same number of holes as that of electrons. From the shape of the Brillouin zone it will be plausible to consider that the holes may exist at both γ and δ. The most important factors affecting these electron overlaps and holes are the magnitude of the energy gaps at the corresponding faces of the Brillouin zone and the axial ratio, c/a, of the structure. If the energy gaps are not changed by a variation of the axial ratio, the electron overlap α and hole δ decrease and the β and the γ increase with the increase of axial ratio. On the contrary, when we take an effect of only the energy gaps on the overlaps and holes in consideration, increasing energy gaps decrease the corresponding electron overlaps and holes, i.e., if the energy gap associated with the B face of the Brillouin zone increases, the overlap β and the hole δ decrease.

Such a model may be adopted, and R_H is given by

$$R_H=-\frac{1}{|e|}\left\{\frac{n_\alpha\mu_\alpha{}^2+n_\beta\mu_\beta{}^2-n_\gamma\mu_\gamma{}^2-n_\delta\mu_\delta{}^2}{(n_\alpha\mu_\alpha+n_\beta\mu_\beta+n_\delta\mu_\delta+n_\delta\mu_\delta)^2}\right\}, \tag{4}$$

where the subscripts α, β, γ and δ refer to the α and β overlaps, and the γ and δ holes, respectively. By assuming that the relative variation of mobilities of the electrons and holes with respect to composition is not very large, a large concentration dependence of the Hall coefficient in magnesium-cadmium alloys will be explained by the change of magnitude of the electrons and holes with composition. According to the calculation of Mott and Jones there is no α overlap for cadmium with axial ratio 1.885 but no β overlap for magnesium with axial ratio 1.6237. And hence the results of our present experiment indicate that the following relation holds among the mobilities of overlaps and holes: $\mu_\delta>\mu_\alpha>\mu_\beta\sim\mu_\gamma$. By neglecting the effect of energy gap, a relation between the axial ratio and the concentration should indicate that the Hall coefficient makes a large change in the region of 60–100 at. % Cd, while in the region of pure magnesium to 60 at. % Cd the change is very small. Contrary to the expectation, little change was found in the region of 60–100 at. % Cd, and a rapid variation of the Hall coefficient in the region of 0–40 at. % Cd. In order to explain such a dependence of the Hall coefficient on the composition, it is sufficient that the energy gaps for the α and β overlaps increase with the increase of the contents of cadmium. Namely, the rapid decrease of the axial ratio with increasing magnesium contents in cadmium-rich regions will tend to decrease the β overlap but the decreasing energy gaps will counterwork. Then the observed Hall coefficients keep almost a constant value. In contrast with this, the axial ratio shows only a very slight increase with the addition of cadmium to pure magnesium, so that the Hall coefficient should be scarcely affected by taking into account of the effect of only the axial ratio on the overlaps and holes. When the effect of the increasing energy gap is taken into account, it may be expected that a considerable increase of the Hall coefficient is shown with the increase of cadmium contents.

The results at room temperature demonstrate the larger positive values of the Hall coefficient of Mg_3Cd and $MgCd_3$, than that of MgCd. The Brillouin zones of both types which are formed by an additional periodicity of super-lattice appreciably differ from each other[7]. It is reasonable to consider that such a difference will cause a different interaction of the Brillouin zone boundaries with the Fermi surface. A considerable distinction of the Hall coefficients may be due to the difference of the interaction.

The writers wish to thank Mr. K. Yonemitsu for the discussions and his helpful assistance with their experiments.

Theory of Thermoelectric Power of Ionic Crystals, IV.

By Eijiro HAGA

Department of Physics, Faculty of Science, Niigata University

(Received May 10, 1960)

The thermoelectric power Q associated with the movement of silver ions in Ag_2X (X=S, Se, Te) is discussed, where Q is obtainable by measuring the potential difference between silver electrodes in an arrangement as $Ag(T_1)|AgI(T_1)|Ag_2X|AgI(T_2)|Ag(T_2)$. When a temperature gradient is applied, Q, in general, changes with time because of the thermal diffusion of both electrons and silver ions, and then reaches its steady value. An information on the heat of transport of a silver ion is obtained from the comparison between theory and experiment.

An explanation on the heat of transport in ionic crystals is given taking into account the variation of vibration frequency of lattice due to the presence of defects. The theory is compared with the experimental data on silver halides and Ag_2X available at present.

§1. Introduction

In §2 we shall discuss the thermoelectric power of Ag_2X (X=S, Se, Te). The thermoelectric power associated with silver ions in these substances has been measured by Reinhold under the arrangement: $Ag(T_1)|Ag_2X|Ag(T_2)$, where T_1 and T_2 are temperatures in the respective places[1]. In this arrangement, silver atoms in Ag(T_1 or T_2) enter into Ag_2X until the equilibrium is attained, when $T_1=T_2$. When a temperature gradient is applied between the two silver electrodes, it is not sure that the thermal equilibrium for silver ions holds at junctions, since it may happen that silver atoms enter into Ag_2X from $Ag(T_2(>T_1))$ and deposit at $Ag(T_1)$, resulting in the net current of silver atom through Ag_2X. The measurements of Reinhold hence will not give the ionic thermoelectric power. This ambiguity on the thermal equilibrium can be removed by inserting a purely ionic conductor such as AgI between Ag and Ag_2X, as

$$Ag(T_1)|AgI(T_1)|Ag_2X|AgI(T_2)|Ag(T_2)\,. \quad (1)$$

In this arrangement, the electrochemical potential of a silver ion, ζ_{Ag^+}, is continuous everywhere and so the difference of the Fermi levels between the two electrodes is related to $d\zeta_{Ag^+}/dx$, which can be obtained by the similar procedure to that in ***III***[2] reported already. When a temperature gradient is applied to the specimen, $d\zeta_{Ag^+}/dx$ changes with time because of the appearance of the current of silver atoms and then reaches the steady value. It will be obvious that, in the steady state, the presence of electrons in the specimen has no effect on the thermoelectric power in the arrangement (1).

Next, in §3, we shall give a theoretical consideration on the heat of transport in ionic crystals. Concerning the heat of transport, the values of $h_F + Q_i^* + Q_v^*$ and $-Q_v^*/T + \partial\mu_v^0/\partial T$ have been obtained from the comparison of the theory of thermoelectric power with experiments in AgCl[3] and AgBr[4], where Q_i^* and Q_v^* and the heat of transport of an interstitial Ag^+ and an Ag^+ vacancy, respectively, h_F is the enthalpy of forming a pair of Frenkel defects and μ_v^0 is the Gibbs free energy of taking out a silver ion from a lattice site in a perfect crystal to the vacuum. The theory of Wirtz[5] on the mechanism of thermal diffusion can not explain these values and hence we shall make a theoretical consideration on the heat of transport, showing a fairly good agreement with experimental values.

§ 2. Ionic Thermoelectric Powers of Ag_2S, Ag_2Se and Ag_2Te

The thermoelectric power Q in the arrangement (1) is related to Q_{Ag^+}, with the same procedure as that in ***I***[6], by

$$eQ = eQ_{Ag^+} + s_{Ag}^{Ag}\,, \tag{2}$$

where eQ_{Ag^+} is the value value obtained by subtracting ζ_{Ag^+} in Ag_2X at a certain point from that at an other point at higher temperature by 1°C, and s_{Ag}^{Ag} is the entropy of a silver atom in a silver atom in a silver metal. Hence we have merely to calculate $d\zeta_{Ag^+}/dx$ as follows.

The electrical current densities of silver ions and electrons, j_i and j_e, are given, respectively, by

$$\left.\begin{aligned} j_i &= \frac{\sigma_i}{e}\left(eE - \left(\frac{\partial\mu_i}{\partial n_i}\right)_T \frac{\partial n_i}{\partial x} - \frac{Q_i^*}{T}\frac{\partial T}{\partial x}\right), \\ j_e &= \frac{\sigma_e}{e}\left(eE + \left(\frac{\partial\mu_e}{\partial n_e}\right)_T \frac{\partial n_e}{\partial x} + \frac{Q_e^*}{T}\frac{\partial T}{\partial x}\right), \end{aligned}\right\} \tag{3}$$

where σ_i, n_i and μ_i are the partial conductivity, the concentration and the chemical potential per ion, of silver ions, respectively, and σ_e, n_e and μ_e are similar quantities on electrons. With use of the condition that the total current does not exist; $j_i + j_e = 0$ and the charge neutrality condition; $\partial n_i/\partial x = \partial n_e/\partial x$, we obtain

$$\begin{aligned} \frac{d\zeta_{Ag^+}}{dx} &= -eE + \frac{d\mu_i}{dx} \\ &= \left[t_e\left(\frac{\partial\mu_{Ag}}{\partial n_{Ag}}\right)_T \frac{(n_i)_{x=L} - (n_i)_{x=0}}{\Delta T}\right. \\ &\quad \left. + \left(\frac{\partial\mu_i}{\partial T}\right)_{n_i} - \frac{t_i Q_i^* - t_e Q_e^*}{T}\right]\frac{\partial T}{\partial x}\,, \end{aligned} \tag{4}$$

where μ_{Ag} and n_{Ag} are the chemical potential per atom and the concentration of silver atom in Ag_2X, t_i and t_e are the transport numbers of silver ions and electrons, respectively, and ΔT is the temperature difference between the ends of the specimen of length L. The difference of n_i between the ends of the specimen, $(n_i)_{x=L} - (n_i)_{x=0}$, changes with time t, after ΔT is applied at $t=0$, since n_i or n_e depends on time because of the thermal diffusion of both electrons and ions. Therefore it is seen from Eqs. (2) and (4) that the thermoelectric power depends on time. This time dependence can be found with use of the similar procedure to that in ***III***[2] as follows. Here, let us consider only the case that L is so long that the time constant τ is much longer than the time required to set up ΔT in the specimen.

The continuity equation for ions

$$\frac{\partial n_i}{\partial t} = -\frac{\partial j_i/e}{\partial x} \tag{5}$$

is reduced with use of Eq. (3) differentiated with respect to x, higher order term than that of $\partial T/\partial x$ being neglected, to

$$\frac{\partial n_i}{\partial t} = \frac{\sigma t_e t_i}{e^2}\left(\frac{\partial\mu_{Ag}}{\partial n_{Ag}}\right)_T \frac{\partial^2 n_i}{\partial x^2}\,, \tag{6}$$

where σ is the total conductivity, $\sigma_i + \sigma_e$. The boundary condition to Eq. (6) is given by

$$(j_i)_{x=0} = (j_i)_{x=L} = 0\,, \tag{7}$$

which is rewritten as

$$\left(\frac{\partial n_i}{\partial x}\right)_{x=0} = \left(\frac{\partial n_i}{\partial x}\right)_{x=L} = -\frac{Q_e^* + Q_i^*}{T(\partial\mu_{Ag}/\partial n_{Ag})_T}\frac{\partial T}{\partial x}\,. \tag{8}$$

On the other hand, the initial condition is $n_i = n_i^0$, n_i^0 being a constant independent of x. Then, solving Eq. (6), we obtain

$$\begin{aligned} &\frac{(n_i)_{x=L} - (n_i)_{x=0}}{\Delta T} \\ &\quad = -\frac{Q_e^* + Q_i^*}{T(\partial\mu_{Ag}/\partial n_{Ag})_T}\left[1 - F\left(\frac{t}{\tau}\right)\right], \end{aligned} \tag{9}$$

where $F(t/\tau)$ is given by Eq. (21) in ***III***[2], and

$$\tau = \frac{e^2L^2}{\pi^2\sigma t_i t_e(\partial\mu_{Ag}/\partial n_{Ag})_T}\,. \tag{10}$$

From Eqs. (2), (4) and (9), we obtain the expression for the thermoelectric power:

$$\begin{aligned} eQ = &-\frac{Q_i^*}{T} + \left(\frac{\partial\mu_i}{\partial T}\right)_{n_i} \\ &+ \frac{t_e}{T}(Q_e^* + Q_i^*)F\left(\frac{t}{\tau}\right) + s_{Ag}^{Ag}\,. \end{aligned} \tag{11}$$

The electrical conduction in Ag_2X has been studied by Miyatani[7], according to whom the concentration of silver atoms can be freely varied within a certain range, and μ_i is independent of n_i in α-phase, while it depends on n_i in β-phase in fairly complicated way. In α-phase, the time constant τ is so short that the usual measurement of the thermoelectric power gives the steady value and so the third term in Eq. (11) is neglected. The value of $Q_i^*/T-\partial\mu_i/\partial T$ is therefore found from the experimental value of Q with use of the value of $s_{\mathrm{Ag}}^{\mathrm{Ag}}$ estimated from the specific heat of Ag. On the other hand, in the β-phase, the thermoelectric power is expected to change with time, since τ is not so small. Accordingly the value of $Q_e^*+Q_i^*$ will be obtained if the time dependence of Q is measured, besides the value of $Q_i^*/T-\partial\mu_i/\partial T$ obtained in the steady state.

In addition, the change of Q, after ΔT is removed at $t=0$ in the steady state, is calculated as follows, where τ is assumed to be much longer than the time required to remove ΔT. The potential difference between the ends of the specimen, ΔV, is given in such a case by

$$e\Delta V=\int_0^L\left(-eE+\left(\frac{\partial\mu_i}{\partial n_i}\right)_T\frac{\partial n_i}{\partial x}\right)dx$$

$$=t_e\left(\frac{\partial\mu_{\mathrm{Ag}}}{\partial n_{\mathrm{Ag}}}\right)_T[(n_i)_{x=L}-(n_i)_{x=0}]\,. \qquad (12)$$

The diffusion equation (6) and the boundary condition (8), $\partial T/\partial x$ being zero, are valid at the present case, while the initial condition is given by

$$n_i=n_i^0-\left(\frac{x}{L}-\frac{1}{2}\right)\frac{Q_e^*+Q_i^*}{T(\partial\mu_{\mathrm{Ag}}/\partial n_{\mathrm{Ag}})_T}\Delta T\,, \qquad (13)$$

which is the solution at $t=\infty$ of Eq. (6). From Eqs. (12) and (13), we obtain

$$e\frac{\Delta V}{\Delta T}=-\frac{t_e}{T}(Q_e^*+Q_i^*)F\left(\frac{t}{\tau}\right), \qquad (14)$$

which is equal to the third term of Eq. (11) depending on time. Such a situation is similar to the case treated in ***III***[2]. The transport number of electrons t_e in Eqs. (11) and (14) can be taken as unity except β-Ag_2S, for any electron density according to the measurement of Miyatani (t_i is of the order of 1% except β-Ag_2S).

The measurement of the thermoelectric power of the α-Ag_2X in the arrangement (1) has been made by Endo for the various concentration of silver ions[8]. Theory predicts that the ionic thermoelectric power is independent of the concentration of silver atoms, since the α-Ag_2X is of an average structure and all silver ions contribute to the ionic conduction. This Ag-concentration-independence of Q has been experimentally confirmed by Endo[8]. The experimental values under the arrangement (1) is remarkably different from those by Reinhold[1] as seen in Table I. The measurement of Reinhold seems to give roughly the electronic thermoelectric power of Ag-saturated specimen, which is obtainable with electrodes like *Pt*. From the experimental values of Endo[8], we obtain the values of $Q_i^*/T-\partial\mu_i/\partial T$ with use of Eq. (11), its third term being neglected, as shown in Table I.

Table I. The experimental values of ionic thermoelectric power of α-Ag_2X and the values of $Q_i^*/T-\partial\mu_i/\partial T$ obtained from Q-values by Endo.

§ 3. Heat of Transport

We first consider a homogeneous substance like AgCl possessing mobile particles under a constant temperature and pressure. Let us imagine that it is divided into two parts **A** and **B** by an imaginary plane and N particles move from **A** to **B**. If such a movement occurs under a constant temperature and pressure, the heat of NQ^* must be, in general, supplied from the environment into **A** and the same amount of heat must be taken away from **B** to the environment. The heat Q^* is called the heat of transport of the particle transported, in the present paper.

We now consider the heat of transport, Q_i^*, of an interstitial ion which is doing thermal vibration around its equilibrium position in **A**. To calculate Q_i^*, let us trace the movement of an interstitial ion which first wanders within **A** and at last enter into **B**. In order for the ion to move from one interstitial site to the next one, it must climb the potential barrier, and, at this time, a certain amount of heat, $\varDelta H$, must be supplied from the environment to **A**. The magnitude of $\varDelta H$, can be obtained as follows. Let x' be the x-coodinate of a (100) plane in **A**, x_1 and x_2 be the x-coordinates of interstitial positions nearest to the (100) plane, x' lying in the middle of x_1 and x_2, and n be an average number of interstitial ions at x_1 or x_2. When an interstitial ion moves from x_1 to x_2, the energy is transported by the amount U_i^*, which can be obtained according to Wert who has computed the transition probability per unit time, w_i, for an ion to move from x_1 to x_2 by means of the statistical mechanics[9]. Let (x, y, z), (p_x, p_y, p_z) and m be the space-coordinate, the conjugate momentum and the mass of an interstitial ion, Q, P and $K(P)$ be the collective coordinate, the conjugate momentum and the total kinetic energy of the lattice ions vibrating at normal sites in **A**, and $\varphi(x, y, z; Q; v)$ be the total potential energy of the system consisting of lattice ions and an interstitial ion in **A** of volume v. Then, the mean energy transported across the plane $x=x'$ in time interval δt is given by

$$nw_iU_i^*\delta t=\frac{\int N_0\frac{p_x}{m}\delta t\,dp_x\int\exp\left[-\frac{T(x',y,z;Q;v)}{kT}\right]S(x',y,z;Q;v)\,dp_y\,dp_z\,dy\,dz\,dP\,dQ\,dv}{\int\exp\left[-\frac{T(x,y,z;Q;v)}{kT}\right]dp_x\,dp_y\,dp_z\,dx\,dy\,dz\,dP\,dQ\,dv}, \tag{15}$$

where

$$\left.\begin{aligned}T(x',y,z;Q;v)&=K(P)+\varphi(x',y,z;Q;v)+\frac{1}{2m}(p_x^2+p_y^2+p_z^2)+p_0v\,,\\ S(x',y,z;Q;v)&=\varphi(x',y,z;Q;v)+\frac{1}{2m}(p_x^2+p_y^2+p_z^2)\,,\end{aligned}\right\} \tag{16}$$

N_0 and p_0 are the total number of interstitial ions in **A** and the pressure, respectively, and the integration with respect to (x, y, z) is taken over the volume in **A**. From Eq. (15), with use of

$$w_i=\nu_i\exp(-\varDelta g_i/kT)\,, \tag{17}$$

where ν_i and $\varDelta g_i$ are the vibration frequency, and the Gibbs free energy of activation, of an interstitial ion, respectively, we easily obtain

$$U_i^*=V(x')+2kT\,, \tag{18}$$

where

$$V(x')=\frac{\int\exp-\frac{1}{kT}[\varphi(x',y,z;Q;v)+p_0v]\varphi(x',y,z;Q;v)\,dy\,dz\,dQ\,dv}{\int\exp-\frac{1}{kT}[\varphi(x',y,z;Q;v)+p_0v]\,dy\,dz\,dQ\,dv} \tag{19}$$

is the mean potential energy of the system which consists of lattice ions in **A** and an interstitial ion at x'. Since $\varDelta H$ is equal to the difference of the enthalpy of the system between when the interstitial ion is at x' and when it is at x_1, we obtain

$$\varDelta H=(V(x')+2kT)-(V(x_1)+K_i)+p_0\varDelta v\,, \tag{20}$$

where K_i is the sum of the kinetic energy of the interstitial ion due to the vibration in (yz) plane and the total energy due to the vibration in x direction, and Δv is the volume increase of **A** when an interstitial ion is activated from x_1 to x'.

Next, when an interstitial ion moves away from the position x' in **A** to **B**, the entropy of lattice ions in **A** varies because of the variation of vibration frequency of lattice ions around x'. Since the movement of an interstitial ion from **A** to **B** takes place reversibly, the contribution of the entropy variation to the heat of transport is $-T\Delta s(x')$, where $\Delta s(x')$ is the increase of the entropy of lattice ions due to the presence of an ion at x'. Hence, we have

$$Q_i^* = \Delta H - T\Delta s(x') \ . \tag{21}$$

From Eqs. (20) and (21), we obtain

$$Q_i^* = -(K_i - Ts_i^{osc}) + T\frac{\partial \mu_i^0}{\partial T} + 2kT + \Delta u_i \ , \tag{22}$$

where

$$\Delta u_i = (V(x') - V(x_1)) - T(\Delta s(x') - \Delta s(x_1)) + p_0\Delta v \ , \tag{23}$$

μ_i^0 is the Gibbs free energy of bringing an ion from the vacuum to the state of thermal vibration at an interstitial position in a perfect crystal, and s_i^{osc} is the vibration entropy of an interstitial ion.

The movement of an Ag^+ vacancy from **A** to **B** is equivalent to that of an lattice ion from **B** to **A**. Hence we have, corresponding to Eq. (22),

$$Q_v^* = K_L - Ts_L^{osc} + T\frac{\partial \mu_v^0}{\partial T} - 2kT - \Delta u_v \ , \tag{24}$$

where K_L, s_L^{osc}, and Δu_v are defined for an lattice ion in a similar way to those for interstitial ion. Summing up Eqs. (22) and (24), we have

$$Q_i^* + Q_v^* = \Delta u_i - \Delta u_v - Ts_F + 3kT \ln \nu_0/\nu_i \ , \tag{25}$$

where ν_0 is the mean vibration frequency of lattice ions, K_L and K_i are both taken as $2kT$, and the entropy of forming a pair of Frenkel defects, s_F, may be written as

$$s_F = -\frac{\partial(\mu_i^0 + \mu_v^0)}{\partial T} = k\sum \ln\frac{\nu}{\nu'} + k\sum \ln\frac{\nu}{\nu_i'} + 3k\ln\frac{\nu_0}{\nu_i} \ , \tag{26}$$

ν, ν', and ν_i' being the frequency of a normal mode of vibration of lattice ions in the perfect crystal, that in the presence of a vacancy, and that in the presence of an interstitial ion, respectively. In Eq. (26), it is expected that the first term is positive and the other terms are negative. The values of s_F found from the conductivity data on AgCl and AgBr by Teltow[10] lead to an extraordinarily large difference between ν and ν'.[10] Hence, we shall assume $\nu_0 \sim \nu_i$ and neglect the last term in Eq. (25). We shall further assume that s_L^{osc} may be approximately taken as a half of the vibration entropy of a pair of positive and negative ions at normal sites, and $\Delta u_{i,v}$ may as the activation energy of the mobility $u_{i,v}$:

$$u_{i,v} = \frac{u_{i,v}^0}{T}\exp\left(-\frac{\Delta u_{i,v}}{kT}\right) , \tag{27}$$

where $u_{i,v}^0$ is a parameter independent of temperature.

Now we can compare the theoretical values obtained from Eqs. (24) and (25) with the experimental values as shown in Table II, where we use the values obtained from the data of Teltow[10] as follows; $h_F=1.69$(AgCl) and 1.27 ev(AgBr), $s_F=1270$ and 1020×10^{-6} ev/°C, $\Delta u_i=0.19$ and $0.19\,ev$, and $\Delta u_v=0.39$ and $0.40\,ev$, two values being of AgCl and AgBr, respectively.

Let us next consider the case of α-Ag_2X. The activation energy of the mobility, Δu, is obtained from the conductivity data of Endo[8] with use of

$$\sigma = \frac{\sigma^0}{T}\exp\left(-\frac{\Delta u}{kT}\right) , \tag{28}$$

where σ is the conductivity and σ^0 is a parameter independent of temperature. From this equation, the values of Δu in Ag_2S, Ag_2Se and Ag_2Te are obtained as 0.093, 0.099 and 0.137 *ev*, respectively. Assuming $s^{0sc}=\frac{1}{3}s^{0sc}_{Ag_2X}$, the value obtained from Eq. (22) can be compared with the values obtained in § 2, as shown in Table III.

Further, the thermoelectric power of α-AgI has been measured as 560 $\mu v/°C$ at 200∼300°C by Reinhold under an arrangement: $Ag(T_1)|AgI|Ag(T_2)$. The activation energy Δu is obtained as 0.101 *ev* from the data of Tubandt, et al.[11] with use of Eq. (28). Assuming $s^{0sc}=\frac{1}{2}s^{0sc}_{AgI}$, the comparison between theory and experiment is also possible as shown in Table III.

Table II. The comparison between theory and experiment for the heat of transport in AgCl and AgBr.

AgCl

°C	$h_F+Q_i^*+Q_v^*(ev)$		$\frac{1}{e}\left(-\frac{Q_v^*}{T}+\frac{\partial\mu_v^0}{\partial T}\right)(\mu v/°C)$	
	Exp.	Theory	Exp.	Theory
250	0.78	0.83	1360	1420
300	0.63	0.76	1480	1380
350	0.52	0.70	1500	1360

AgBr

°C	$h_F+Q_i^*+Q_v^*(ev)$		$\frac{1}{e}\left(-\frac{Q_v^*}{T}+\frac{\partial\mu_v^0}{\partial T}\right)(\mu v/°C)$	
	Exp.	Theory	Exp.	Theory
175	0.70	0.60	1380	1560
250	0.58	0.53	1370	1480

Table III. The comparison between theory and experiment for $(Q_i^*/T-\partial\mu_i/\partial T)/e$ (in $\mu v/°C$) in Ag_2S, Ag_2Se, Ag_2Te and AgI.

°C	Ag_2S		Ag_2Se		Ag_2Te		AgI	
	Exp.	Theory	Exp.	Theory	Exp.	Theory	Exp.	Theory
200	780	860	800	920	990	1170	1110	960
250	810	870	830	930	1000	1170	1140	970
300	840	880	860	940	1020	1180	1170	990

From Tables II and III, it is seen that the theory developed in the present section fits fairly well with experiments though we made several rough assumptions under a simple model. The present theory will be also available to the case of $NaCl+CdCl_2$ and will be compared with experiment if Q is measured with *e.g.* chlorine gas electrodes, though such a measurement seems not to be carried out as yet.

The writer wishes to express his cordial thanks to Mr. S. Endo who kindly carried out the measurements on α-Ag_2X, available to the comparison with theory. The writer is also very much indebted to Drs. S. Miyatani, I. Yokota, T. Kurozawa and Profs. Y. Suzuki, R. Kubo for their useful discussions. The present work was supported by the Scientific Research Fund of the Ministry of Education.

Measurement of Microwave Dielectric Constants of Ferroelectrics

Part I. Dielectric Constants of $BaTiO_3$ Single Crystal at 3.3 KMc/s.

By Eiji NAKAMURA and Jiro FURUICHI

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received May 12, 1960)

Horner et al's method of dielectric measurement at microwave region has been extended so that it can be applied for cylindrical specimens of arbitrary cross-sections with relatively high loss tangent and high permittivity. Small amount of Specimen is good enough for our method. As the first application of our method, dielectric constants of $BaTiO_3$ single crystal have been measured from room temperature to 170°C at a frequency of 3.3KMc/s. Above the Curie point, dielectric constants measured at 3.3KMc/s agree well with those measured at 24KMc/s by Benedict and Durand, while the loss tangents slightly above the Curie point are 0.01 ± 0.007 in our case compared to 0.1 in the case of Benedict and Durand.

§1. Introduction

Investigations of dielectric properties of ferroelectrics at microwave region provide an information on the mechanism of ferroelectric phase transition, as well as on their usefulness in microwave circuits. That is, if a dielectric dispersion is observed in a single crystal at microwave region, it can be considered as a strong evidence that the transition is order-disorder type. Several workers measured microwave dielectric constants of ferroelectrics. Yager[1] had found dielectric dispersion of Rochelle salt in microwave region about ten years ago, and Akao et al[2] did very detailed investigation of this dispersion. Very recently Nishioka and Takeuchi[3] have observed dielectric behaviour of $(glycine)_3 H_2SO_4$, at about 10 KMc/s, and found that dielectric anomaly at the Curie point still occurs in this region though the dielectric constant at room temperature is smaller than that of low frequency value. Several workers measured dielectric constants of ceramic $BaTiO_3$, and found dispersions at microwave frequencies. But since phase transition in $BaTiO_3$ cannot be considered as order-disorder type[4] it was doubted whether single crystal exhibited the same dispersion in microwave region. Because of the difficulties in growing big single crystals and in measuring microwave dielectric constants of small specimens, this question had not been answered until the paper of Benedict and Durand.[5] They have shown that the dielectric constants at 24 KMc/s are not so small compared to low frequency values as in ceramics though loss tangents are not very small. The present authors planned measurements of microwave dielectric constants of $BaTiO_3$ single crystal before the paper of Benedict and Durand appeared, and developed a method of measuring dielectric constants of small specimens. Although our results are almost the same as those of Benedict and Durand's, it was thought worthwhile to publish our results by the following reasons: (1) Our method is different from theirs, and it seems worthwhile to introduce our method and to compare our results to those of Benedict and Durand's especially since we are intending to apply our method to other ferroelectrics. (2) Our frequency (3.3 KMc/s) is different from theirs (24 KMc/s) and our values of loss tangents were quite different from those reported by them.

This paper is the first part of our reports on microwave measurements of ferroelectrics. In part II measurements on other ferroelectrics will be reported.

§2. Principle of Measurement

Horner et al[6] studied the field of TM_{010} mode in a cylindrical cavity which has a cylindrical dielectric specimen placed coaxially in it. They assumed that the specimen has a small radius, low dielectric constant and negligible loss, and obtained the following expressions for the dielectric constant $\mathcal{E}'$ and the loss factor tan δ;

$$\mathcal{E}'=0.539\frac{a^2}{b^2}\frac{\Delta f}{f}+1\ ,$$

and

$$\tan\delta=\frac{0.269}{\mathcal{E}'}\frac{a^2}{b^2}\left(\frac{1}{Q_2}-\frac{1}{Q_1}\right)\ , \tag{1}$$

where a and b are radii of the cavity and the sample respectively, f is a resonant frequency of the cavity and Δf is the difference between a resonant frequency of the empty cavity and that of the cavity containing the specimen, respectively.

The main purpose of this section is to prove that practically the same equation as Eq. (1) can be derived with less restrictions on shapes and properties of the dielectric specimen than those put by Horner et al, and show that the resonant cavity method is applicable also for ferroelectrics. Below, discussions will be made under the following assumption: the dielectric specimen is cylindrical, and placed parallel to the axis of the circularly cylindrical cavity, both ends of the cylindrical specimen being in contact with the cavity wall; cross-section of the specimen has a very small area, but may have any shape; real and imaginary parts of the dielectric constants of the specimen may be reasonably high as far as they are finite; the specimen may be dielectrically anisotropic, but one of the principal axes of dielectric tensor is parallel to the axis of the cavity. In the present section, discussions will be limited to TM_{010} mode. Of course, similar discussions can be applied to other modes, and we can also treat other shapes of specimens if we consider depolarization effects. However, these will lead us too far afield in this section.

According to Bethe and Schwinger[7], deviation of the cavity resonant frequency due to existence of an isotropic dielectric specimen is given by

$$\frac{\Delta f}{f_2}=\frac{\int_{v_s}(\mathcal{E}_2-1)\boldsymbol{E}_1\cdot\boldsymbol{E}_2dv+\int_{v_s}(\mu_2-1)\boldsymbol{H}_1\cdot\boldsymbol{H}_2\,dv}{\int_{v_s}(\boldsymbol{E}_1\cdot\boldsymbol{E}_2+\boldsymbol{H}_1\cdot\boldsymbol{H}_2)dv}\ , \tag{2}$$

where $f=f'+if''$ is the complex resonant frequency, and $\Delta f\equiv f_1-f_2$. Here and throughout the paper, subscripts 1 and 2 mean that the quantities are those of the empty cavity and those of the cavity containing a specimen, respectively. $\mathcal{E}$ and μ are complex dielectric constant and complex magnetic permeability, respectively. $\int_{v_s}dv$ and $\int_{v_s}dv$ mean that the integrations should be carried out within the specimen and within the cavity respectively. Eq. (2) can be applied to any dielectric specimen of any shape, and, as proved in Appendix, it holds also for anisotropic dielectrics if we use a tensor dielectric constant.

Due to our assumptions, the dielectric specimen has its side surface and its principal axis of dielectric tensor parallel to $\boldsymbol{E}_1$ in case of TM_{010} mode, therefore, no electric charge seems to be induced on its side surface. Since $\boldsymbol{E}_2$ is parallel to $\boldsymbol{E}_1$ for such a case, and $\mu_2=1$, Eq. (2) can be rewritten as

$$\frac{\Delta f}{f_2}=\frac{(\mathcal{E}_{20}-1)\int_{v_s}\boldsymbol{E}_1\cdot\boldsymbol{E}_2\,dv}{\int_{v_c}(\boldsymbol{E}_1\cdot\boldsymbol{E}_2+\boldsymbol{H}_1\cdot\boldsymbol{H}_2)dv}\ , \tag{3}$$

where is $\mathcal{E}_{20}$ is the principal dielectric constant along the cavity axis.

If field distortion due to insertion of the specimen is negligible, $\boldsymbol{E}_2$ may be approximated by

$$\boldsymbol{E}_2=A\boldsymbol{E}_1\ , \tag{4}$$

where A is a scalar constant. In the present case Eq. (2) may hold approximately even inside the specimen owing to the boundary conditions for $\boldsymbol{E}$. This approximation may hold if $|\Delta f/f_2|$ is very small, as shown by Spencer et al[8]. On this assumption Eq. (3) can be rewritten as

$$\frac{\Delta f}{f_2}=\frac{(\mathcal{E}_{20}-1)\int_{v_s}E_1{}^2dv}{2\int_{v_c}E_1{}^2dv}\ . \tag{5}$$

Here use was made of the relation, $\int_{v_c}E_1{}^2dv=\int_{v_c}H_1{}^2\,dv$. Using the cylindrical coordinates (r, θ, z), the components of E_1 for the TM_{010} mode are given by

$$\left.\begin{array}{l}E_r=E_\theta=0\ ,\\ E_z=J_0(kr)\ ,\end{array}\right\} \tag{6}$$

where $J_0(kr)$ is the zeroth order Bessel function, and k is the wave number constant. Using Eq. (6) and assuming that the specimen is placed near the center axis of the cavity, Eq. (5) becomes

$$\varepsilon_{20}=0.539\frac{v_c}{v_s}\frac{\Delta f}{f_2}+1 \qquad (7)$$

where v_c and v_s stand for volumes of the cavity and of the specimen, respectively. It should be mentioned here that there is no restrictions on the magnitude of dielectric constant and loss factor insofar as $|\Delta f/f_2|$ remains very small. According to Eq. (7), one can make $|\Delta f/f_2|$ small by making v_s small. The dielectric constant ε_{20} and resonance frequencies f_1 and f_2 are complex quantities by their definitions, and therefore, one can calculate the real dielectric constant ε'_{20} and loss factor $\tan\delta$ using Eq. (7). The results obtained are

$$\left.\begin{aligned}&\varepsilon'_{20}=0.539\frac{v_c}{v_s}\frac{\Delta f}{f_2}+1\,,\\ &\text{and}\\ &\tan\delta=\frac{0.269}{\varepsilon'_{20}}\frac{v_c}{v_s}\left(\frac{1}{Q_2}-\frac{1}{Q_1}\right).\end{aligned}\right\} \qquad (8)$$

These equations are identical with Eq. (1) if the specimen has a circular cross-section.

§ 3. Experimental Set-up and Specimens

The block diagram of the microwave circuit is shown in Fig. 1. A klystron of 726A type was used as the oscillator. Sawtooth voltage was supplied to its reflector electrode for frequency modulation. The out put signals from the test cavity and the cavity wavemeter were fed to an oscilloscope. f and the Q-factor of the test cavity were determined from patterns on the oscilloscope screen.

The test cavity is 67.7 mm in diameter and 5.3 mm in height. Frequency deviation associated with temperature change was −0.068 Mc/deg. The Q–factor of the empty cavity was about 500 and practically independent of temperature.

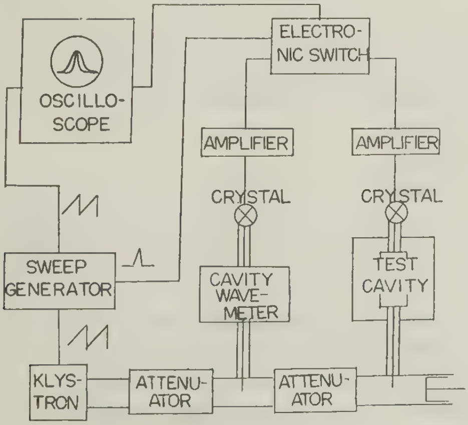

Fig. 1. Block diagram of the experimental set-up.

Table I.

Sample	Cross-section (cm²)	$\lvert\Delta f/f_2\rvert_{max}$
1 (single crystal)	1.70×10^{-4}	0.043
2 (single crystal)	1.50×10^{-4}	0.053
3 (ceramics)	0.96×10^{-4}	0.011

Table I gives cross-sections and maximum frequency deviations for the samples used in our measurement. All the samples are cylindrical-shapes with square cross-sections. The single crystals were supplied by Bell Telephone Laboratory.* Ceramic samples which were used as a check of the method were supplied by Kobayashi Institute of Physical Research.**

The crystals were cut by ultrasonic cutter* and then finished up by polishing with fine SiC powder. We tried to make the specimen a single domain crystal of which the long axis is parallel to the c-axis. However, small domains of which the c-axis are perpendicular to the long axis were observed at room temperature.

In the case of high permittivity specimen, even a small gap is a source of large error. To avoid this error, we painted conductive plastics between the ends of the specimen and the cavity wall.

§ 4. Experimental Results

Measured dielectric constants are shown as a function of temperature in Fig. 2 in comparison with Benedict and Durand's results[5]. These values are calculated by Eq. (8). The data of the samples 1 and 2 agreed well with those of Benedict and Durand's data above the Curie temperature. For ceramic sample (sample 3), the data are consistent with those of Powles and Jackson's[9].

---

*, ** The authors are indebted to Dr. J. W. Nielsen and Mr. J. P. Remeika of Bell Telephone Laboratory, Dr. T. Mitsui of Laboratory for Insulation Research of Massachusetts Institute of Technology and Dr. M. Marutake and Dr. Y. Tokita of Kobayashi Institute of Physical Research for supplying samples.

*** The authors wish to thank Dr. N. Sakamoto of Electrotechnical Laboratory and Dr. S. Kawaji of Gakushuin University for their kindness for cutting crystals by ultrasonic cutter.

Below the Curie temperature our results are quite different from those of Benedict and Durand's. This seems to come from differences in domain structure as will be discussed in the next section.

Dielectric loss could be measured with reliable accuracy only above the Curie point. The results are shown in Fig. 3.

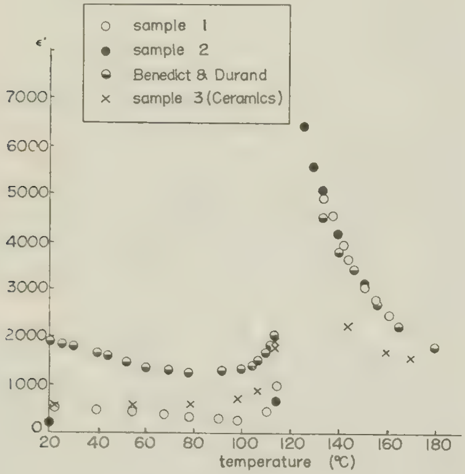

Fig. 2. ε' vs temperature.

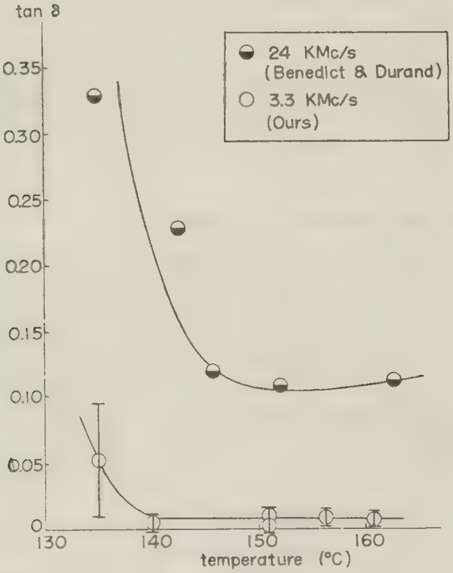

Fig. 3. tan δ vs temperature.

The difference between our results and those of Benedict and Durand is more than experimental error, ±0.007. As Table 1 shows the sample 3 (ceramics) is smaller than samples 1 and 2 in cross-section, but tan δ of the ceramics was too high to be measured even for this small specimen.

§ 5. Discussion

1) *Above the Curie temperature.*

Figs. 2 and 3, show that the $BaTiO_3$ single crystal does not exhibit dielectric dispersion up to 3 KMc/s region above the Curie temperature. Using ceramic samples, Powles and Jackson and others[8] observed decrease of ε' and increase of $\tan\delta$ with increasing frequency even above the Curie point, though that dispersion was smaller above the Curie point than below the Curie point. According to their results, $\tan\delta$ at 10 KMc/s and at 1.5 Mc/s are about 10^{-1} and 10^{-2}, respectively. The former value agrees with those which have been obtained by Benedict and Durand at 24 KMc/s for single crystals. Of course, the value of $\tan\delta=0.1$ at microwave region is too large to be attributed to conductivity. Then, it can be considered that dielectric dispersion occur near 24 KMc/s in the single crystal. And discrepancy of $\tan\delta$ between our result and Benedict and Durand's suggests that ionic resonance absorption frequency which appears in infrared region in ordinary ionic crystals is shifted to millimeter wave region in $BaTiO_3$, at temperature slightly above the Curie point, as Landauer[10] showed theoretically.

2) *Below the Curie temperature.*

Since our samples are multi-domain crystals our results may differ from the results on the single domain crystals below the Curie temperature. On the single domain crystals, as Benedict and Durand have shown, $\tan\delta$ is approximately the same above and below the Curie point except for temperatures close to the Curie point where $\tan\delta$ is large. Large dielectric loss observed below the Curie point in our measurement, though it could not be measured quantitatively, suggests the existence of some mechanism of dielectric dispersion due to multi-domain structure, which could also be the origin of the dispersion in ceramics.

As shown in Fig. 2, the sample 1 has a region where $\partial\varepsilon'/\partial T$ is negative. No definite interpretation is given for this fact, but one possible explanation seems to be that a tension, which was originated from the difference of expansion coefficients between cavity material and $BaTiO_3$, forced the c-axis of small domains to reorientate parallel to the field direction.

Appendix

We will show here that Eq. (2) is applicable for a specimen having anisotropic dielectric constant, by using Slater's normal mode method[11].

From the Maxwell's equations

$$\operatorname{curl} \boldsymbol{E}_1 = -i\omega_1 \boldsymbol{H}_1 \qquad \text{(A 1)}$$

and

$$\operatorname{curl} \boldsymbol{H}_1 = i\omega_1 \boldsymbol{E}_1 \qquad \text{(A 2)}$$

following wave equations hold in the cavity 1,

$$\left.\begin{aligned} &\nabla^2 \boldsymbol{E}_1 + \boldsymbol{k}_1 \boldsymbol{E}_1 = 0\,, \\ \text{and}\quad &\nabla^2 \boldsymbol{H}_1 + \boldsymbol{k}_1 \boldsymbol{H}_1 = 0\,. \end{aligned}\right\} \qquad \text{(A 3)}$$

To each eigen value $\boldsymbol{k}_i$ corresponds solutions of $\boldsymbol{E}_{1i}$ and $\boldsymbol{H}_{1i}$. It is easy to show that sets of solutions $(\boldsymbol{E}_{11},\cdots, \boldsymbol{E}_{1i},\cdots)$ and $(\boldsymbol{H}_{11},\cdots \boldsymbol{H}_{1i}\cdots)$ form complete systems of orthogonal functions. The fields $\boldsymbol{E}_{1i}$ and $\boldsymbol{H}_{1i}$ are the field of ith mode.

In cavity 2, the Maxwell's equations become as

$$\operatorname{curl} \boldsymbol{H}_2 = i\omega_2 \mathcal{E}_2 \boldsymbol{E}_2 \qquad \text{(A 4)}$$

and

$$\operatorname{curl} \boldsymbol{E}_2 = -i\omega_2 \mu_2 \boldsymbol{H}_2 \qquad \text{(A 5)}$$

where $\mathcal{E}_2$ is a tensor, in general, and expressed by a matrix $(\mathcal{E}_{jk})$ $(j, k=1,2,3)$. Expanding the left hand side of (A 4) with $\boldsymbol{E}_{1i}$,

$$\operatorname{curl} \boldsymbol{H}_2 = \sum_i \boldsymbol{E}_{1i} \int_{v_c} \operatorname{curl} \boldsymbol{H}_2 \cdot \boldsymbol{E}_{1i}{}^* dv = \sum_i \boldsymbol{E}_{1i} \left[\int_{v_c} i\omega_1 \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^* dv + \int_{v_c} \operatorname{div}(\boldsymbol{H}_2 \times \boldsymbol{E}_{1i}{}^*) dv \right],$$

where $\boldsymbol{E}_{1i}{}^*$ is the complex conjugate of $\boldsymbol{E}_{1i}$, and so on. From the boundary conditions,

$$\int_{v_c} \operatorname{div}(\boldsymbol{H}_2 \times \boldsymbol{E}_{1i}{}^*) dv = \int_s \boldsymbol{n} \cdot (\boldsymbol{H}_2 \times \boldsymbol{E}_{1i}{}^*) ds = \int_s (\boldsymbol{E}_{1i}{}^* \times \boldsymbol{n}) ds \simeq 0$$

where S is surface of the cavity and $\boldsymbol{n}$ is a normal unit vector. Expanding the right hand side of (A 4) with $\boldsymbol{E}_{1i}$ and comparing coefficients of $\boldsymbol{E}_{1i}$, following relation can be derived

$$\omega_1 \int_{v_c} \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^* dv = \omega_1 \int_{v_c} (\mathcal{E}_2 \boldsymbol{E}_2) \cdot \boldsymbol{E}_{1i}{}^* dv = \omega_2 \int_{v_c} \sum_j \sum_k \mathcal{E}_{jk} E_{2,j} \cdot E_{1i,k}{}^* dv\,, \qquad \text{(A 6)}$$

where $E_{2,j}$ is a component of the vector $\boldsymbol{E}_2$, and so on. Similary, development of (A 5) with $\boldsymbol{H}_{1i}$ gives

$$\omega_1 \int_{v_c} \boldsymbol{E}_2 \cdot \boldsymbol{E}_{1i}{}^* dv = \omega_2 \int_{v_c} \mu_2 \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^* dv\,, \qquad \text{(A 7)}$$

where $\int_s \boldsymbol{E}_{1i}{}^* \cdot (\boldsymbol{n} \times \boldsymbol{E}_2) ds \simeq 0$ is used. Then, from (A 6) and (A 7)

$$\frac{\omega_1}{\omega_2} = \frac{\displaystyle\int_{v_c} \sum_j \sum_k \mathcal{E}_{jk} E_{2,j} \cdot E_{1i,k}\, dv + \int_{v_c} \mu_2 \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^* dv}{\displaystyle\int_{v_c} \boldsymbol{E}_{1i}{}^* \cdot \boldsymbol{E}_2\, dv + \int_{v_c} \boldsymbol{H}_{1i}{}^* \cdot \boldsymbol{H}_2\, dv}\,,$$

therefore

$$\frac{\omega_1 - \omega_2}{\omega_2} = \frac{\displaystyle\int_{v_s} \left[\sum_j \sum_k \mathcal{E}_{jk} E_{2,j} E_{1i,k}{}^* - \boldsymbol{E}_2 \cdot \boldsymbol{E}_{1i}{}^* \right] dv + \int_{v_s} (\mu_2 - 1) \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^* dv}{\displaystyle\int_{v_c} (\boldsymbol{E}_{1i}{}^* \cdot \boldsymbol{E}_2 + \boldsymbol{H}_{1i}{}^* \cdot \boldsymbol{H}_2)\, dv} \qquad \text{(A 8)}$$

because $\mathcal{E}_2 = \mu_2 = 1$ in the cavity 2 except in v_s. If we introduce the unit matrix $\mathbf{1} = \begin{pmatrix} 100 \\ 010 \\ 001 \end{pmatrix}$, (A 8) can be written as

$$\frac{\omega_1 - \omega_2}{\omega_2} = \frac{\displaystyle\int_{v_s} \{(\mathcal{E}_2 - \mathbf{1}) \boldsymbol{E}_2\} \cdot \boldsymbol{E}_{1i}{}^*\, dv + \int_{v_s} (\mu_2 - 1) \boldsymbol{H}_2 \cdot \boldsymbol{H}_{1i}{}^*\, dv}{\displaystyle\int_{v_c} (\boldsymbol{E}_{1i}{}^* \cdot \boldsymbol{E}_2 + \boldsymbol{H}_{1i}{}^* \cdot \boldsymbol{H}_2)\, dv}\,.$$

Theory of Resistance Minimum in Dilute Paramagnetic Alloys

By Kensuke TANI*

Department of Physics, Faculty of Science, Osaka University, Osaka

(Received May 18, 1960)

We have calculated the electrical resistance of dilute paramagnetic alloys from the standpoint of seeing if the resistance minimum could arise from the short range order of the spins of the solute atoms.

In order that the resistivity minimum appears it is found that (i) the magnetic ion pairs which make the dominant contribution must be those ferromagnetically coupled and the scattering due to them must be dominantly elastic, and (ii) the functional form of the exchange integral $J(r)$ must be similar to that of the radial distribution of the 3d electrons.

A difficulty in the present interpretation is that the temperature at which the resistance minimum occurs is about ten times higher than that of experiments.

In the October 1 issue of the Physical Reivew Letters, Brailsford and Overhauser[1] published a paper with the same title as above. The present author has independently performed** a similar calculation from the same standpoint in order to see if the resistance minimum could arise from the short range order of the spins of the solute paramagnetic atoms.

The paramagnetic atoms are here assumed to have spins of magnitude of 1/2, and the neighbouring atoms are assumed to couple each other either ferromagnetically or antiferromagnetically. (Brailsford and Overhauser assumed spins of arbitrary magnitude, but considered only the case of ferromagnetic coupling). We take a pair of paramagnetic atoms at positions $\boldsymbol{R}_1$ and $\boldsymbol{R}_2$ $(\boldsymbol{R}_2-\boldsymbol{R}_1=\boldsymbol{R})$

which interact with the Hamiltonian:

$$H_0=-2\mathfrak{J}(\boldsymbol{R})\boldsymbol{S}_1\cdot\boldsymbol{S}_2 \qquad (S_1=S_2={}^1/_2). \tag{1}$$

The scattering potential for a conduction electron due to this pair may be written as[2]:

$$H^1=-N^{-1}\sum_{n\boldsymbol{kk}'\uparrow\downarrow}\{V(\boldsymbol{kk}')\pm S_n^z J(\boldsymbol{kk}')\}e^{i(\boldsymbol{k}-\boldsymbol{k}')\boldsymbol{R}_n}a^*_{\boldsymbol{k}'\uparrow\downarrow}\,a_{\boldsymbol{k}\uparrow\downarrow}$$
$$-N^{-1}\sum_{n\boldsymbol{kk}'}J(\boldsymbol{kk}')e^{i(\boldsymbol{k}-\boldsymbol{k}')\boldsymbol{R}_n}(a^*_{\boldsymbol{k}'\downarrow}\,a_{\boldsymbol{k}\uparrow}\,S_n{}^+ + a^*_{\boldsymbol{k}'\uparrow}\,a_{\boldsymbol{k}\downarrow}\,S_n{}^-) \tag{2}$$

Making use of these two assumptions (1) and (2), the temperature-dependent part of the resistivity was calculated, obtaining

$$R=\frac{3\pi^2}{e^2}\frac{m}{E_f}\left(\frac{\hbar}{2m}\right)^{3/2}B\,,^{(*)} \tag{3}$$

$$B\equiv\int\frac{V}{8\pi^3}\frac{1}{2}\left(\frac{2m}{\hbar^2}\right)^{3/2}\frac{2\pi}{\hbar}N^{-2}\left|J(2k_F\sin\theta/2)\right|^2(1$$
$$-\cos\theta)\sin\theta\times\left\{3A^{-1}e^{J\beta/2}\left[1+\frac{\sin(2k_FR\sin\theta/2)}{2k_FR\sin\theta/2}\right]\right.$$
$$\left.+\frac{5}{2}A^{-1}\frac{2e^{J\beta/2}}{e^{2J\beta}+1}\left[1-\frac{\sin(2k_FR\sin\theta/2)}{2k_FR\sin\theta/2}\right]\right\}d\theta\,,$$

with $A=3e^{J\beta/2}+e^{-3J\beta/2}$ and $\beta=1/kT$, V being the volume of the sample and θ the scattering angle.

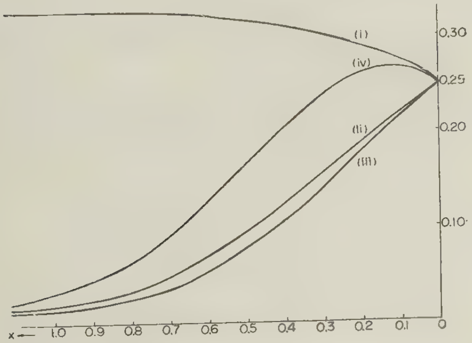

Fig. 1. Temperature dependences of elastic factor $A^{-1}e^{J\beta/2}$ are given by curve (i) for $J>0$ and curve (ii) for $J>0$. Curve (iii) and (iv) draw the temperature dependence of inelastic factor $A^{-1}\,2e^{J\beta/2}/(c^{2J\beta}+1)$ for $J>0$ and $J>0$, respectively.

The first term in the curly brackets in B comes from the elastic scattering by the triplet state, while the second term corresponds to inelastic scattering associated with the transition between the triplet and singlet states. The temperature dependence of the elastic term is given through the factor $A^{-1}\exp(J\beta/2)$, and its explicit form is shown in Fig. 1 by the increasing difficulty for them to lose their curve (i) for the case of ferromagnetic coupling ($J>0$) and by curve (ii) for the case of antiferromagnetic coupling ($J>0$), the abscissa being $x=J\beta/2$. On the other hand, the temperature dependence of the inelastic term is due to the factor $A^{-1}\exp(J\beta/2)/[\exp(2J\beta)+1]$, and it is shown by curve (iii) for $J>0$ and by curve (iv) for $J<0$. The physical interpretation of these behaviours is as follows.

Curve (i): the population of the triplet state increases monotonously with lowering temperature, thus $1/4\rightarrow1/3$ as $\beta=0\rightarrow\infty$.

Curve (ii): the population of the triplet state decreases monotonously as the temperature is lowered, thus $1/4\rightarrow0$ as $\beta=0\rightarrow\infty$.

In curves (iii) and (iv), the decrease of the resistivity at low temperatures comes from the fact that the population of the upper level decreases and therefore the inelastic scattering occurs mainly by exciting the pair, the conduction electron giving its energy. However, this is difficult because of the increasing degeneracy of the conduction electrons and thus energy. The second in each of the solid brackets in B represents the interference effect between the scattering by one of the paired paramagnetic atoms and that by the other. Contributions to the resistivity of these interference terms depend sensitively on the functional of $J(2k_F\sin\theta/2)$.

The integrals

Table I. Values of the integrals (4) divided by $J_0{}^2$. a and b are chosen to be $(0.093\text{Å})^{-1}$ and $(0.51\text{Å})^{-1}$, respectively, which have been determined to represent approximately the radial distribution function of the 3d electron cloud of Mn^{++}.

	$J(r)=J_0\delta(r)$		$J_0r\exp(-ar)$		$J_0\exp(-b^2r^2)$	
	elastic	inelastic	elastic	inelastic	elastic	inelastic
$R_{\text{n.n.}}$	6.42	5.35	12.69	1.18	3.10	3.17
$R_{\text{2.n.}}$	6.26	4.79	nearly the same as above		3.44	2.64

(*) In this calculation we neglect $\mathfrak{J}$ compared with E_F,

$$\int \left|J(2k_F \sin\theta/2)\right|^2 (1-\cos\theta)\sin\theta \times\left[1\pm\frac{\sin(2k_F R\sin\theta/2)}{2k_F R\sin\theta/2}\right]d\theta \qquad (4)$$

have been calculated for $J(r)$ of the three types as shown in Table I, where are shown their numerical values for the nearest neighbour distance $R=R_{\text{n.n.}}$ and the second neighbour distance $R=R_{\text{2.n.}}$ for the f.c.c. lattice.

If we know, for instance, the concentration of the Mn atoms in Cu, we can calculate the concentration of the pairs of nearest neighbours, that the pairs of second neighbours, and so on. The resistivity of the Cu-Mn dilute alloy is then calculated as the sum of the contributions from these pairs.

In order that the resistivity minimum appears, curve (i) in Fig. 1 must make the dominant contribution to the resistivity, since the resistivity due to lattice vibrations, which has to be added, increases rapidly with increasing temperature. In other words, the pairs which make the dominant contribution must be those ferromagnetically coupled and the scattering due to them must be dominantly elastic. These conditions are satisfied if the n.n. pairs and 2.n. pairs are the main contributors and they are ferromagnetically coupled, and also the functional form of $J(r)$ is similar to that of the radial distribution of the 3d electrons (the second column in Table I).

A difficulty in the present interpretation of the resistivity minimum is that it should occur at a high temperature of the order of J/k, while the observed temperature is only several times higher than the temperature of the resistivity maximum which corresponds to the Néel temperature of the interactining Mn atoms, the latter being expected to be at czJ/k (c=concentration, $z=12$) which is $\sim 10^{-2}$ J/k for $c=10^{-3}$. However, in the lack of detailed theoretical knowledge of the Néel temperature of the dilute alloys at the present moment, this difficulty cannot be taken too seriously.

Direct Observation of Lattice Defects in Cold-worked High Manganese Steels by Means of Electron Microscopy*

By Zenji NISHIYAMA and Ken-ichi SIMIZU

Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka-fu, Japan

(Received June 20, 1960)

Thin foils have been made by electrolytic polishing from bulk specimens of cold-worked high manganese steel. They have been observed by electron microscopy with the object of studying lattice defects formed by cold-working. From the micrographs and the selected area electron diffraction patterns obtained it is concluded that on {111} planes of the austenite matrix very thin (<100Å) plates of a hexagonal close-packed phase (ε) are formed, which correspond to the origins of strain markings formerly found on the etched surface by using the replica, and that ordinary stacking faults as found in 18–8 stainless steels are also present.

§ 1. Introduction

It is expected from the dislocation theory that in the face-centred cubic (FCC) metals stacking faults are easily formed in {111} planes by cold-working if the energy of the faults is small. Actually Hirsch et al.[1] observed the interference fringes due to the stacking faults in cold-worked 18–8 stainless steels by means of transmission electron microscopy.

If the stacking fault is induced, every two-layers of (111) planes in the FCC phase a hexagonal close-packed (HCP) phase is formed. Such a phenomenon will easily occur for the alloy having an equilibrium diagram in which there is a HCP phase region close to the FCC phase region. High manganese (Had-field) steel as well as Cu–Si alloy will belong to such a category.

As is well known, the high manganese steel is so much hardened by cold-working that it is very difficult to explain the reason only in terms of the ordinary work hardening. To clarify this fact a number of works[2] have been made, but the reason remains in question. In the preceding paper[3], it was tried to solve this problem by investigating the nature of strain markings seen on the etched surface of the cold-worked specimen. The observation was made by electron microscopy using the replicas of the surface. From the results it was suggested that there would be a very thin plate of HCP (ε) phase passing through every strain marking.

Thereafter the present writers succeeded in making thin foils of the steel for transmission electron microscopy, and so could test the former presumption, the result of which will be described in this paper dealing with the lattice defect produced by cold-working.

§ 2. Experimental method

For specimens a steel plate containing 0.97% C and 9.75% Mn was hot-forged to 1 mm thick, and the surface layers on both sides were ground off to a thickness of 0.5 mm. To austenitize the steel, it was solution-treated by heating for four hours at 1000°C in vacuum, followed by quenching into water. After it was electrolytically polished down to 0.3 mm thick for removing the surface layers, it was beaten with a hammer to cold-work. Lastly the plate was again electrolytically polished down to a thin foil by Bollmann's[4] method using electrolyte

Phosphoric acid	200 c.c.
Chromic acid	100 gr.

with the current of 1.5 Amp, 20 Volt at 70°C for the plate having an area of 2 cm in diameter.

It was subjected to direct observation by an electron microscope (JEM-5G) with 100 kV for Figs. 1, 2 (a), 6, 7, 8 and with 80 kV for Figs. 4, 5 (a).

§ 3. Experimental results

Fig. 1 is a transmission electron micrograph of an area in the specimen cold-worked. In

* This paper was read before the 9th Annual Meeting of the Physical Society of Japan held at Hiroshima University, in October, 1959.

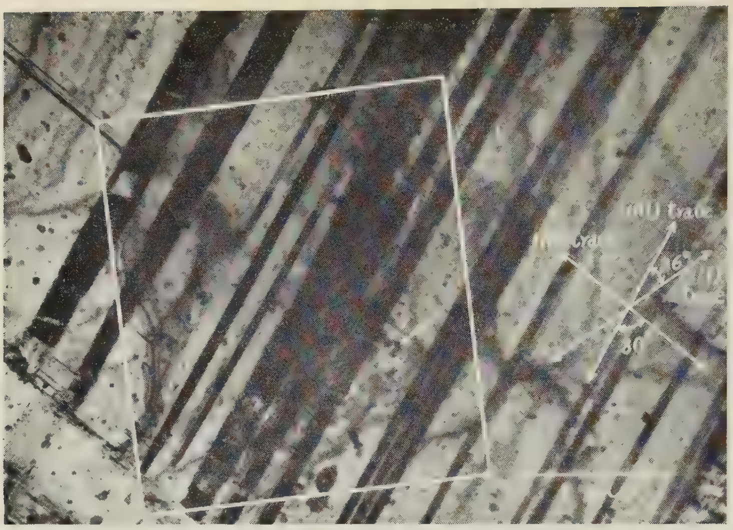

Fig. 1. Transmission elecron micrograph of a thin foil made by electrolytic polishing from a beaten sheet of high manganese steel, showing parallel bands of ε-phase.

this photograph a number of dark parallel bands are seen, which appear to have been formed in {111} planes of the FCC matrix (white ground) by cold-working. To study the crystal structure of these bands, the selected area electron diffraction pattern was taken of the white-framed region. Fig. 2 (a) is the pattern taken, which is considered to consist mainly of reflections from the parallel bands, because the darkness of the bands in Fig. 1 indicates that they have made stronger Bragg reflections than from the matrix. The main spots appeared in this diffraction pattern constitute a distribution of hexagonal array somewhat deformed. The distances between these spots are as shown in Fig. 3: A=8.28 mm, B=8.31 mm, C=7.25 mm (equivalent camera length=430 mm).

Let us first assume that the bands seen in Fig. 1 are due to parallel plates of ε-phase occurred parallel to its basal plane (0001). When the plates are very thin, their reciprocal lattice points will elongate in the direction of c-axis. If so, their diffraction pattern will appear as the section of the reciprocal lattice (elongated in the c direction) by a plane parallel to the foil. On this assumption and considering that AB direction (Fig. 3) was nearly parallel* to the bands in Fig. 1, we can calculate the orientation of the foil with respect to the crystallographic axes of the ε-phase plate using the distances between spots, Fig. 3. The result of the calculations** is

		H	K	I	L
	(i)	0.201	0.193	−0.404	1
or	(ii)	−0.201	−0.193	0.404	1

Assuming the orientation relationships between HCP plate and FCC matrix to be Shoji-Nishiyama's[5], we have the orientation*** of the foil referred to the FCC matrix axes to be

		h	k	l
	(i)	0.492	0.864	0.105
or	(ii)	0.482	0.110	0.869

From these orientations, we expect the traces of $(\bar{1}11)$, $(1\bar{1}1)$, $(11\bar{1})$ to be at (i) 78.7°, 29.1°, 180°-41.8° or (ii) 79.8°, 180°-43.6°, 27.9° from (111) trace. Actually, of these traces, $(\bar{1}11)$

---

Table I.

	Angle between (111) trace and other traces		Inclination of plates, calc.		Width of unit band (smallest), obs.
	Calc.	Obs.	Angle	Cosine	
(111) trace			32.4°	0.844	360Å
($\bar{1}$11) trace	79.8°	80°	73.3°	0.287	120Å
(11$\bar{1}$) trace	27.9°	26°	80.8°	0.160	<100Å

trace is realized at the left upper corner of Fig. 1, and (11$\bar{1}$) trace is seen very weakly at the middle region shown by an arrow. Their observed trace angles 80°, 26° are fairly coincident with the calculated ones of orientation (ii) (Table I). Moreover the observed widths of these traces are approximately proportional to the calculated cosine of the inclination of the plates of orientation (ii). These facts justify the orientation (ii).

Since this orientation is near $(102)_{\rm FCC}$ deviating only by 6.8°, spots due to the matrix will be also predicted to appear near the reciprocal lattice points on a plane parallel to (102) if the Bragg conditions are satisfied. These predicted positions, however, are only part of the observed spots as shown in Fig. 2 (b), mark ○. While, ε-phase of orientation (ii) can interprete almost all the observed regular spots as the small elongation ($0.02\,\text{Å}^{-1}$ at most) of the reciprocal lattice points on $(\bar{1},\bar{1}\cdot 1)$ plane, except four spots marked by arrows, as shown in Fig. 2 (c). The latter four, however, can be interpreted as the large elongation of the reciprocal lattice points $\{11\cdot 2\}$ which is about $0.24\,\text{Å}^{-1}$ apart from Ewald sphere in the c direction. Such a large amount of elongation may be allowable owing to very thin plates.

An alternative interpretation of the dark bands in Fig. 1 is that they are merely twins produced at {111} planes of the matrix. If so and if the orientation of the matrix is near (102), we predict the spots as shown by mark ▲ in Fig. 2 (b), besides the spots of the matrix marked by ○. In this way some of the observed spots can be interpreted, but there still remain some spots (×) unexplained*. But if we consider that the reciprocal lattice points of the thin twin plates are elongated in the direction perpendicular to the twin plane, all the observed spots can be interpreted, as shown in Fig, 2 (d), provided that the amount of the elongation reaches $0.24\,\text{Å}^{-1}$. Thus the bands seen in Fig. 1 can be attributed to the thin plates of twins as well as of ε-phase, so far as Figs. 1 and 2 (a) are concerned.

Fig. 4 is a photograph of another region in the foil. Of the white-framed portion in this photograph a selected area electron diffraction pattern was taken, which is shown in Fig. 5 (a). For analysis of this pattern, we assume the orientation of the matrix such that the foil plane is parallel to $(0\bar{1}1)$, since two sets of bands seen in Fig. 5 are both narrow and intersect with an angle of 71° which is almost equal to the angle (70°32′) between two of {111} planes. Then we expect the diffraction spots of the matrix at position, as shown by mark (o) in Fig. 5 (b), (c) and (d), if they appear. Spots are found at those positions in the actual photograph (a). The other spots,

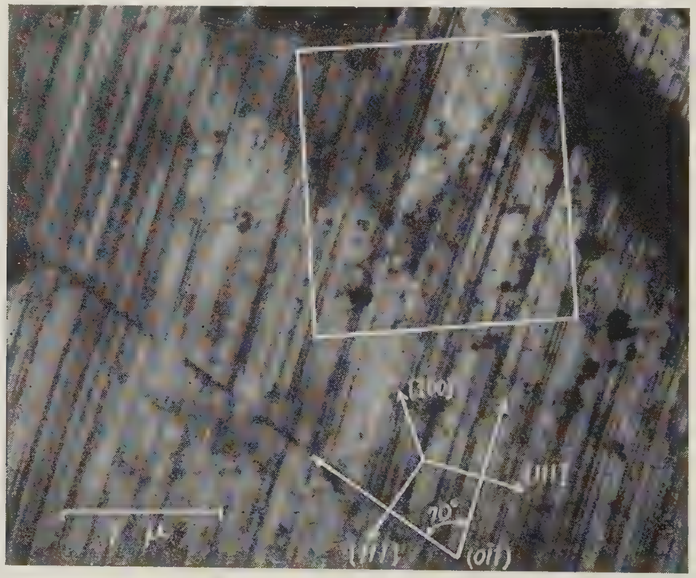

Fig. 4. Transmission electron micrograph of a thin foil of beaten high manganese steel, showing a parallel-line structure of ε-phase.

---

* If there exists the periodic error due to the coherency between the matrix and the twins, the junction spots may appear at positions unexplained. But such a possibility is very little, because the bands in question are formed running through the region near the selected area for electron diffraction.

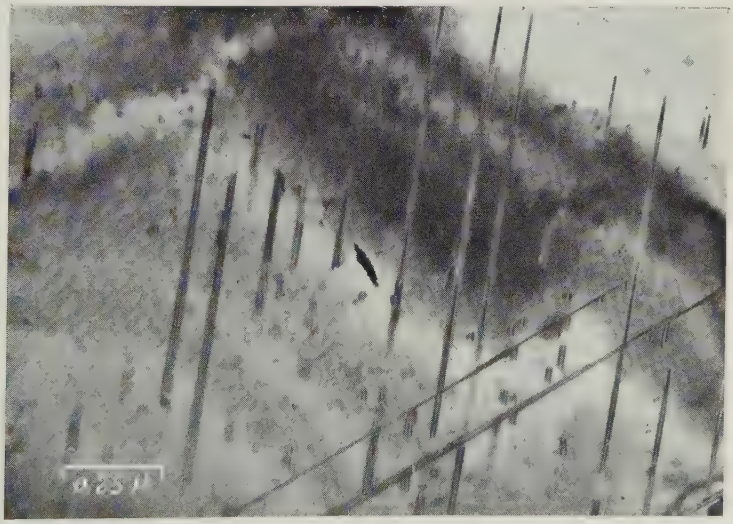

Fig. 6. Transmission electron micrograph of a thin foil of beaten high manganese steel, showing parallel fringes due to the stacking fault.

especially marked by ↑, can be interpreted as due to HCP (ε) phase in the bands but not due to twins.

If the above interpretation is correct, the plates of ε phase must be almost perpendicular to the foil, and the thickness of each plate can be directly estimated from the photograph. The estimated value is less than 100 Å. From these thin plates it is expected that the HCP spots and the central spot are accompanied by streaks in the direction perpendicular to the bands, as actually observed in the horizontal direction. It is moreover noted that the spots $H-K\neq 3n$ (in hexagonal index) of the matrix are not accompanied by such streaks. This indicates that there are no stacking faults in the matrix of this region, although we cannot say so for the interior of the ε-plate.

Fig. 6 is a micrograph of another region in the specimen, where the degree of cold-working may be different from those in Figs. 1 and 4. In Fig. 6, many bands are also seen, each band consisting of a few lines of fringes which exhibit the reversal in intensity in the region where extinction contours (broad dark

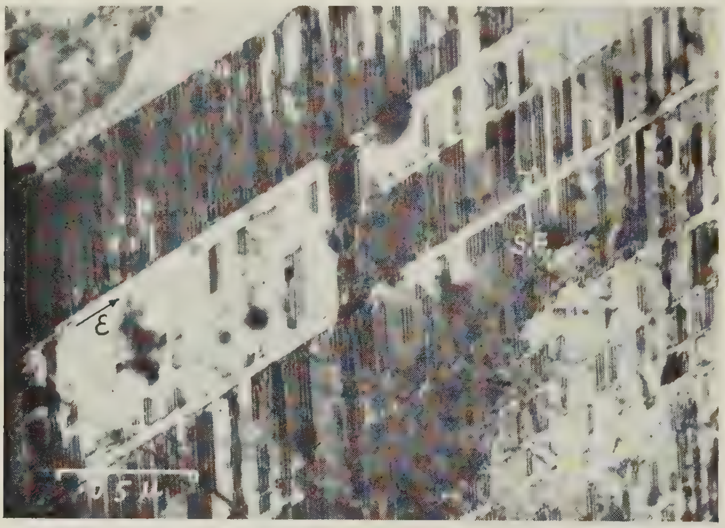

Fig. 7. Transmission electron micrograph of a thin foil of beaten high manganese steel, showing parallel fringes due to the stacking fault (S.F.) and no-reflecting bands of ε-phase.

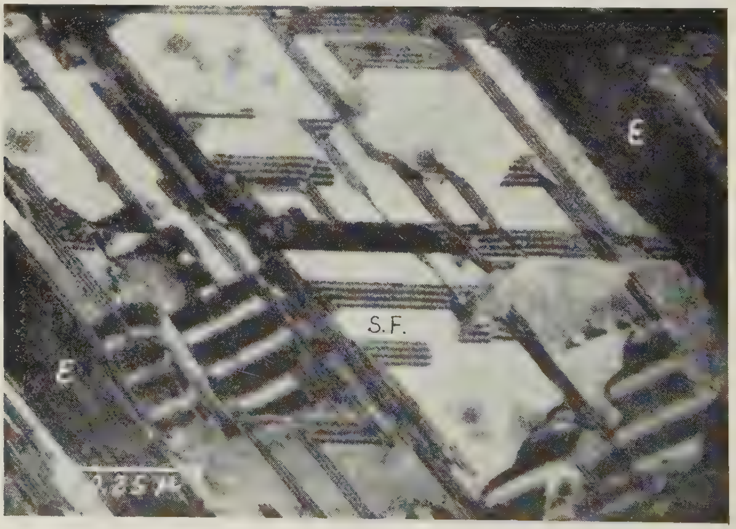

Fig. 8. Transmission electron micrograph of a thin foil of beaten high manganese steel, showing parallel fringes due to the stacking fault (S.F.) and reflecting bands of ε-phase.

region running from right-bottom to left-top) are appeared. As in the case of the photograph given by Hirsch et al.[1] in 18–8 stainless steel, the behaviors of these fringes indicate that each band is due to a stacking fault plane inclined to the foil. The short fringe seen here and there are due to dislocations which are just to begin to extend. In this figure there are also seen three bands intersecting with the stacking fault fringes. From their behaviors it seems that they are rather due to HCP (ε) plates as mentioned before.

Fig. 7 is a photograph of another region, in which two kinds of bands are also seen: Fringes marked by S. F. are due to a stacking fault and white (no-reflecting) bands marked by ε are due to ε plates.

Fig. 8 is another enlarged micrograph, in which various kinds of bent stacking faults having a stair-rod dislocation are clearly seen, and ε phase regions which are reflecting look to consist of many thin plates.

§ 4. Discussion

As shown in the micrographs described above, there are present stacking faults in some regions but ε plates in other regions. This inhomogenuity is caused by non-uniformity of the degree or rate of cold-working due to hand-hammering. Any way, from the experimental facts we recognize the formation of ε plates as well as stacking faults in {111} planes of FCC matrix.

The ε plate seems to be less than 100 Å in thickness and of less amount than the matrix. The reason why the diffracton pattern of such plates of less amount was seen is on the condition that the matrix did Bragg reflection less in intensity than ε plates. And it is highly probable that this ε plate corresponds to the origin of the strain markings revealed on the etched surface. By this means, it may be said that the present experiment confirmed the former presumption that the origin of the strain marking is the thin ε plate but not the cluster of stacking faults as assumed in the case of Cu–Si alloy by C. S. Barrett[8].

From these facts it may be concluded that the enormous work-hardening of the high manganese steel is because of the formation of stacking faults and thin plates of ε-phase.

The authors wish to express their gratitute to Mr. A. Tanaka, the Faculty of Medicine, Osaka University, for his help to take electron micrographs.

University of Osaka Prefecture

(Received June 23, 1960)

Using the far-infrared spectrometer constructed recently in Osaka University, measurements of the optical absorption were made on the single crystal of NiO (Néel temperature=523°K) in the wave-length range of 210 to 385 microns and at temperatures 90° to 470°K. No magnetic field was applied. An absorption peak was clearly observed whose wave-length varied with temperature. With increasing temperature it shifted toward the longer wave-length side and at the same time the peak height diminished. At room temperature (291°K) the peak was at 293±5 microns ($34.1\pm0.6\,\mathrm{cm}^{-1}$) and the wave-length value extrapolated to absolute zero was 274 microns ($36.5\,\mathrm{cm}^{-1}$). This absorption peak is attributed to the antiferromagnetic resonance of the mode in which the antiparallel sublattice magnetizations oscillate perpendicularly to the easy plane of magnetization, (111). The constant, K, of the anisotropy energy which constrains the sublattice magnetizations in the easy plane is calculated to be 4.96×10^6 erg/cc at 0°K from the theoretical formula $\omega=(ge/2mc)(2K/\chi_\perp)^{1/2}$, assuming $g=2.23$. This can be compared with theoretical value, 7.01×10^6 erg/cc, based on the magnetic dipolar interaction between Ni^{++} ions, but the experimental value is smaller.

§ 1. Introduction

Since Nagamiya[1] and Kittel[2] initiated the theory of the antiferromagnetic resonance (AFMR), the microwave resonance experiments in centimeter and millimeter regions have been made on a number of antiferromagnetic materials, and it was found that the expermental results were essentially in good agreement with the theory. The microwave resonance experiments with moderate fields on $\mathrm{CuCl_2\cdot2H_2O}$ ($T_N=4.3$°K) by Leiden Group[3] and on $\mathrm{CuCl_2\cdot2H_2O}$ ($T_N=4.7$°K) and $\mathrm{CuBr_2\cdot2H_2O}$ ($T_N=5°\sim6.5$°K) by Date[4] could be interpreted by the theory of Yosida[5] and Nagamiya[6] for orthorhombic crystal. For antiferromagnetics having higher Néel temperature and hence larger exchange field, a very high frequency or a very high magnetic field is necessary to observe the AFMR. Johnson and Nethercot[7] measured the AFMR in $\mathrm{MnF_2}$ ($T_N=68$°K) with short millimeter waves and Foner[8] used high pulse magnetic field to observe AFMR in $\mathrm{MnF_2}$ and $\mathrm{Cr_2O_3}$ ($T_N=308$°K). An earlier experiment on $\mathrm{Cr_2O_3}$ by Dayhoff[9] using lower fields could not reveal the whole behavior of the resonance phenomenon. These experiments could be well interpreted by the theory of Nagamiya[1] and Keffer and Kittel[10] for uniaxial crystal and gave valuable informations about the temperature-dependent anisotropy energy constant of these crystals.

The technique of far-infrared spectroscopy should also be valuable for this study. In Berkeley, Tinkham[11] has succeeded to measure with a far-infrared spectrometer the AFMR in $\mathrm{FeF_2}$ ($T_N=79$°K) which has a high crystalline field anisotropy energy. A far-infrared spectrometer[12] was constructed a few years ago in Osaka University by Prof. Yoshinaga, and by his courtesy the present author was able to study the AFMR in NiO ($T_N=523$°K). The range of wave-length studied was 210 to 385 microns, since the theoretical estimate of the resonance wavelength, based on the dipolar anisotropy energy constant, was 231 microns ($43.3\,\mathrm{cm}^{-1}$) at 0°K. The resonance was detected, and the present paper will give the detailed account of our experimental procedure and theoretical interpretation of the results.

§ 2. Theoretical Estimate of the Antiferromagnetic Resonance Frequency

The crystal structure of NiO is of the NaCl type with a slight rhombohedral deformation below the Néel temperature. Neutron diffraction experiments[13),22),23)] showed that the spin arrangement is of the Néel type, i.e., there are alternating (111) sheets of plus spins and minus spins, and that the spin axis is confined in the (111) plane. Since the Ni^{++} ions in the cubic crystalline field of NiO should possess an isotropic g-value, no crystalline field anisotropy energy can be expected, and the anisotropy energy in NiO should arise for the most part from the magnetic dipolar interaction among the Ni^{++} ions. This anisotropy energy can be expressed in the form

$$U=(2/3)K(\alpha\beta+\beta\gamma+\gamma\alpha)\,, \qquad (1)$$

where α, β, and γ are the direction cosines of the spin axis relative to the cubic principal axes. The constant K has been calculated by Kaplan[14)] and it is positive, so that the spin axis is to be confined in the (111) plane. For absolute zero, K is expressed in the form

$$K=(3/2)(57.41)(gS\mu_B)^2a^{-6}\,, \qquad (2)$$

(a is the lattice constant and $S=1$ for Ni^{++}) and it is calculated to be

$$K=7.01\times10^6\ \mathrm{erg/cc} \qquad \text{for NiO}\,, \qquad (3)$$

assuming $g=2.23$ and using $a=4.17\times10^{-8}$ cm. This g-value was taken from Low's[15)] paramagnetic resonance measurement of the g-value of Ni^{++} in MgO.

There are two modes of eigen-oscillation of the sublattice magnetizations. One is such that the antiparallel sublattice magnetizations oscillate with a large amplitude in the (111) plane and the net magnetization oscillates with a phase difference of $\pi/2$ in the direction perpendicular to the plane. The frequency of this oscillation in the absence of any external field is proportional to the square root of the product between the molecular field constant, A, which is the reciprocal perpendicular susceptibility, and the small (if any) anisotropy energy constant within the easy plane. The other mode is such that the large motion takes place perpendicularly to the easy plane and the small bending oscillation within the easy plane. This mode has a frequency

$$\omega=(ge/2mc)(2AK)^{1/2}=(ge/2mc)(2K/\chi_\perp)^{1/2}\,, \qquad (4)$$

where K is the anisotropy energy constant for the out-of-plane motion.

With the use of the observed perpendicular susceptibility $\chi_\perp=80.5\times10^{-6}$ emu/cc[16)]* and the value of K given by (3), we can estimate the frequency of the second mode at absolute zero to be $\nu_0(\text{theor.})=\omega/2\pi=43.3\ \mathrm{cm}^{-1}$, the corresponding wave-length being 231 microns.

Since K arises from the dipolar interaction, it should vary with temperature proportionally to the square of the magnitude of the sublattice magnetizations if the temperature is sufficiently high. With the Brillouin function formula, the K value at room temperature is estimated to be by 21 percents less than that at absolute zero, and correspondingly the resonance wave-length at room temperature comes out at 259 microns (38.6 cm^{-1}).**

With these expectations, the author has carried out an absorption experiment on NiO crystal in the wave-length range of 210 to 385 microns, varying the temperature from 90° to 470°K.***

§ 3. Experimental

NiO samples used in the present experiment were slabs cut from single crystals grown by the flame fusion method by Dr. Nakazumi[20)]. Results given in Figs. 1–3 were obtained with slabs whose basal surfaces were parallel to (111). These samples were obtained by cutting and polishing the mother crystals into plates 1 to 2 mm thick.**** This procedure was followed, since at first a measurement with a sample cleaved along a (100) plane gave only a faint absorption peak. Later we found that crystals cleaved along (100) gave as good results as crystals polished along (111); when both kinds of samples were annealed well at 1600°~1670°C in argon atomosphere, as Roth and Slack[22] did, the crystals became much more perfect, but the position and shape of the absorption peak measured at room temperature remained the same.

---

* This value of $\chi_\perp$ was taken from Singer's measurements on stress-annealed single crystal. It is the value at 523°K where there is the maximum of the specific heat and where the present author has found[17)] the torque in magnetic field to vanish, i.e., the parallel and perpendicular susceptibilities to coincide with each other. The susceptibility has a maximum at 630°K and the maximum value is 88.7 emu/cc.

** The spin wave treatment shows that[18)] at low temperatures K is proportional to the cube of the magnetization, and the resonance frequency[19)] is then not given by $\sqrt{2AK(T)}$ but it is given by $\sqrt{2AK(T)}\cdot(M(O)/M(T))^{1/2}$, therefore the frequency is proportional to $M(T)$. We assume here the classical molecular field picture.

*** It was not possible to detect the peak beyond 430°K due to decreasing incident beam intensities for longer wave-lengths than 385 microns and diminishing peak height.

**** This thickness was chosen as being smaller than the skin depth, which could be estimated from the conductivity measurements by Yamaka[21)] to be of the order of 30 cm at room temperature and 0.2 cm at 440°K for wave-lengths of 300 microns. (The values of the resistivity are 5×10^7 ohm-cm at 300°K and 2×10^3 ohm-cm at 440°K),

At room temperature, a single slab with an area of about 1.5 cm^2 could be used, which was put close to the Golay detector[12]. For measurements at higher and lower temperatures, the sample had to be put at the entrance slit (maximum area$=50\times20$ mm^2) which is far away from the detector, and therefore a large area was required for the sample to obtain a sufficient beam intensity at the detector. For this purpose, a plate of aluminium with a dozen holes was prepared and NiO slabs, all with (111) surfaces and with thickness of 1.5 ~1.7 mm, were fitted in them. Furthermore, to make a good thermal contact, two other plates of aluminium having smaller holes were pressed on it from the both sides. The total effective area of the crystals was then 9.3 cm^2. The beam was made to focus at the slit with an aperture of 6°. At room temperature, both samples gave the same main absorption peak, although some differences were found in the side peaks which appeared in some of the curves as seen in Figs. 1 and 2. Temperature measurements of the sample were made with a copper-constantan thermocouple whose one end was made to contact with a crystal which was mounted near the center of the aluminium plate. The temperature difference between the crystals and the thermo-bath was estimated to be within 5° in thermally stationary state.

The sample, the thermo-bath, and the optical system were all set in a vacuum tank and they were remote-controlled. Thermal radiation from the bath could be eliminated with the use of the technique of chopping the beam and detecting the corresponding alternating intensity[12]. The resolution of the spectrum was about 10 microns in the neighborhood of 300 microns. As the beam intensity fell rapidly above 375 microns, it was not possible to extend our measurements beyond 385 microns (26.0 cm^{-1}).

Observations were made of the intensity, I', in the presence of the sample and the intensity, I, in the absence of the crystal. The ratio I'/I gives the transmission rate. The plots of this ratio for different thickness of the sample and different temperature are given in Figs. 1 and 2.

§ 4. Results

Optical absorptions were all measured in the absence of external field. Measurements at room temperature (291°K) were made with single slabs of thickness 1.0 mm, 1.3 mm, and 2.0 mm. The corresponding values of the transmission rate, I'/I, are shown in Fig. 1.

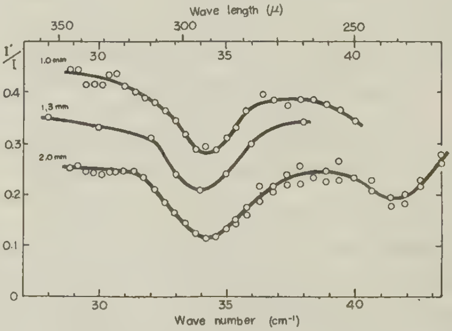

Fig. 1. Transmission rate, I'/I, through single slabs of thickness 1.0 mm, 1.3 mm, and 2.0 mm at room temperature. Incident beam is perpendicular to the (111) surface of the crystal.

These curves indicate clearly an absorption peak at 293±5 microns (34.1±0.6 cm^{-1}) and show further that the absorption rate increases with increasing thickness. In order to check that this absorption peak is characteristic of NiO, a sample of CoO was examined in the neighborhood of this wave-length. No absorption anomaly was found, however.

Variation with temperature of the absorption curve was studied with another kind of sample (having a dozen crystals) mentioned in the preceding section. The results are shown in Fig. 2. The frequency of the absorption maximum shifts to smaller values with increasing temperature, and these values are plotted in Fig. 3. As the incident beam intensity decreased with decreasing frequency and the transmission rate decreased with increasing temperature, no absorption peak was detectable beyond 430°K (the Néel tempera-

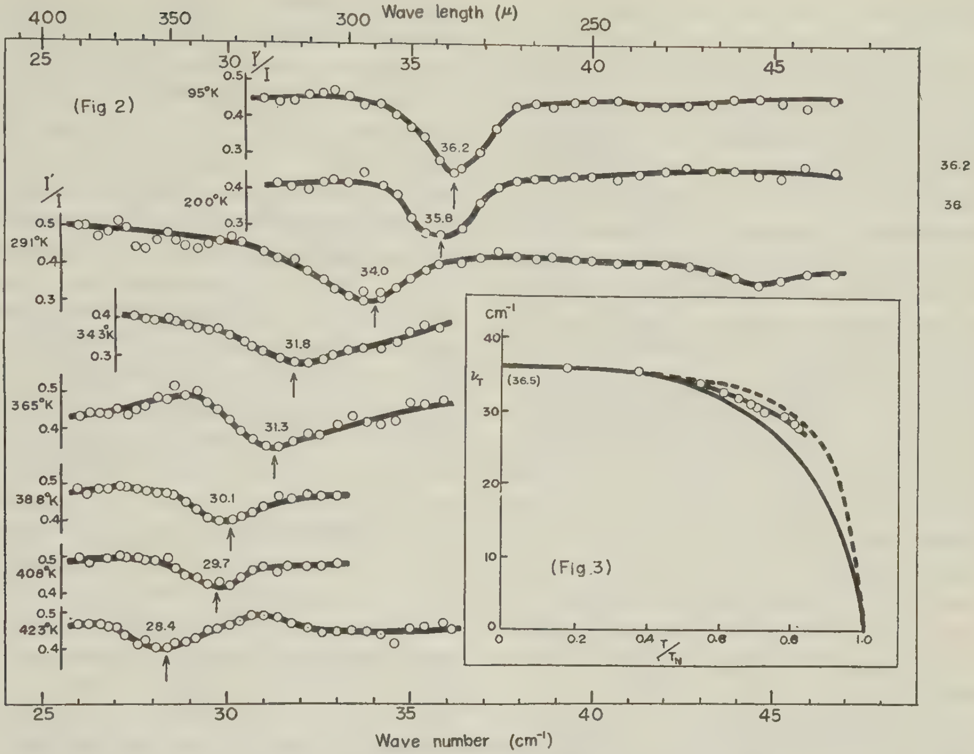

Fig. 2. Transmission rate, I'/I, through a sample having a dozen crystals, at various temperature. Incident beam is perpendicular to the (111) surfaces of the crystals.

Fig. 3. Temperature dependence of the frequency of the absorption maximum. Experimental points are plotted from the data of Fig. 2. A thin curve is the Brillouin curve with $S=1$ and a dotted curve the variation of sublattice magnetizations with temperature obtained from the neutron diffraction experiment by Roth. These two curves are so normalized as to coincide with our experimental value of wave number at 0°K and at room temperature, respectively.

ture is at 523°K). The wave number extrapolated in Fig. 3 to absolute zero is found to be 36.5 cm^{-1} (274 microns).

From the formula (4), and with this absorption frequency value at 0°K and the perpendicular susceptibility $\chi_{\perp}=80.5\times10^{-6}$ emu/cc, the value of the magnetic anisotropy constant, $K(exp.)$, is calculated to be 4.96×10^6 erg/cc at 0°K. On the other hand, the value of the corresponding anisotropy energy due to the magnetic dipolar interaction between Ni^{++} ions, $K(theor.)$, is given by (3), i.e., 7.01×10^6 erg/cc. This theoretical value of the anisotropy constant corresponds to an absorption frequency of $\nu_0(theor.)=43.3$ cm^{-1}. (If the g-value were taken to be 2.00, one would have obtained $K(exp.)=6.16\times10^6$ erg/cc and $K(theor.)=5.64\times10^6$ erg/cc).

Since $K(theor.)$ should be proportional to the square of the magnitude of the sublattice magnetizations, if only dipolar anisotropy energy is taken into account, the temperature dependence of the resonance wave-number snould be theoretically given by the Brillouin curve with $S=1$. In Fig. 3 this theoretical curve is shown together with the experimental one.

§ 5. Discussion

We see from Fig. 3 that at absolute zero $\nu_0(exp.)=36.5$ cm^{-1} is smaller than $\nu_0(theor.)=43.3$ cm^{-1} and that the measured resonance wave number decreases with temperature more steeply near the Néel temperature than that predicted by the theory. The temperature dependence of the sublattice magnetzaitions has been measured by the neutron diffraction experiment by Roth[13] and it is also shown in Fig. 3 by a dotted curve, which was so normalized that it coincides with our resonance wave number curve at 291°K. It is seen that the behavior of this curve is more similar to that of our resonance wave number curve.

In the estimate of ν_0(*theor.*), ambiguities are introduced by the use of the value of $\chi_\perp$ and the isotropic g-value. Roth and Slack[22] have recently prepared a very good single crystal of NiO which contained untwinned domain to 98.7 percents, and they measured the magnetic anisotropy by the torque method. Combining their data with Singer's measurements of the single crystal susceptibility, they estimated the value of $\chi_\perp$ to be 71.5×10^{-6} emu/cc. This value is smaller by about 10 percents than that used in the present paper which was based on Singer's measurements alone. If this smaller value of $\chi_\perp$ is assumed, the discrepancy between ν_0(*theor.*) and ν_0(*exp.*) becomes even greater. As for the g-value, we have used that of Ni^{++} in MgO, since the g-value of Ni^{++} in NiO is not known. The g-value comes into the frequency formula by a factor g^2, so that a small change in g can influence ν_0(*theor.*) rather drastically.

The difference between ν_0(*theor.*) and ν_0(*exp.*), as well as the difference in the temperature dependence of the resonance wave number, could partly be due to the contribution of the crystalline field anisotropy energy. However, the value of the latter expected from rhombohedral deformation of the order of 0.1 percents should be very small.

Interaction between different antiferromagnetic domains may also give rise to a shift in the resonance frequency. However, we have observed in specimens annealed at 1670° C in argon atomosphere the same wave number for the absorption peak at room temperature. The origin of the discrepancy is therefore not clear at the present moment.

It was found that the temperature dependence of the line width of the absorption peak differs from that of the AFMR in other antiferromagnetic materials hitherto investigated: (1) the line width is much broader than that of MnF_2 or $CuCl_2\cdot2H_2O$ at the same reduced temperature T/T_N, and (2) the line width changes little with temperature and only the height of the absorption peak decreases with increasing temperature. In vergin NiO crystals prepared by the flame fusion method, we observed a number of small twin domains of a dimension of ~10 microns, but in crystals annealed at 1670°C in argon atmosphere and then cooled slowly to room temperature, we may have large domains. For both these samples we observed the same line width and the same position of the absorption peak. Therefore the twin domains may be little responsible for the line width. Roth and Slack[22] observed that the line intensities of the neutron diffraction pattern for a twinless NiO crystal changed with the intensity of the external field, and from this result, together with his result of the torque measurements, they concluded that in low fields NiO may consist of small antiferromagnetic domains with random distribution of the axis of magnetization. These antiferromagnetic domains may give rise to a fluctuation of the molecular field for individual spins and may broaden and shift the absorption peak. The anisotropy field will also fluctuate and produce a similar effect. Furthermore, motion of the domain walls and demagnetizing field from free poles produced at the walls due to different precessions in different domains may also have some effect. If these were the origin of the line width (and a possible line shift), we could expect that the absorption line becomes sharper by application of a high field. However, we have done no such experiment.

§ 5. Acknowledgements

The author would like to express his great appreciation to Professor T. Nagamiya for suggesting this problem and for his continual guidance during the course of this research. The author would like also to express his sincere thanks to Professor H. Yoshinaga for allowing the author to use his spectrometer and giving him instructions concerning the measurements. Furthermore, he is indebted to Dr. A. Mitsuishi for kind assistance and discussion as regards instrumental problems, Dr. A. Tachiki for stimulating discussion, Dr. Y. Nakazumi for providing him with crystals, Mr. N. Fukuoka for helpful assistance, and finally to Professor E. Uchida for warm encouragement throughout this work.

Magnetostriction and Crystal Anisotropy of Nickel-Chromium and Nickel-Vanadium Alloys

By Tokuo WAKIYAMA

Kobayashi Institute of Physical Research, Tokyo

and Sōshin CHIKAZUMI

Institute for Solid State Physics, University of Tokyo, Tokyo

(Received June 27, 1960)

Magnetostriction constants, λ_{100} and λ_{111}, of nickel-chromium and nickel-vanadium alloys were measured at room and liquid nitrogen temperatures by a strain gauge method. Both constants were negative and their magnitudes decreased monotonically with increasing the composition of adding elements. Magnetocrystalline anisotropy constants were also measured at the same temperatures. The concentration dependence of the anisotropy constants was more drastic than that of the magnetostriction constants.

The present data and other available data of nickel binary alloys were analysed on the basis of Néel's theory and the coefficients of dipole-dipole and quadrupole-quadrupole interactions of atom pairs in nickel alloys were estimated. The dipole-dipole interactions of Ni-M (where M=V, Cr, Mn, Fe, Co, Ni and Cu) atom pairs were fairly well explained under the assumption of the spin-orbit interaction.

§1. Introduction

It is well known that the magnetostriction constants are closely related with the dipole-dipole interaction between magnetic atoms and its dependence on the lattice spacing. L. Néel[1] showed this relation in a phenomenological way in connection with the theory of magnetic annealing. The purpose of the present investigation is to determine the coefficient of dipole-dipole interaction between various sorts of magnetic atoms by using the magnetostriction constants measured by various investigators[2)-4)]. Unfortunately we could not find out the experimental data on Ni–Cr and Ni–V alloys, so we measured these constants at room and liquid nitrogen temperatures. Crystal anisotropy constants were also measured at the same temperatures and a phenomenological quadrupole-quadrupole interaction coefficient was determined for various atom paris[5)-8)].

§2. Specimens and Experimental Procedure

Specimens used in this experiment were prepared by melting electrolytic nickel and chromium, and high-purity vanadium in a high vacuum induction furnace. Large crystals were obtained by solidifying the alloy slowly in a crucible. These crystals were cut into disk plates parallel to (110). The size of the specimen was 8∼15 mm in diameter and 0.3∼1 mm in thickness. The compositions of Ni–Cr crystals are 0, 1.47, 2.52 and 4.08 at.% chromium and those of Ni–V crystals are 1.28 2.95 and 3.93 at.% vanadium. In advance to the measurement, all specimens were annealed for 2 hours at 1300°C and quenched from 700°C to secure the disorder state.

Measurement of the magnetostriction constants was carried out by means of strain gauge technique, using the apparatus as shown in Fig. 1. Strain gauges were placed on the crystals in both [001] and $[\bar{1}11]$ crystallographic directions. The change in the electric resistace of the strain gauge was measured by an ordinary Wheatstone bridge. An unbalanced current was measured by a galvanometer directly. The strain sensitivity was the order of 0.65×10^{-6} per 1 mm deflection of the scale. Magnetostricton was plotted against the direction of the field at every 5° from 0 to 180°. The angle θ is always measured from [001] direction.

Measurement of the anisotropy constant was carried out by means of the torque magnetometer as shown in Fig. 2. This apparatus is characterized by a pair of two air-flow bearings, almost the same as used by R. F. Penoyer[9], which enable the frictionless rotation of specimen holder about the vertical axis.

The intensity of the magnetic field is about 8000 œ, which is strong enough to saturate the specimen, at room and liquid nitrogen temperatures.

§3. Experimental Results

One of the results of magnetostriction measurement in the [001] and [$\bar{1}$11] direction in (110) plane is shown in Fig. 3 as a function of θ. These curves were analyzed by assuming the two-constants expression

$$\lambda=\frac{3}{2}\lambda_{100}\left(\alpha_1{}^2\beta_1{}^2+\alpha_2{}^2\beta_2{}^2+\alpha_3{}^2\beta_3{}^2-\frac{1}{3}\right)$$
$$+3\lambda_{111}(\alpha_1\alpha_2\beta_1\beta_2+\alpha_2\alpha_3\beta_2\beta_3+\alpha_3\alpha_1\beta_3\beta_1),\qquad (1)$$

where λ is the spontaneous saturation magnetostriction, α_1, α_2 and α_3 are the direction cosines of the spontaneous magnetization β_1, β_2 and β_3 are those of the direction of measurement with respect to the crystal axes. This formula well expresses the experiment as shown by the solid curves in Fig. 3. The values of the magnetostriction constants thus obtained are tabulated in Table I, and are also plotted as a function of the alloy composition in Figs. 4 and 5 for Ni-Cr and Ni-V alloys respectively. In both cases the obtained curves are similar in shape and λ_{100} and λ_{111} are negative values for any chromium or vanadium content and their absolute values

decrease monotonically with increasing concentration. At liquid nitrogen temperature, both constants were increased in their absolute values, though the general feature of the curves was not changed.

One of the torque curves is shown in Fig. 6. The values of the anisotropy constant K_1 were calculated by the Fourier analysis. The values of K_1 thus obtained are tabulated in Table. II, and are also graphically shown in Figs. 7 and 8 as a function of the alloy composition. The anisotropy constant K_1 of Ni–Cr or Ni–V alloys remains negative for any chromium or vanadium content, and fades out much more rapidly with increasing chromium or vanadium content than the intensity of magnetization does. It is interesting to note that the concentration dependence of K_1 of Ni–Cr alloys is more drastic than that of Ni–V alloys, whereas its saturation magnetization decreased more slowly with concentration than that of Ni–V alloys[10].

§4. Analysis of the Experimental Results

Magnetostriction is the phenomenon that the crystal lattice is deformed by the interaction of atomic magnetic moments. According to L. Néel[1], the energy due to interaction between neighboring atoms should be a function of the distance between the two atoms and also of the angle φ between magnetization and pair direction, so that it can be expressed by the Legendre polynomials.

$$w=g+\left(l+m\delta r\right)\left(\cos^2\varphi-\frac{1}{3}\right)+\left(q+s\delta r\right)\left(\cos^4\varphi-\frac{6}{7}\cos^2\varphi+\frac{3}{35}\right)+\cdots, \quad (2)$$

where g is the isotropic interaction such as exchange interaction, l and q are the coefficient of dipole-dipole and quadrupole-quadrupole interaction respectively, m and s are the differential coefficients of l and q with respect to r and δr is the variation of the distance r. Starting from the formula (2), Néel calculated the magnetostriction constants and obtained for face-centered cubic crystal

$$\left.\begin{aligned}\lambda_{100}&=-\frac{nN}{72VC_2}(6l+mr_0),\\ \lambda_{111}&=-\frac{nN}{36VC_3}(2l+mr_0),\end{aligned}\right\} \quad (3)$$

where n is the number of the nearest neighbors, N the Avogadro number, V the atomic volume, C_2 and C_3 the elastic constants, and r_0 the distance between the nearest neighbors for undeformed lattice. From these relations, we can solve l and m, thus

$$\left.\begin{aligned}\frac{nNl}{2V}&=\frac{9}{2}(C_3\lambda_{111}-2C_2\lambda_{100})\,,\\ \frac{nNmr_0}{2V}&=9(2C_2\lambda_{100}-3C_3\lambda_{111})\,.\end{aligned}\right\}\tag{4}$$

Now in the case of the alloy, interaction between the atoms should be different for different pair of atoms, so that l and m for AA, BB and AB pairs should be denoted by l_{AA}, m_{AA}, l_{BB}, m_{BB} and l_{AB}, m_{AB} respectively. In the case of disordered state, the number of each kind of pairs is proportional to $C_A{}^2$, $C_B{}^2$ $2C_AC_B$, where C_A and C_B are the concentration of A and B atoms, so the average value of l and m should be given by

$$l=l_{AA}C_A{}^2+2l_{AB}C_AC_B+l_{BB}C_B{}^2\,,\tag{5}$$

$$m=m_{AA}C_A{}^2+2m_{AB}C_AC_B+m_{BB}C_B{}^2\,.\tag{6}$$

Since λ_{100} and λ_{111} are expressed as a linear function of l and m as shown in (3), they should also depend upon the atomic concentration in the same way as (5) or (6). In other words, λ versus C_B curves are expected to be parabolic. This is actually the case for most of ferromagnetic alloys.

Figs. 4 and 5 show the concentration dependence of magnetostriction constants measured for Ni–Cr and Ni–V alloys, just fitted by quadratic functions by adjusting the parameters. Using the values of the parameters and $V=6.55$ cc, $C_2=0.45\times10^{12}$ dyne/cm^2 and $C_3=1.185\times10^{12}$ dyne/cm^2, which are observed for nickel, we can calculate the values of l and m for Ni–Ni, Ni–V and V–V pairs. The values are tabulated in Table III together with the values for other nickel alloys.

Table III. Coefficient of the dipole-dipole interaction and its differential coefficient with respect to r of each atom pair in various face-centered cubic nickel alloys.

A–B	Nl_{AA}	Nl_{AB}	Nl_{BB}	$Nm_{AA}r_0$	$Nm_{AB}r_0$	$Nm_{BB}r_0$
Ni–V	0.73×10^8 erg/mol 0.42*	0.54×10^8 erg/mol 4.5*	-193×10^8 erg/mol −116*	5.4×10^8 erg/mol 7.7*	-73×10^8 erg/mol −75*	965×10^8 erg/mol 720*
Ni–Cr	0.79 0.47*	0.90 3.3*	−167 − 74*	5.2 7.3*	−76 −68*	110×10 611*
Ni–Mn	1.0	−3.7	13	4.3	−14	43
Ni–Fe	0.8**	−3.8**	12**	4.6**	−7.3**	− 28**
Ni–Co	1.0	−6.9	− 11	3.1	28	17
Ni–Cu	1.1	0.23	−4.5	3.0	−5.5	9.9

(*: at 77°K, **: after L. Néel[1)])

The crystalline anisotropy constant K_1 can be related to the third term of (2), as shown by Néel, thus

$$K_1=\frac{N}{V}q\,.\tag{7}$$

Since there is a possibility that dipole-dipole interaction can gives rise to the cubic anistropy[11)], the value of q thus obtained from K_1 should involve both of the dipole and quadrupole interaction terms.

Fig. 6 shows the torque curve measured for (110) plane of 3.93 at.% V–Ni at 300°K. The concentration depence of K_1 is also fitted by quadratic function of atomic concentration as shown in Fig. 7. The values of q thus determined for various atom pairs are tabulated in Table IV.

Table IV. Coefficient of quadrupole-quadrupole interaction of each atom pair in various face centered cubic nickel alloys.

A–B	Nq_{AA}	Nq_{AB}	Nq_{BB}
Ni–V	-0.32×10^6 erg/mol	7.4×10^6 erg/mol	-183×10^6 erg/mol
Ni–Cr	−0.31	9.6	−280

Ni–Fe	−0.33	0.58	−0.49
Ni–Co	−0.20	1.0	−5.0
Ni–Cu	−0.37	0.84	−2.0

At 77° K, $Nq_{NiNi}=-4.8\times10^6$ erg/mol

§5. Discussion

Since we determined the values of l and m by using nickel-rich alloys, the values for B–B pair are not reliable. The values of l_{NiNi} and m_{NiNi} are almost the same for all alloys. This is simply because the parabolic curves drawn to fit the experimental points pass the vicinity of nickel point in every cases. The most significant values obtained from magnetostriction constants are those of l and m for Ni–B pairs. In Fig. 9 we plotted the l_{NiB} as a function of electron concentration of B atom, where we can see a fairly regular dependence of l value upon the number of $3d$ electrons.

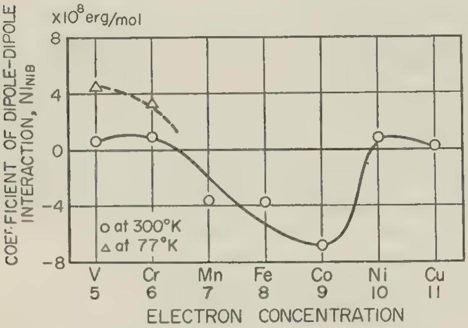

Fig. 9. Dependence of the coefficient of dipole-dipole interaction for Ni–B pairs on the electron concentration of B atom.

The features of this curve are summarized as follows:

i) Negative part of the curve starts from $n=6.5\sim7.0$, where n is the number of electrons outside the argon shell of the B atom, and takes the muximum at about $n=9$.

ii) l_{NiB} takes the positive value in the regions $n<6.5\sim7.0$ and $n>9.8$.

iii) The order of magnitude of l_{NiB} is $10^8\sim10^9$ erg/mol.

The origin of dipole-dipole interaction in ferromagnetic crystals was first discussed by N.S. Akulov[12)] and by R. Becker[13)], who showed that the purely magnetic dipole-dipole interaction is too small to account for the actual magnitude of uniaxial crystal anisotropy and that of magnetostriction. As pointed by Van Vleck[11)], the actual origin is belived to be a combined effect of spin-orbit interaction and overlapping wave functions between the neighboring atoms. The presence of some orbital angular mometum and overlapping of the neighboring $3d$ orbits are, therefore, prerequisite for the pseudo-dipole interaction. From this point of view, we can interprete several features of the experimental curve.

Since the number of $4s$ conduction electrons is believed to be about one at Cr or Mn[14)], the remaining $3d$ electrons should take $3d^5$ state (S state) at about $n=6$, where the atom should have no orbital angular momentum, so that we cannot expect any pseudo-dipole interaction at this point. As the number of electrons increases from this point, the orbital angular momentum should be increased, provided the atom stays in a free state. Actually, however, the atom is under the action of the strong crystalline field. In the case of the face-centered cubic metals, each atom is surrounded by 12 cations, each of which is found in ⟨110⟩ direction from the center atom. In such a case, d-orbits should split into $d\varepsilon$ and $d\gamma$ orbits, where $d\varepsilon$ orbits extend towards ⟨110⟩ directions, while $d\gamma$ oribits extend along the coordinate axes. Since each atom shoud find neighboring cations in ⟨110⟩ directions, $d\varepsilon$ orbits might be more stable than $d\gamma$ orbits, as is the case for octahedral sites of ferrite. In this case, $3d^6$ and $3d^7$ should have triply degenerate ground state, where the orbital angular momentum is remained unchanged. This is not exactly the case for actual metal, where the large part of the orbital angular momentum is quenched as being expected from the g-value. The tendency of leaving some orbital angular momentum at about $n=7\sim8$, however, is found for the actual metals, because the observed value of g-factor, which is nearly equal to 2 at $n=7$, begin to deviate from 2 with an increase of n, and its deviation takes the maximum at about $n=9$.[15)] This behavior of the orbital angular momentum seems to explain the experimental fact i) fairly well.

When $n<6$ and $n>9$, the last electron should occupy $d\gamma$ orbits. These regions are corresponding to those indicated in ii). It is, however, not clear whether or not the positive value of l_{NiB} can be related to the $d\gamma$ orbit.

As pointed out by C. Kittel[16),17)], the order of magnitude of pseudo-dipole interaction can be given by

$$|l| \approx J(g-2)^2, \qquad (8)$$

where J is the exchange integral. Since $J\approx10^{10}\sim10^{11}$ erg/mol and $g-2\approx0.05\sim0.08$, (8) gives the value of l of the order of magnitude $10^7\sim10^9$ erg/mol, which is in good agreement with the experimental value stated in iii).

It should be noted here that the value of

m_{NiB} depends upon the electron concentration n of the B atom almost in the same way as that of l_{NiB}. This fact may be explained by assuming that the dependence of l_{NiB} upon the lattice constant is mainly caused by a change in the overlapping of $3d$ shells between Ni and B atoms.

Acknowledgements

The authors express their hearty thanks to Dr. J. C. Slonczewski of IBM Research Laboratory, Dr. T. Moriya of Bell Telephone Laboratories and Dr. M. Tachiki of the Osaka University for their valuable advices about theoretical argument of this paper and also to Dr. T. Nakamichi of the Research Institute for Iron, Steel and Other Metals, who informed his data of Ni-Mn alloys.

Studies on the Preparation of Pure Alkali Chlorides*

By Koichi KOBAYASHI and Tetsuhiko TOMIKI

Department of Physics, Tohoku University, Sendai

(Received June 27, 1960)

Systematic studies were made on the preparation of pure KCl and NaCl crystals. Effects of the starting material on the purity of crystal were studied with KCl and NaCl powders of reagent grade of several different brands and with those prepared from bicarbonate and hydrochloric acid. Methods by distillation and crystallization in vacuum and by Kyropoulos technique in air were used for the crystallization procedures to study on each of their advantages. To estimate the concentration of impurities in crystals, the measurement of ionic conductivity was made for multivalent metallic ions, optical absorption for hydroxyl ions, and chemical analysis for bromine ions. The purest crystal in respect of these impurities was found to be the one grown from its powder prepared from bicarbonate and hydrochloric acid by the method of distillation and crystallization in vacuum. After the studies on the edge of the fundamental absorption in connection with the concentration of bromine, an absorption band due to the presence of bromine was found in KCl of which maximum is at 7.12 ev at room temperature.

§ 1. Introduction

In the past three decades, considerable efforts have been devoted to study on alkali chloride crystals by a number of workers to investigate their intrinsic natures as a typical example of an ionic crystal. It is well known, however, that some of their properties are found to be different from crystal to crystal and the experimental results are influenced strongly by chemical impurities and physical imperfections in the crystal. One example is a growth rate of color centers at room temperature. This is known to be so sensitive to the density of impurities and of dislocations that one has to be careful in measuring the true magnitude of the energy of formation of a color center by an ionizing radiation from its growth curve. One does not know also whether the very poor photoelectric response of alkali chloride during an irradiation in the fundamental optical absorption region is characteristic of its perfect crystal, since the Schubweg of electrons might be shortened considerably by the presence of imperfections. Even on a color center itself, it is not so certain whether the experimental results are completely free from any effects due to imperfections, since the color center concentration with which investigations have been carried is of the same order as or less than the concentration of impurities in most cases. Therefore, it may be important to study with a very perfect crystal to reduce any influences due to the presence of imperfections for investigating the intrinsic nature of alkali chloride. This is the reason for the present studies on the preparation on pure crystals.

In the present work, we have studied on KCl and NaCl as typical examples of alkali chlorides. At the first step of our systematic studies on the preparation of perfect crystals, our interests have been concentrated on their chemical impurities. We have investigated on multivalent metallic ions, hydroxyl ions, and halogen ions of other kinds present in KCl and NaCl as impurities, and have developed a method of preparation of pure crystal in respect of these impurities. After examinations of the edge of the fundamental absorption in both crystals, it has been found that its position is related primarily to the concentration of impurity bromine, which has been found to be one of the most abundant impurities in the crystals. Furthermore, a new absorption band due to the presence of bromine has been found in KCl just at the edge of its fundamental absorption band.

* A part of the present work has been carried out during our temporary stay in Prof. Kanzaki's laboratory of the Institute for Solid State Physics, University of Tokyo.

§ 2 Experimental

1) *Preparation of Crystals*

Crystals were grown from their powders of defferent kinds by different methods of crystallization to investigate their effects on the purity of the crystals.

a. Starting materials

Alkali chloride powders of two different kinds were used as a starting material. One was the powder made from alkali bicarbonate and hydrochloric acid through a chemical reaction. The other was powders obtained from different companies as reagent grade chemicals. The former was prepared for trying to make a starting material as pure as possible by a conventional chemical technique before the crystallization. The following are the reasons of using bicarbonate and hydrochloric acid: Firstly, it is possible to purify alkali and chloride ions separately by chemical means. The second is that the chemical purification of bicarbonate and hydrochloric acid is much easier than that of alkali chloride. Thirdly, the purity of alkali bicarbonate and hydrochloric acid available commercially is believed to be better than that of commercial alkali chlorides.

Synthetic KCl powders were made from $KHCO_3$ and HCl in their aquous solution. HCl was purified through two times ether extractions followed by a careful distillation. The aquous solution of $KHCO_3$, which was prepared from this salt of reagent grade without further chemical purification, was then mixed with this HCl. The resultants were KCl, H_2O, and CO_2, the last of which was able to be eliminated easily just by heating. KCl powder was obtained after cooling its saturated solution and was dried in vacuum.

Synthetic NaCl powders were made from $NaHCO_3$ and HCl. $NaHCO_3$ was purified by a chloroform solution of dithizone and 8-hydroxyquinoline. NaCl powder was prepared with HCl purified by ether extraction through the same procedure as for KCl, except the precipitation of this salt by an addition of alcohol to its saturated solution. No trace of metal impurity was found in this NaCl by a spectroscopic analysis except potassium.

Commercial KCl and NaCl powders were of G.R. grade made by the Kanto Chemical Company, the Wako Pure Chemical Industries, and the Merck Company in Germany.

b. Crystal growing

Two methods were used for growing single crystals in this study. One was the usual Kyropoulos technique and crystals were pulled up in air from their melts in a platinum crucible. The other was the method through distillation and crystallization in vacuum inside a quartz tube which was developed by Kanzaki and Kido[1].

Crystals prepared by the above methods are listed in Tables I and II. In the column of starting material, powder made from alkali bicarbonate and hydrochloric acid is denoted as *a*, while powders obtained from Kanto, Wako, and Merck are indicated as *b*, *c*, and *d*, respectively. In the column of crystal growing, *K* and *V* represent the method of Kyropoulos and of distillation and crystallization in vacuum, respectively.

It should be noted that the crystals grown by the method of distillation and crystallization in vacuum did not show good planes after cleavage and may contain dislocations in much higher concentration than Kyropoulos crystals. Particularly, NaCl crystals grown in this way were found to be deformed severely. NaCl–aV–2 listed in Table II is the worst crystal in this respect, of which cleavage planes are curved.

2) *Ionic Conductivity*

As a mearsure of an amount of multivalent metallic ion impurities, an ionic conductivity was measured on each of crystals with d.c. technique.

Fig. 1 indicates the results of the ionic conductivity of KCl prepared in this study. The conductivity of Harshaw crystal is also shown in this figure for the purpose of comparison. It was found usually that the conductivity in its structure sensitive region varies within a factor of two between crystals prepared from commercial powders in different bottles obtained from the same company.

The concentrations of electric carriers in KCl were estimated from the present conductivity data in the structure sensitive region and the vacancy mobility measured by Kelting and Witt[2]. They are listed in Table I as *n*/cc.

Among Kyropoulos KCl crystals in Table I, KCl–aK–1, the crystal which was grown from

Table I. KCl crystals.

Crystal	Starting material	Crystal growing	*n*/cc	OH/cc	ev at $k=10$ cm^{-1}	Bromine concentration
KCl-aK-1	*a*	*K*	1×10^{15}	2×10^{15}	7.027	$9\ \times10^{-6}$
KCl-HA-1	Harshaw		9×10^{15}	8×10^{15}	6.985	7.1×10^{-5}
KCl-bc2K-1	*b*+*c*	*K*	8×10^{15}	2×10^{15}	6.919	1.1×10^{-4}
KCl-bK-1	*b*	*K*	4×10^{15}	2×10^{15}	6.904	1.3×10^{-4}
KCl-dK-1	*d*	*K*	7×10^{15}	2×10^{15}	6.847	3.6×10^{-4}
KCl-bc2K-2	*b*+*c*	*K*	1×10^{16}	2×10^{15}	6.822	8.1×10^{-4}
KCl-B-II-3*	*b*	*V*	1×10^{15}	$<3\times10^{14}$	6.828	—

* Kindly supplied by Prof. H. Kanzaki of the Institute for Solide State Physics, University of Tokyo.

KCl powder prepared from $KHCO_3$ and HCl, has the lowest *n* of which magnitude is as small as 1×10^{15} per cc. One may note that this amount is smaller than that of Harshaw KCl by a factor of nine and is comparable to that of KCl–B–II–3 which was purified through careful distillation and crystallization in vacuum. If one assumes that the concentration of electric carriers is related directly to that of multivalent metallic ion impurities, one can say that the concentration of multivalent metallic ions in KCl–aK–1 is considerably lower than that of crystals grown directly from commercial KCl powders.

To estimate an amount of reduction of multivalent metallic ions in KCl by the Kyropoulos procedure, crystallization from the melt was repeated carefully four times in air and the ionic conductivity was measured with the crystal after each step. The starting meterial was the commercial KCl powder of G.R. grade. The concentration of electric carriers was found to be decreased in the manner, 1.1×10^{16}, 8.2×10^{15}, 3.6×10^{15}, and 2.3×10^{15} per cc according to the successive crystallization from the melts. This would indicate that the concentration of multivalent metallic ion impurities can be reduced to one fifth of its original amount by applications of Kyropoulos technique in three times. The concentration of multivalent metallic ions in the final crystal is about twice that of KCl–aK–1 in magnitude.

Electric conductivities were measured also on NaCl crystals prepared by different procedures. The results are shown in Fig. 2. Concentrations of electric carriers, *n*, were estimated with the vacancy mobility given by Etzel and Maurer[3)] and are tabulated in Table

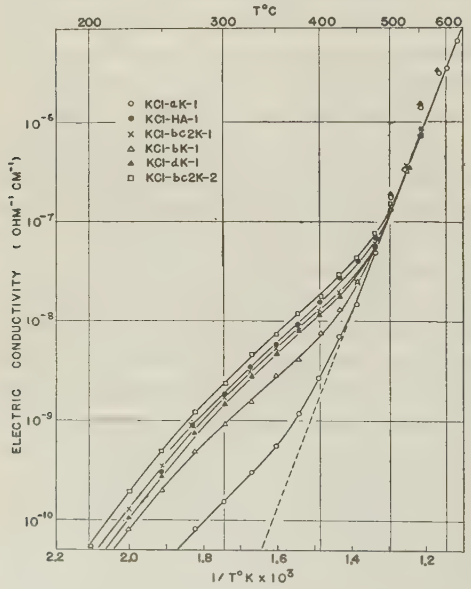

Fig. 1. Ionic conductivities of KCl crystals.

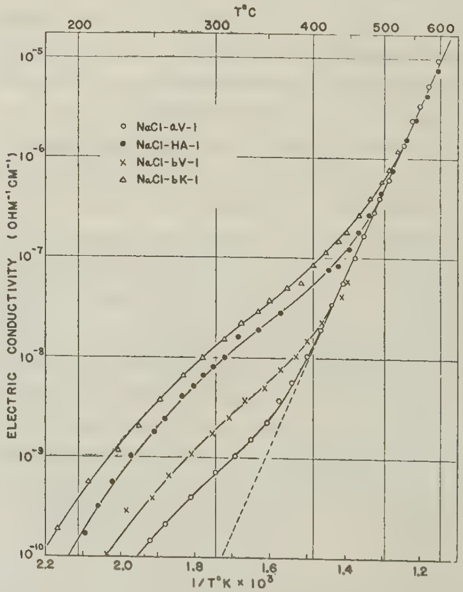

Fig. 2. Ionic conductivities of NaCl crystals,

II. One may notice that n for NaCl–bV–1 is smaller by six times than that for NaCl–bK–1. The former was grown from the commercial KCl powder by the method of distillation and crystallization in vacuum, while the latter was grown from the same material but by the Kyropoulos method.

Both NaCl–aV–1 and NaCl–bV–1 are grown by the method of distillation and crystallization in vacuum. However, the former was started with NaCl prepared from bicarbonate and hydrochloric acid and the latter was with the commercial one. The magnitude of n for NaCl–aV–1 was found to be smaller by three times than that for NaCl–bV–1. One may note also that this magnitude is smaller by a factor of more than ten than that for Harshaw NaCl.

It may be interesting to note that the concentrations of electric carriers at the both ends of the boule of NaCl–aV–1 were found to be different only by a factor of 1.1, while those of the boule of NaCl–bV–1 by a factor of 2.2. Therefore, it would be very probable that the NaCl powder which was prepared from bicarbonate and hydrochloric acid already contain little multivalent metallic ions which can be removed effectively by the crystallization from the melts.

NaCl–aV–2 in Table II is the crystal prepared from the same starting material and by the same growing procedure as NaCl–aV–1. However, the large deformation of the former has been found to be introduced during the course of crystallization in vacuum.

Table II. NaCl crystals.

Crystal	Starting material	Crystal growing	n/cc	OH/cc	ev at $k=10$ cm^{-1}	Bromine concentration
NaCl–aV–1	*a*	V*	2.5×10^{15}	$<6\times10^{14}$	7.222	1.1×10^{-5}
NaCl–HA–1	Harshaw		3×10^{16}	3×10^{16}	7.213	1.4×10^{-5}
NaCl–bV–1	*b*	V*	8×10^{15}	$<6\times10^{14}$	7.174	—
NaCl–bK–1	*b*	K	5×10^{16}	2×10^{16}	7.158	4.0×10^{-5}
NaCl–aV–2	*a*	V*	5×10^{15}	$<6\times10^{14}$	7.190	—

* Distillation and crystallization in vacuum was performed kindly by Mr. K. Kido at the Institute for Solid State Physics, University of Tokyo.

3) *Optical absorption*

Optical absorptions were measured on KCl and NaCl crystals at room temperature to find any absorptions due to the presence of impurities. In the infrared region, a Perkin-Elmer Model 21 infrared spectrophotometer was used to cover from 2.5 to 15μ. No absorption band was found in KCl and NaCl listed in Tables I and II in this spectral range. In the region from visible up to 2.5 μ, a Hitachi recording spectrophotometer was used and again no absorption band was detected in these crystals.

Optical absorption measurements in the range from 240 mμ down to the fundamental absorption edge, however, indicate significant differences between crystals. They were measured at 12°C with a vacuum ultraviolet spectrophotometer which was constructed by Ueta and his collaborators. The results are shown in Fig. 3 for KCl and in Fig. 4 for NaCl. The thickness of the crystal used in this measurement was ranging from 0.6 mm to 1.0 mm. The absorption coefficient was determined by taking into account of the reflection loss. The reflectivity used in this calculation was estimated from the index of refraction for both KCl and NaCl given by Gyulai[4] in the range from 240 to 185 mμ. In the wave length region shorter than 185 mμ, the reflectivity measured by Hartman et al[5] was used after having been normalized to the one calculated from the index of refraction at 185 mμ. One may notice in both figures the presence of so called OH-band and the large difference in the position of the fundamental absorption edge between crystals.

a. OH band

The results in Fig. 3 indicate the presence of absorption band at 204 mμ in all KCl crystals except KCl–B–II–3. This is known to be the absorption due to OH ion present as an impurity in KCl[6]. The absorption coefficient of KCl–B–II–3 which was prepared by distillation and crystallization in vacuum was almost zero in the range from 190 to 240 mμ and therefore no OH absorption was observed within our experimental error. The intensity of this absorption band was found to be the highest in KCl–HA–1, the Harshaw KCl, among the KCl crystals studied. All other crystals which were grown from different KCl powders by the same procedure, that is the Kyropoulos method in air, show the presence of OH band with small but almost the same intensity. The concentration of OH ion in KCl was estimated under the assumption that its oscillator strength is 1.9[6]. The results are listed in Table I.

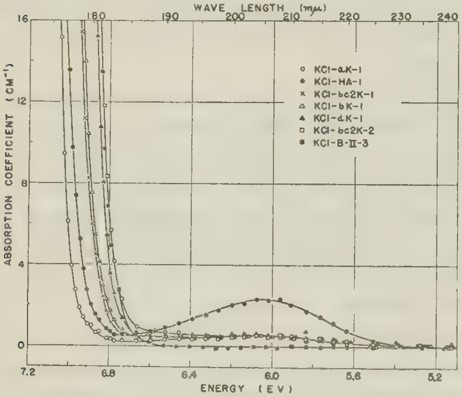

Fig. 3. Absorption spectra of KCl crystals in the ultraviolet region.

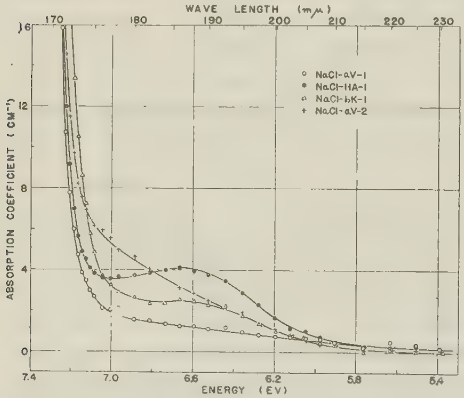

Fig. 4. Absorption spectra of NaCl crystals in the ultraviolet region.

In Fig. 4, one may find that the absorption band at 185 mμ due to OH ion in NaCl[6] is present apparently in NaCl–HA–1, the Harshaw crystal, and in NaCl–bK–1 which was grown in air by the Kyropoulos method. Its intensity is much higher in the former crystal than in the latter. Crystals NaCl–aV–1 and NaCl–aV–2 have a pronounced tail extending from the edge of the fundamental absorption to the region of OH band but there is no sign of a hump in their absorption curves in the region of OH band. Both crystals have been grown from the same starting material and by the same vacuum distillation and crystallization method. However, NaCl–aV–2 has been deformed much more severely than NaCl–aV–1, so that the only significant difference between them may be of their concentration of dislocations. Since the tail is much larger in the former crystal than in the latter, the tails of both crystals are possibly due to the dislocations but not to the chemical impurities. Therefore, it may be said that no hydroxyl ions detectable by optical means are present in NaCl crystals prepared by the distillation and crystallization in vacuum. In Table II, the concentrations of hydroxyl ion in NaCl are listed which were estimated under the assumption that the oscillator strength is unity.

b. Edge of the fundamental absorption

In Fig 3, considerable difference is observed in the position of the edge of the fundamental absorption between KCl crystals. The photon energies where the absorption coefficient, k, is 10 cm^{-1} are listed in ev in Table I for the indication of the position of the edge of each crystals. The difference of the position of this kind was found also in NaCl crystals as shown in Fig. 4. The photon energies at $k=10$ cm^{-1} for NaCl are list in Table II. It is clear from these tables and figures that the absorption edge positioned at the shortest wave length was of KCl–aK–1 among KCls and of NaCl–aV–1 among NaCls, both of which were grown from their powders prepared from bicarbonate and hydrochloric acid.

From the data in Tables I and II, one may find that there is no definite relation between the position of the fundamental edge and the concentration of electric carriers or of hydroxyl ions. Therefore, the shift of the position of the edge may not be due to the presence of multivalent metallic ions or hydroxyl ions in KCl and NaCl. It may be possible to imagine that the difference of the edge position might be explained by the different concentrations of dislocations in the crystals. However, the positions of the edge of NaCl–HA–1 and NaCl–bK–1 are in the longer wave length side than that of NaCl–aV–1 while the dislocation densities of the former two are believed to be much lower than that of the latter. Also, in Fig. 3, all of the KCl crystals do not show any tail with appreciable intensity in spite of their different position of the fundamental absorption edge. Therefore, one may conclude that the difference in the position of the edge is not caused by the difference in the dislocation density in crystals.

Other impurity possibly present in alkali chlorides is halogen of other kinds, particularly bromine. Therefore the colorimetric chemical analysis of bromine[7] was made on each crystal of KCl and NaCl. The amount of bromine was determined by measuring the intensity of the optical absorption at 580 mμ due to bromophenol blue resulting from the addition of sodium hypochlorite and phenol red to the aqueous solution of the sample. The minimum amount of bromine in a crystal which was able to be determined by this method was about 3×10^{-6} in mole fraction. The results are listed in Tables I and II in the unit of mole fraction of the bromine ions to the total halogen ions. The concentrations of bromine thus found are of surprisingly large, so that the bromine may be one of the major impurities in alkali chlorides. The crystal which contains the least bromine among KCls was KCl–aK–1 and among NaCls was NaCl–aV–1, both of which were grown from their powders prepared from bicarbonate and hydrochloric acid.

It may be clear in Tables I and II that the position of the fundamental absorption edge of both KCl and NaCl is related directly to the concentration of bromine in the crystal in such a way that the former is shifted to the longer wave length side with the increase of the latter. Therefore, one may conclude that the position of the edge of the fundamental absorption in both KCl and NaCl commonly used depends primarily upon the amount of impurity bromine in the crystal.

To investigate further details of the absorption edge in KCl, absorption measurements were made in higher absorption coefficient region with thin crystals of about 0.15 mm in their thickness. Absorption coefficients thus measured on the thin crystals were found to be in good agreement with those obtained on the thick crystals in Fig. 3, in the range between $k=10\ \mathrm{cm}^{-1}$ and $40\ \mathrm{cm}^{-1}$. In Fig.5, the absorption coefficient at the edge of KCl crystals is plotted in a logarithmic scale as a function of the photon energy in much wider range than in Fig. 3. These data are taken from absorption coefficients of the thin crystals in the range of $k>20\ \mathrm{cm}^{-1}$ and from those of the thick crystals below it. Below $k=40\mathrm{cm}^{-1}$, it is found that there is a linear relation between log k and the photon energy for all crystals, and their slopes are almost the same between each other except that of KCl–aK–1 which is the purest in respect of the impurity bromine. Above $40\ \mathrm{cm}^{-1}$ in k, however, absorption curves bend over and appear to approach asymptotically at high k value to the absorption curve of KCl–aK–1 which is linear in log k versus energy relation in the entire range of the measurement.

The absorption curve of KCl–aK–1 was extrapolated linearly in this semilogarithmic scale to $k=10^6\ \mathrm{cm}^{-1}$ which is assumed as the maximum absorption coefficient of the first exciton absorption in KCl. Then the photon energy at this point was given as 7.59 ev. This value is very close to 7.56 ev which is estimated from the absorption curve given by Hartman et al[5] as the photon energy at the maximum of the long wave length side absorption band of the first exciton doublet in KCl at 300° K. Extrapolations of absorptions curves for other crystals led to the

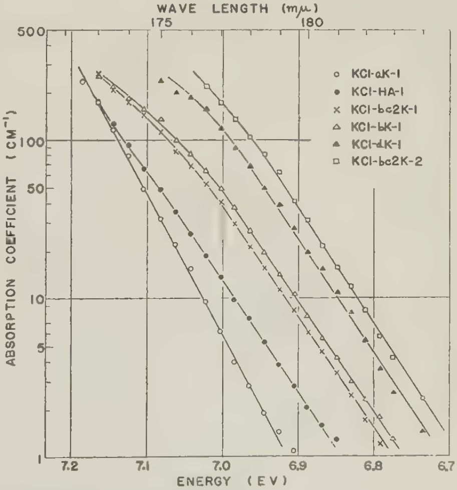

Fig. 5. Fundamental absorption edges of KCl crystals.

photon energies at $k=10^6\ cm^{-1}$ which are completely different from 7.56 ev.

To investigate the efficiency of the method of crystallization from the melt on the elimination of the impurity bromine from alkali halides, the chemical analysis for bromine was made also on the starting materials for the crystals KCl-bK-1, KCl-dK-1, and NaCl-bK-1. It was found that only 10% of bromine in KCl and 20% of bromine in NaCl was able to be removed during a single process of crystallization though the Kyropoulos technique. This may indicate that the method of crystallization from the melt, such as Kyropoulos or zone melting technique, seems not to be so efficient on the purification of alkali chlorides in respect of the impurity bromine.

§ 3. Discussion

1) *Preparation of pure alkali chloride crystals*

In Table I, we have seen that the concentration of the electric carriers or of the multivalent metallic ions in KCl-aK-1, which was grown from the powder prepared from $KHCO_3$ and HCl, is considerably smaller than those in other Kyropoulos KCl crystals. Therefore, it would be clear that it is of advantage to the preparation of pure crystal by the Kyropoulos method to use this KCl powder as the starting material. In the case of NaCl, it has been shown that the magnitude of n for NaCl-bV-1 is much smaller than that for NaCl-bK-1. This would indicate that the method of distillation and crystallization in vacuum is more effective than the Kyropoulos method on the elimination of multivalent metallic ions from NaCl. This result is similar to the one found by Kanzaki and Kido in KCl[1]. However, we have also found that n for NaCl-aV-1 is smaller by a factor of three than that for NaCl-bV-1. Then it may be said that the method started with bicabonate and hydrochloric acid is better than that started directly with commercial NaCl powder even in the case of the application of vacuum distillation and crystallization technique.

The presence of hydroxyl ions has not been detected optically in all KCl and NaCl crystals as far as they are prepared through distillation and crystallization in vacuum, while all other Kyropoulos crystals show the presence of hydroxyl ions. Therefore, the method of distillation and crystallization in vacuum may be an excellent one for the preparation of alkali chlorides free from hydroxyl ions.

It has been indicated that little bromine can be removed from alkali chloride during the process of the crystallization from the melt. Therefore, to prepare a pure crystal of KCl and of NaCl in respect of bromine, it must be necessary to start with their powders of which bromine concentrations are as small as possible. Commercial KCl and NaCl have been found to contain a large amount of bromine of an order of 10^{-4} in mole fraction which is difficult to be removed from alkali chloride by a usual chemical technique. However, if one looks at the procedure of the preparation of alkali chloride powder from bicarbonate and hydrochloric acid, one may find that the only possible source of bromine in alkali chloride is hydrochloric acid. Hydrochloric acid is believed to contain less bromine than alkali chloride and can be purified easily by fractional distillations. Crystals KCl-aK-1 and NaCl-aV-1 show certainly the presence of bromine in smaller concentrations than other crystals grown directly from their commercial powders.

The efficiency of the elimination of bromine from alkali chlorides by the method of distillation and crystallization in vacuum has not been studied. However, the bromine concentration of KCl-B-II-3, which is grown directly from the commercial KCl by the above method, is estimated as high as 7×10^{-4} from the position of its fundamental edge by the interpolation of the relation between the edge position and the bromine concentration. Therefore, the vacuum distillation of alkali chlorides seems not to be so effective on the elimination of the bromine.

At the present stage of this study, it is concluded that the following way would be recommeded for the preparation of pure KCl and NaCl crystals in respect of multivalent metallic ions, hydroxyl ions, and bromine ions: Alkali chloride powders are prepared from bicarbonate and hydrochloric acid both of which are purified chemically. Then they are crystallized by the method of distillation and crystallization in vacuum. It should be noted that, although the crystal thus prepared is quite pure in chemical impurity, its density of dislocations is always higher than that of the Kyropoulos crystal. This is the serious problem of this method, and the preparation of crystal free from dislocations has been left to future studies.

2) *Absorption band due to the presence of bromine in KCl**

We have shown that the edge of the fundamental absorption in KCl is shifted to the longer wave length side with an increase of the concentration of bromine. At the fundamental absorption edge, the absorption curves of the crystals with bromine in appreciable amount have been found to deviate from the linear relation and bend over as have been shown in Fig. 5. Since the concentration of bromine in KCl–aK–1 is far lower than those of other KCls and so the position of its fundamental edge is at the shortest wave length, it may be reasonable to assume that the absorption edge of KCl–aK–1 is almost of pure KCl. This assumption may also be supported by the previously mentioned fact that only the position of the fundamental edge of KCl–aK–1 at $k=10^6$ cm^{-1}, which is estimated by the extrapolation, is close to that of the first excition peak of KCl. Therefore, the difference between the absorption coefficients of KCl–aK–1 and those of other KCl crystals would be an excess absorption due to the presence of bromine. In Fig. 6, these differences are plotted in a logarithmic scale as a function of photon energy. The curves thus obtained are the bands which shapes are similar to one another, although their shape at the short wave length side of the band is not so clear because of the error in measurements at high absorption coefficient. Moreover, the positions of the maximum of the bands for KCl–HA–1, KCl–bc2K–1, and KCl–bK–1 are all at 7.12 ev, so that they are the bands of one kind with different intensities.

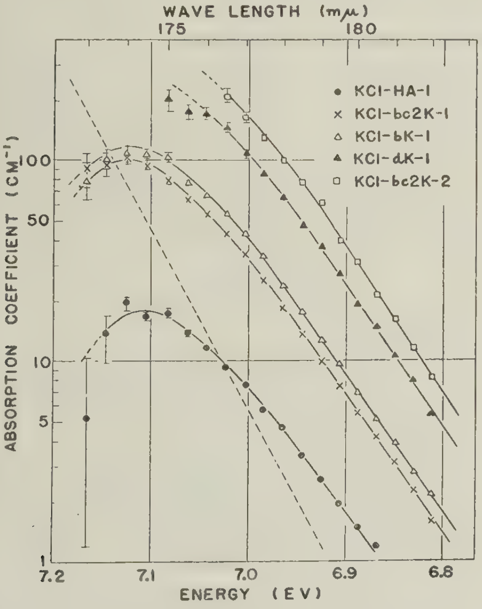

Fig. 6. Absorption band due to the presence of bromine in KCl. Edge of the fundamental absorption band of pure KCl is shown as a straight broken line.

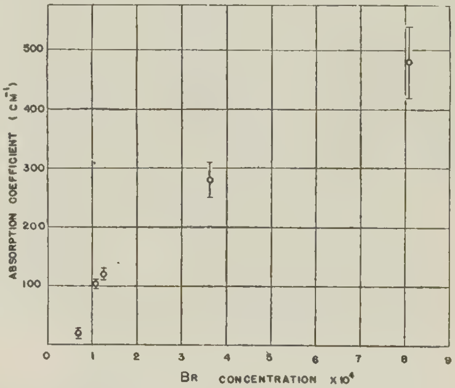

Fig. 7. Plots of the maximum absorption coefficient of the band at 7.12 ev as a function of bromine concentration in KCl.

In Fig. 7, the maximum heights of these absorption bands are plotted as a function of their bromine concentration. It is seen in this figure that the band grows certainly with the increase of the bromine concentration. Therefore, one may conclude that the absorption band at 7.12 ev is due to the presence of bromine in KCl.

It may be noted that the absorption curve at the long wave length side of this band is represented by a straight line below one third of its maximum in the plot of log k versus photon energy. This is exactly the same relation as has been found in the fundamental absorption edge of silver halides[8] and other alkali halides[9]. Therefore, it can be said that the Urbach rule where the temparature is constant holds nicely even in the case of the absorption due to the small amount bromine in KCl lattice.

The half width of this band is found to be

---

* A preliminary account of the work in this section was published as a *short note* in J. Phys. Soc. Japan **15** (1960) 1350.

0.18 ev if the band shape is symmetric. This value is very close to 0.20 ev, the half width of the first exciton absorption band in KBr at room temperature which is estimated roughly from the absorption curve given by Eby et al.[10] However, the position of the maximum of this band is at 7.12 ev which is far from 6.61 ev[10], the position of the maximum of the first excition band in KBr. From these facts, one may say that the nature of the absorption band due to the presence of small amount bromine in KCl is not so different from that of the exciton band due to the excitation of bromine in KBr, except the difference in the position of their absorption maxima, which is probably due to the difference of the lattice distance around the bromine.

One may estimate the oscillator strength of this absorption from the data in Fig. 7 assuming that the absorption is due to the bromine itself. However, the relation between the maximum height and the bromine concentration is not so perfectly linear, so that only a rough estimation was made. The oscillator strength was estimated as 0.07 ± 0.02 by the aid of the Smakula's formula in the first approximation.

We have assumed so far that the edge of the fundamental absorption of KCl–aK–1 is of pure KCl, and all of the estimations in this section has been based upon this assumption. However, this crystal actually contains bromine of 9×10^{-6} in mole fraction, so that its absorption edge is not of pure KCl. If we use 0.07 as the oscillator strength of the absorption due to bromine, then this excess absorption in KCl–aK–1 can be calculated as $8\,\mathrm{cm}^{-1}$ at 7.12 ev, the position of the maximum of this absorption. The absorption coefficient of KCl–aK–1 measured at this photon energy is $67\,\mathrm{cm}^{-1}$. Then, about 12% of the measured absorption of KCl–aK–1 at 7.12 ev may come from the absorption due to bromine. However, since the difference in absorption coefficient between KCl–aK–1 and other KCls at the edge is much larger than $8\,\mathrm{cm}^{-1}$, the estimations of the absorption due to bromine with the assumption that the absorption edge of KCl–aK–1 is of pure KCl may not be incorrect. We have seen in Fig. 6 that the slope of the absorption band due to bromine is smaller than that of the absorption edge of pure KCl. Then, the contribution of the bromine absorption to the measured absorption at the edge of KCl should become larger at the longer wave length. Therefore, the true absorption edge of the pure KCl may be a little steeper than that of KCl–aK–1. This may be one of the reasons for that 7.59 ev, the assumed value of the photon energy of KCl–aK–1 at $k=10^6\,\mathrm{cm}^{-1}$ by the linear extrapolation, is larger than 7.56 ev, the position of the maximum of the exciton band of KCl.

In Fig. 6, the edge of the fundamental absorption of KCl–aK–1, which is almost of pure KCl, is indicated as a straight broken line. One may notice in this figure that the absorption due to bromine in KCl commonly used is much stronger than the fundamental absorption of pure KCl at the absorption tail. Therefore, cares must be taken on the optical excitation at the edge to study the true nature of the exciton absorption in KCl crystal.

Acknowledgement

We wish to thank Professor M. Ueta for his giving us an opportunity to use his vacuum ultraviolet spectrophotometer, and Professor H. Kanzaki for his stimulating discussions and letting us use some of his instruments. Thanks are also due to Mr. S. Tamura for his many valuable suggestions on chemistry and to Mr. K. Kido for his growing some crystals by the method of distillation and crystallization in vacuum. A part of this work was supported by the Research Grant from the Ministry of Education.

On the Magnetic Anisotropy of Single Crystal of Chromium Telluride

By Tokutaro HIRONE and Shôko CHIBA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Recieved June 27, 1960)

The anisotropy of a ferromagnetic single crystal of CrTe with NiAs structure was investigated by magnetic torque measurements. From the experiment it was seen that the axis of easy magnetization is [001] and it does not change from room temperature to liq. He temperature. At 0°K the uniaxial anisotropy constant will be about 5×10^6 erg per cm^3. As for the origin of anisotropy, the dipole-dipole energy can account for only about 20 percent of the observed value.

§ 1. Introduction

Recently the magnetic anisotropy of single crystals of ferro- or ferrimagnetic compounds with nickel arsenide structure was investigated by several authors. In the case of MnBi[1] the axis of easy magnetization was found to be [001] near room temperature and change to [100] at 85°K, being associated with a gradual change of the magnetic anisotropy constant with temperature. It has also been shown that in the case of MnSb[1] the axis of easy magnetization is invariantly [001] and moreover the magnetic anisotropy constant remains unchanged with the decrease of temperature down to 20°K. In the case of ferrimagnetic compound Fe_7Se_8[2] the axis of easy magnetization lies in the c-plane at room temperature and it approaches to the c-axis with lowering temperature. In this paper the authors report the variation of the magnetic anisotropy of the ferromagnetic chromium telluride with the same crystal structure.

§ 2. Specimen and Experimental Procedure

For the pupose of the preparation of single crystals of the compound CrTe, powder of chromium (96% purity) and crushed grains of tellurium (99.99%) were mixed in proper raito. The mixture was sealed in an evacuated silica tube, heated in an electric furnace to 1100°C for 24 hours, and cooled slowly. The reaction product was crushed again and mixed well in a mortar. From this reaction product a single crystal was prepared by the Bridgann method. As shown in Fig. 1, the reaction product was put into a fused silica tube (10 mm in diameter), one end of which was joined to a balloon filled with argon gas. The sample in the silica tube was set so as to put the meniscus of the molten specimen in the hottest part of the furnace, as shown in Fig. 1. After keeping several hours at high temperature it was cooled at a rate of 50° per hour. When the temperature of the specimen reached 1050°C on the cooling the specimen was quenched into water.

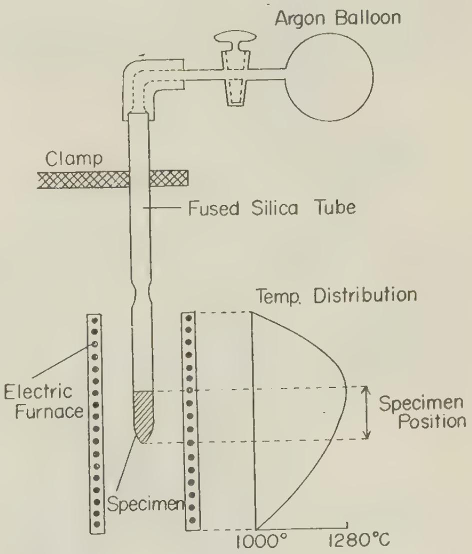

Fig. 1. The apparatus to prepare a single crystal.

A part of the single crystal thus obtained was crushed and a Debye-Scherrer photograph was taken, which showed that the structure was of NiAs type with $a=3.93$Å, $c=6.15$Å and $c/a=1.56$. These results coincide with the results previously reported by Oftedal[3]. Circular disks with the disk plane (100) as well as (001) were prepared with the aid of the Laue photograph. The size of the disks was 4.5 mm in diameter and 1 mm in thickness. The composition of the specimen was confirmed by chemical analysis to be 53 at % Te.

§ 3. Experimental Results

Magnetic torque curves were measured for the disk with (100) plane at room temperature, −77°, −183° and −268°C. The maximum field used in the measurements was 22,000 oe above −183° and was 17,000 oe at liquid He temperature. The curves obtained are shown in Figs. 2, 3, 4 and 5. As seen from these figures the curves obtained show two-fold symmetry. The orientation of easy magnetization lies along the *c*-axis. The value of the torque in the direction of difficult magnetization was not easily determined. The axis of easy magnetization does not show any change with a drop in temperature down to the helium point. Let the polar angle of the

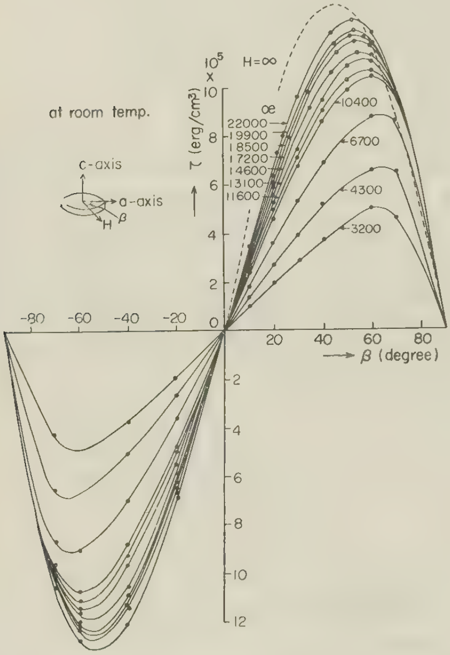

Fig. 2. The magnetic torque curves at room temperature.

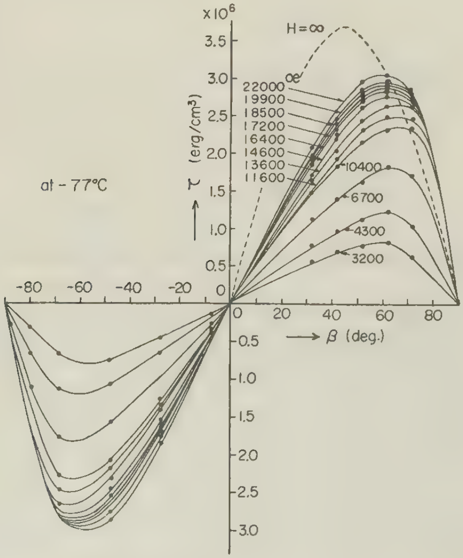

Fig. 3. The magnetic torque curves at −77°C.

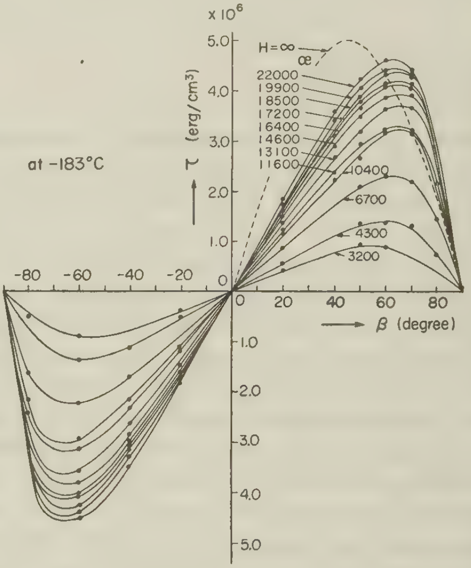

Fig. 4. The magnetic torque curves at −183°C.

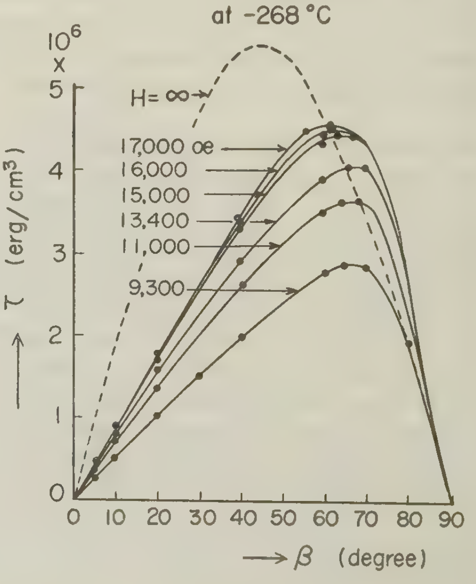

Fig. 5. The magnetic torque curves at −268°C.

field direction from the c-axis be β. At low field strength the maximum of the torque was found to lie a little near $\beta=90°$, and with the increase of the field it approachs $\beta=45°$, with the increase in amplitude of the torque curve.

Next, the magnetizing curve in the direction of easy magnetization was taken by means of an induction type magnetometer due to Chiba's design[4], the results at room temperature being shown in Fig. 6. It was seen from this curve that the saturation magnetisation is already attained at about H=2,000 oe. The magnetization vs. temperature curve at 8,000 oe was taken in the region above the liquid nitrogen temperature. The curve obtained is shown in Fig. 7. As seen in the figure, the temperature dependence of the saturation magnetization is given by the Weiss curve with the spin quantum number $S \geq 2$. The value shown by the symbol ■ at T=0°K is the presumed value at 0°K for the present composition calculated from the data of $\sigma_0=74.57$ which is obtained for stoichiometric chromium-telluride by Guillaud[5]. This is consistent with the present data. The value of saturation moment per Cr atom at 0°K is 2.39μ_b. The extrapolation of σ^2-T curve gives that the Curie point of this specimen is 61°C. It should be mentioned here that Tsubokawa[6] has measured the change of susceptibility with temperature above the Curie point with the specimens from the same source as that of the present study. According to his results the Curie-Weiss law holds in the paramagnetic region with the paramagnetic Curie point, θ_p of 57°C, the Curie constant, C_m of 2.08, the effective magneton, number, μ_{eff} of 4.08, and S of 1.6 if g-value is assumed to be two. Therefore, the S value obtained from the magnetization at low temperatures does not coincide with that obtained from the Curie constant in the high temperature region.

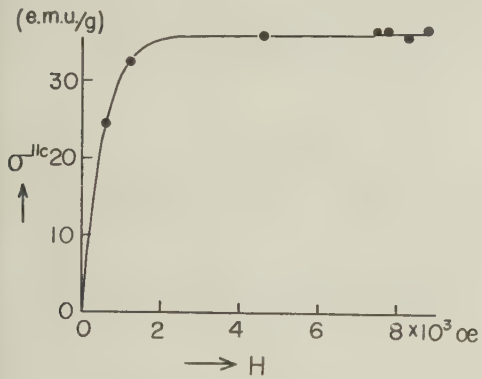

Fig. 6. Magnetization vs. magnetic field curve for a single crystal.

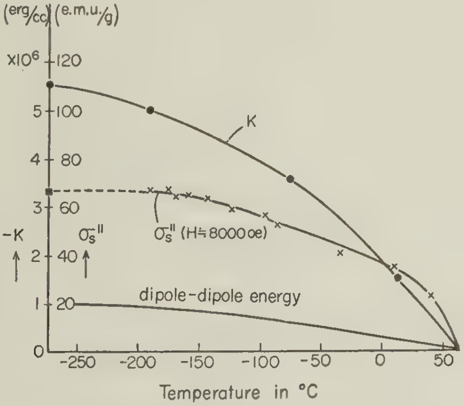

Fig. 7. Anisotropy K vs. temperature curve. Magnetization σ_s vs. temperature curve. Dipole-dipole interaction energy vs. temperature curve.

§ 4. The Value of Anisotropy Constant K

Based on the torque curves shown in the foregoing section the anisotropy constant K was calculated by using the following relation.

$$\frac{1}{2K}=\frac{1}{HJ_s}-\left(\frac{d\beta}{d\tau}\right)_0 , \tag{1}$$

τ; torque per unit volume, cm³ .

$\left(\frac{d\beta}{d\tau}\right)_0$; derivative of τ near $\beta=0$.

The value $(d\beta/d\tau)_0$ was obtained from the torque curves of each field and the experimental value of saturation magnetization per unit volume was used as J_s. The K value is

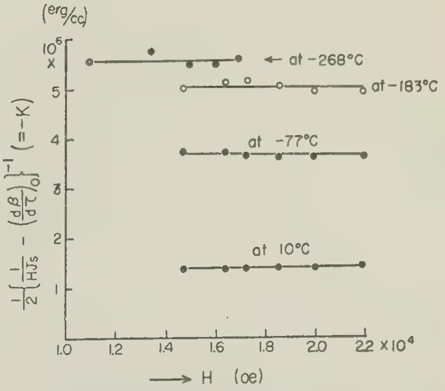

Fig. 8. The value of K as derived from equation (1) vs. magnetic field curvcs.

calculated from equation (1). In Fig. 8, calculated K values were plotted against the field strengths used for the measurement of torque curves. As seen from this figure, K shows a constant value irrespective of the field strength at each temperature, which shows that the equation (1) is reasonably hold in this case. The anisotropy constant K vs. temperature curve is shown in Fig. 7, which shows that the anisotropy of this compound decreases gradually with the increase of temperature. The saturation torque curves calculated from the obtained anisotropy constant are shown by dotted curves in Figs. 2, 3, 4 and 5.

Some considerations will be given to the origin of the anisotropy energy mentioned above. The dipole-dipole interaction was calculated for this compound, the result of which is shown in Fig. 6. As seen in Fig. 6. this term is consistent in sign with the experimental result but the value reaches only about 20 percent of the result of observation. The gap between theory and experiment will be filled by the calculation of the anisotropy due to the spin-orbit interaction of Cr ions influenced by the crystalline field. But in this case a simple ionic model is not sufficient to start the calculation of the anisotropy since the ionic moment in the low temperature region was found to be far less than that in the high temperature region. So that, in the interpretation of this experimental result a detailed discussion on the electronic structure of this compound will be required.

Finally the authors wish to express their hearty thanks to Dr. Maeda and Dr. Watanabe for their useful discussions, and to Mr. Adachi for valuable suggesions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 11, NOVEMBER, 1960

Total Cross Sections of Carbon, Oxygen, Fluorine and Thorium for Fast Neutrons

By Kineo TSUKADA and Takayoshi FUSE*

Japan Atomic Energy Research Institute Tokai-mura, Ibaraki-ken

(Received July 25, 1960)

The neutron total cross sections of carbon, oxygen, fluorine and thorium have been measured in the energy range of 3.3 to 5.0 MeV. Measurements were made with a good-geometry arrangement and an energy resolution of about 20 keV, using a neutron detector which had a high efficiency and a good characteristic for gamma-ray discrimination. For carbon, oxygen and fluorine, several resonances in the cross sections were analyzed to give spin assignments. For thorium, a giant resonance was observed at 4.2±0.2 MeV.

§1. Introduction

The neutron total cross sections are of great interest in nuclear physics aside from their importance in practical problems. The resonances appearing in the total cross sections are associated with quasi-stationary energy states of the compound system of the target nucleus plus a neutron. The knowledge about

---

* On leave of absence from Transportation Technical Research Institute, Mitaka, Tokyo.

the characteristics of levels or the statistics of their distribution can be obtained from the measurement of the height or the number of the resonance peaks. Sharp resonances disappear with the increase of neutron energy, because of the overlapping of levels and the spread of neutron energy. This phenomenon occurs at low energy region for heavy nuclei (e.g. at 1 keV for thorium as compared with 10 MeV for oxygen)1). But the resonance of another type, that is, the giant resonance, is seen in this continuum region. This is due to the size effect of nuclei, which is explained by the optical model2).

It is not so easy to measure the neutron total cross sections with high accuracy and resolution because of the large spread of the incident neutron energy, the high background of neutrons and gamma rays, the low efficiency of neutron detectors and the difficulty involved in determining neutron energies. The measurement of this sort is so tedious and time-consuming that the experiment with complicated arrangements are troublesome. Recently, a simple scintillation detector3) which has a good characteristic for the discrimination of gamma rays against neutrons has been developed. In an organic phosphor the decay time of the fluorescence4) excited by neutrons is different from that by gamma rays, and one can make use of this difference for the purpose of discrimination of gamma rays with only a minor change in the conventional photomultiplier circuit. This detector has an efficiency higher than that of the Hornyack button, because of its large sensitive for neutron counting. A detector of high efficiency is especially indispensable in the high resolution work with a good geometry, because neutron flux available is in general very low.

In the present work an attempt was made to measure the neutron total cross sections of carbon, oxygen, fluorine and thorium in an energy range of 3.3 to 5.0 MeV using the detector mentioned above. The assignment of the spin and parity was tried for several resolved resonances. For thorium, a giant resonance was observed as expected by the systematics5).

§ 2. Experimental

The measurements were made at the JAERI 2-MV Van de Graaff accelerator. Neutrons, energy of which was 3.3 to 5 MeV, were produced by using the $D(d,n)He^3$ reaction. The experimental area was 3.6 meters above the ground and had little amount of neutron scattering material nearby in order to minimize the background. By a couple of electrostatic quadrupole lenses, deuterium beam was focused on a target, which was located 8 meters away from a 90-degree beam analyzing magnet. This decreased the machine background remarkably. The experimental arrangement was designed for a good-geometry transmission measurement, as shown in Fig. 1.

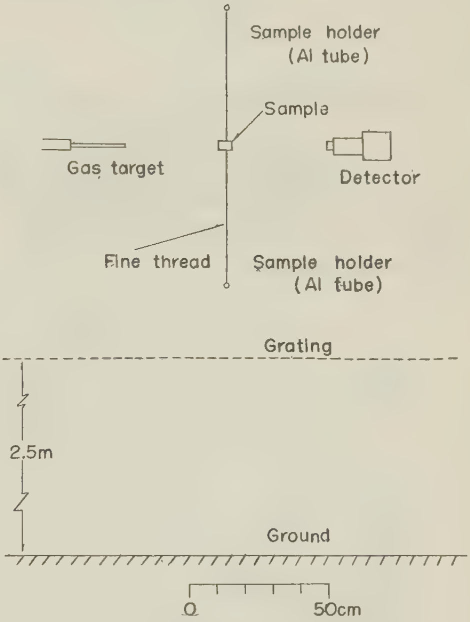

Fig. 1. Experimental Arrangement.

Thorium dioxide (ThO_2, purity 99.9%), Teflon (C_nF_{2n+2}, commercial product), and graphite (C, reactor grade) were used as samples. The thorium oxide sample was of powder form and filled in a lucite cylinder, whose inner diameter and length were 3.7 and 9.0 cm, respectively. The Teflon and graphite samples were 3.0 cm in diameter, and 5.0 and 4.5 cm in length, respectively. The neutron transmission was about 50% in each case. The samples were placed at the middle of the neutron source and the detector, and alined with a transit. The distance from the source to the detector was 75 cm in almost all cases*.

---

* This distance was 50 cm for dots " · " in Fig. 3, in the energy range of 3.3 to 4.4 MeV.

The neutron source was composed of a gas chamber, whose length and inside diameter were 3 cm and 1 cm, respectively. Its entrance window was nickel foil of 0.00005″ thickness. The pressure of deuterium was 5.0 cm Hg* in almost all cases. The neutron energy and its spread were estimated by calculating the loss and straggling of the deuteron energy in the nickel window and the gas. The energy value obtained by the calculation was lower by 20 keV than that obtained by the comparison of the resonance energies of oxygen with those in the results of Becker et al.[6] and Walton et al.[7] In Fig. 3, the corrected value is shown. The neutron detector consisted of a 1″×1″ϕ anthracene crystal and a Du Mont 6467 photomultiplier. In order to discriminate gamma rays against neutrons by the method stated in § 1, the voltage difference between the last dynode and the anode was decreased to 18 volts.** This introduced a serious space charge limitation and magnified the difference between the decay of the fluorecence by the neutrons and that by the gamma rays. The output signal was delivered from the last dynode. Fig. 2 shows the energy dependence of the maximum pulse height of the output signal for the neutrons

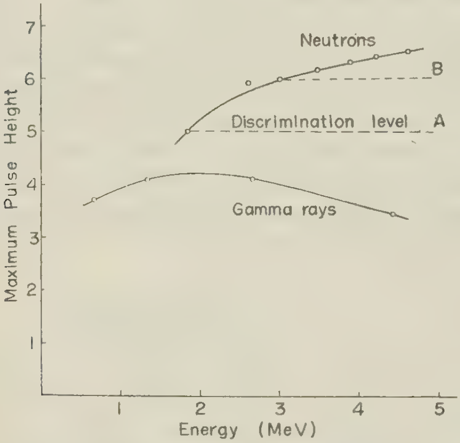

Fig. 2. Energy dependence of the maximum pulse height of the output signal from the anthracene scintillation counter with the space-charge-limited photomultiplier.

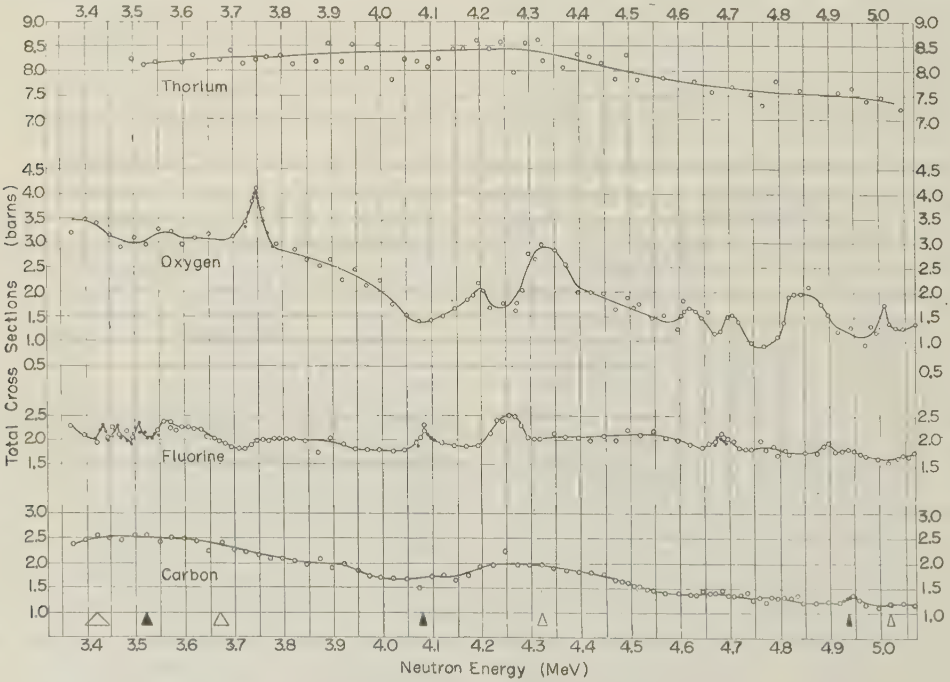

Fig. 3. Neutron total cross sections of carbon, oxygen, fluorine and thorium. The energy resolution is shown as equivalent triangles at several energies. The open and solid triangles correspond to the open and solid circles respectively.

---

* This pressure was 2.5 cm Hg for dots "·" in Fig. 3.

** The voltage differences of the other parts were kept at a normal rate and the total voltage difference between the photo-cathode and the anode was 1,400 volts.

and gamma rays. In this detector system, precaution had to be paid for overloading because of its rather long pulse processing time.

Evaluation of the background counts was done by using a copper bar, whose length and diameter were 50 cm and 3 cm, respectively. The background was less than 0.7%. Existence of energy-degraded neutrons due to the deuterium adsorbed in the window and the wall of the target chamber was checked by counting the neutrons with the chamber evacuated, which yielded less than 1% of the normal output. Neutrons were monitored with a current integrater and two long counters.

§ 3. Results and Discussions

Counts obtained were processed by the following formula to give the total cross section σ.

$$\exp(-N\sigma)=\frac{C_{\text{sample in}}-C_{\text{copper bar}}}{C_{\text{sample out}}-C_{\text{copper bar}}}, \qquad (1)$$

$C_{\text{sample in}}$: counts per charge Q of the incident deuterons when the sample was placed,

$C_{\text{sample out}}$: counts per charge Q when the sample was taken out or the empty can was placed instead of the thorium sample,

$C_{\text{copper bar}}$: counts per charge Q when the copper bar (§ 2) was placed,

N: number of nuclei per unit area in the sample.

An in-scattering correction to be applied to the results obtained through the procedure written above were calculated by Eq. (2)[8] and found to be less than 2%.

The total cross section of fluorine was obtained from the transmission data of Teflon by subtracting the contribution of carbon. In order to obtain the cross sections of oxygen and thorium, following procedure was adopted. At first, the cross section of thorium was assumed to have gradual change and no sharp resonances and the cross section of oxygen which had been published by Becker et al.[6] and Walton et al.[7] was subtracted from the transmission data of thorium oxide and then the curve of the remainder was smoothed out to give the cross section curve for thorium. The necessity for this procedure was due to the fact that data of different origin had different energy resolution. Next, the cross section of thorium was subtracted from the transmission data of thorium oxide and the

* Binding energy of a neutron was taken as 4.946 MeV.[11]
Binding energy of a neutron was taken as 4.146 MeV.[11]
Binding energy of a neutron was taken as 6.606 MeV.[11]

cross section of oxygen measured with the energy resolution of the present work was thus obtained. The resolution was about two times better than that in the Walton's measurement, and nearly equal to that in the Becker's. These results are shown in Fig. 3.

The statistical error was about 1% in the whole range. The neutron energy spread calculated from each energy is shown in Fig. 3. These values, however, may be increased a little, because of the local variation in the thickness of the nickel foil (may be less than a few keV).

The comparison of the present data with the others[1] shows that, for carbon, there are some apparent systematic disagreements* amounting to more than 10%. But these disagreements can be eliminated by taking account of the difference in the spread of neutron energies. For fluorine, the published data[1] has an energy resolution too poor to be compared with the present result. For oxygen, present data agree with those of Becker et al.[6] and Walton et al.[7] fairly well. For thorium, there has been no published data in the energy region of the present work.

Some informations about the energy levels of the compound nuclei, C^{13}, O^{17} and F^{20}** have been obtained from the position and the peak height of the resonances. The height of a resonance peak is given by $4\pi\lambda\!\!\!^{-2} g_{Jl}$***, which is a function of the spin J of the compound nucleus and the neutron anguler momentum l, as far as the elastic scattering is predominant over other reactions and, moreover, the resonance is isolated and well-resolved. In Fig. 4, the calculated values of $4\pi\lambda\!\!\!^{-2} g_J$ are inserted. The dip of the oxygen cross section at 4.06 MeV may correspond to a s resonance ($l=0$), as seen by the comparison with that of the (α, n) reaction[10] inserted in the same figure. Estimation of the J value was tried for each resolved resonance and the results are shown in Table I with those obtained from other sources[11]. The resonances listed in Table I do not cover all of the resonances in this energy region, even for carbon.

For thorium, a giant resonance was observed at 4.2±0.2 MeV. The peak cross section was 8.5 barns****. Fig. 5 shows not only the present data for thorium but also the results in the lower energy region[1] and at 14 MeV[1].

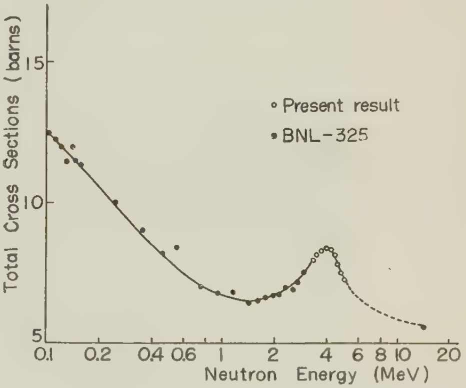

Fig. 5. Neutron total cross section of thorium.

The authors would like to express their appreciation to Dr. T. Momota for his invaluable help and advice. The authors are greatly indebted to Mr. C. Kobayashi, Mr. Y. Sato and members of the fast neutron group for operation and maintenance of the Van de Graaff accelerator, and to Mr. R. Ito for his assistance in the measurements.

Temperature Dependence of Surface Potential in Silver Chloride Single Crystals

By Hisawo WAKABAYASI

Faculty of Engineering, Chuo University, Tokyo

(Received July 27, 1960)

The temperature dependence of the surface potential of silver chloride single crystals is similar to that of silver bromide single crystals. The knee point moves to the higher temperature as the content of cadmium in the specimen is increased. The formation energy of Frenkel defect and other quantities are obtained. Comparing with the results of ionic conductivity measurements, the intrinsic and the structure-sensitive regions of silver chloride single crystal determined by surface potential were found to correspond to those determined by ionic conductivity, respectively. From the difference between the reciprocals of the knee point temperatures determined by the two methods, the ratio of the mobility of an interstitial silver ion to a silver vacancy may be obtained.

§ 1. Introduction

In the previous paper[1)], we have shown the following things. The surface potential versus temperature curve for a silver bromide single crystal is composed of two straight lines, one of which corresponds to the structure-sensitive region of the crystal and the other to its intrinsic region. They, when extended, intersect each other at a knee point, the temperature of which is determined by the amount of doped divalent cations which are supposed to dissolve into the crystal lattice. Of course, the curve deviates from the straight lines near the knee point. The knee point moves to higher temperature with increasing amount of divalent cations doped into the crystal. We also proposed the interpretation for these facts. The variation of the surface potential with temperature is due to the change in the space charge potential on the side of the silver-coated surface of a silver halide crystal. Near and on its free surface, silver ions and electrons move under the condition that their change cancels the variation of potential due to the space charge on this side.

To verify whether the surface potential in a single crystal of silver chloride varies similarly with temperature as in a silver bromide, the surface potential measurements were carried out the same as before. We also measured the ionic conductivity and each region determined by surface potential measurements was concluded to correspond to that determined by the ionic conductivity measurements, respectively.

§ 2. Apparatus

The apparatus is that used for measurements of surface potential in silver bromide single crystals. The specimens were cut by Ti-saw from silver chloride single crystals which were made from the melt in air by Kyropoulos method. They were lapped and etched in series by sodium thiosulfate, ammonium hydroxide and hydrochloric acid. After etching, they were rinsed in flowing water for about twenty minutes and at last washed by distilled water. They were nearly

1 mm thick. All measurements were carried out after keeping the specimens at measuring temperature for about twenty minutes in the case of surface potential measurements.

To measure the temperature of the surface of specimens, a thermocouple was attached to their surfaces. It indicated too low temperature degrees, which might be attributed to the low thermal conductivity of the specimens and the thermal loss through the thermocouple wires. When the thermocouple was welded on a silver metal block placed on the platinum plate electrode, on which a specimen was placed for measurements, a curve was obtained from which the concentration of Frenkel defect was calculated to be too large, and the results were contradictory to ionic conductivity measurements. According to our interpretation, the surface potential variation with temperature is attributed to the change of potential due to the ionic space charge layer on the side of the silver-coated surface, so that the temperature of this side must been measured. The thermal loss of radiation from the surface of a specimen is hindered by the vibrating reed of the electrometer over it and specimens are thin, so that the temperature of their surfaces may be assumed to be equal to that of their silver-coated surfaces. We might identify the temperature of a specimen with that of the surface of the plate electrode to which a specimen is in contact. It was at last decided to measure the temperature by the thermocouple pressed against the plate electrode.

The concentration of doped impurity—cadmium ions in our case—was chemically analysed. Cadmium in silver chloride was extracted by the method of Church. The amount of cadmium was quantitatively analysed by the colorimetrical method, using Hitachi photoelectric spectrometer. Standard samples were made by solving cadmium acetate into water, and they contained 5γ, 10γ, 30γ, 50γ of cadmium, respectively. The chemical analysis was carried out in Japan Analytical Chemistry Research Institute.

§ 3. Experimental Results

(1) *Surface potential variation with temperature*

The peculiar variation of surface potential in the first run which appeared in the case of silver bromide single crystals, was not observed in silver chloride single crystals[1].

Experimental results are plotted in Fig. 1. It is easily seen that the temperature dependence of surface potential in a silver chloride single crystal is also represented by two straight lines and the knee point temperature moves to higher temperature as more divalent cations are doped into the crystal. It is higher in silver chloride than in silver bromide when doped with the same amount of divalent cations. The values for various other quantities were obtained by the same way as in silver bromide crystals. They are shown in Table I. The symbols are the same as in the previous paper[1].

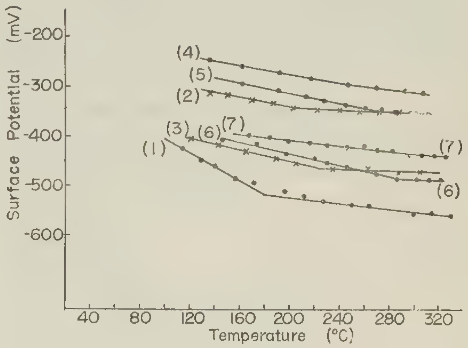

Fig. 1. The variation of the surface potential of silver chloride crystals with temperature. The associated numbers which ascend from 1 to 7 indicate the specimens which are doped with 0, 0.125, 0.25, 0.5, 1.0, 2.5, and 5.0 Mol.-% of cadmium ions, respectively. The knee point moves to higher temperature as more amount of cadmium is doped into crystal.

The values of N_1B_1/N_2B_2 which contains only the internal factors are seen to be in agreement with each other, but the values of A_1A_2/B_2 differ from specimen to specimen and this must be attributed to the different values of A_2. The N_1B_1/N_2B_2 versus α and the A_1A_2/B_2 versus α curves are shown in Fig. 2. N_1B_1/N_2B_2 seems to be independent of α which is due to the surface condition. There is a tendency that A_1A_2/B_2 decreases as α increases. A_1A_2/B_2 is large for specimens in which the straight line in the intrinsic region has a steep slope. α seems to become smaller as the slope of the straight line in the structure-sensitive region increases.

The knee point temperature —T_S— is de-

Table I.

Specimen	Concentration of cadmium ions	$2e\cdot(V_{1S}-V_{2S})$	α	$\frac{N_1B_1}{N_2B_2}$	$\frac{A_1A_2}{B_2}$	T_S
OCIP-3	0.51×10^{-3} Mol.-%	0.90 eV	0.44	1.7×10^7	4820	453°K
OCII′Cd 0.125-1	1.66	0.45	0.72	2.0	25	478
OCI Cd 0.25-1	2.8	0.44	0.73	2.6	61	488
OCI Cd 0.5-2	5.6	0.18	0.89	2.3	54	507
OCI′Cd 1-1	1.66×10^{-2}	0.40	0.75	1.5	26	548
OCI Cd 2.5-2	2.8	0.51	0.68	2.7	57	556
OCII Cd 5-1	6.0	0.21	0.87	3.2	13	578

termined by the following equation.

$$c^2=N_1B_1/N_2B_2 \exp-(E_{F0}/kT_S) \qquad (1)$$

where no factors appear which are related to the surface condition. The logarithm of the concentration of dissolved divalent cations versus the reciprocal of the knee point temperature (in the absolute unit) curve is shown in Fig. 3. From the slope of the line, the formation energy at 0°K of Frenkel defect in a silver chloride single crystal was found to be 1.6 eV, which is nearly equal to 1.69 eV[2]. N_1B_1/N_2B_2 is equal to 2.1×10^7. The temperature dependence of the formation energy of Frenkel defect in silver chloride is given by

$$E_F=1.6-1.4\times10^{-3}T\,.$$

From the experimental curves, the value of $N_1B_1/N_2B_2c^2$ is obtained but the values of N_1B_1/N_2B_2 and c are not determined separately. The amount of cadmium ions which replace silver ions at normal lattice sites would not be equal to the chemically analyzed amount, but we have no knowledge about the difference between two quantities. The above obtained values in Table I are calculated under the assumption that c is either equal to or

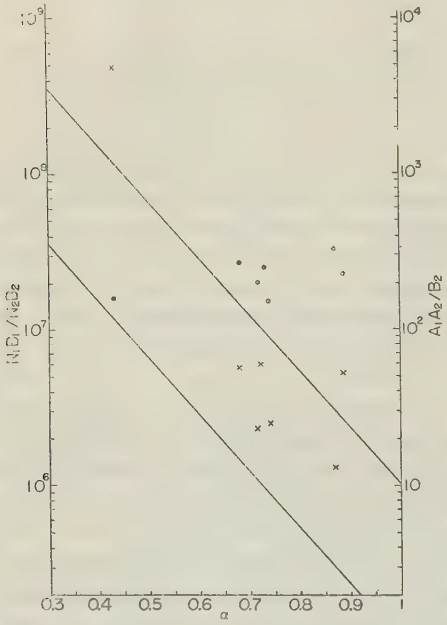

Fig. 2. N_1B_1/N_2B_2 and A_1A_2/B_2 plotted against α, being denoted by solid circles and crosses, respectively. N_1B_1/N_2B_2 is independent of α, but A_1A_2/B_2 decreases with α. The lower and upper straight lines are

$$\log A_1A_2/B_2=(1-\alpha)/2\cdot\log 2\times10^7\,,$$

and

$$\log A_1A_2/B_2=(1-\alpha)/2\cdot\log 2\times10^7+\log 10\,,$$

respectively.

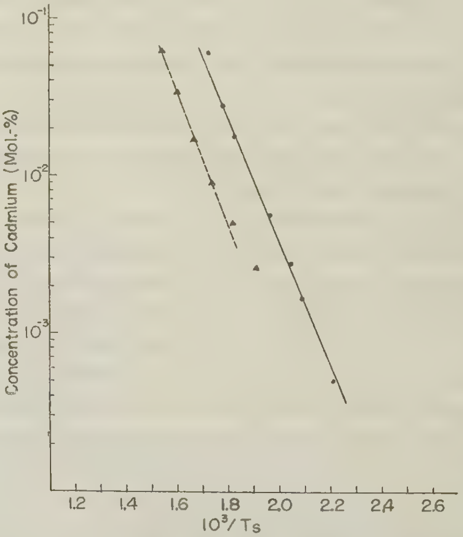

Fig. 3. The logarithm of the concentration of the dissolved cadmium ions plotted against $1/T_S$, where T_S is the knee point temperature for the specimens doped with the above-mentioned amount of cadmium ions. From the slope of the line we have E_{F0}=1.6 ev, and $N_1B_1/N_2B_2=2.1\times10^7$. The broken curve is one obtained by Ebert and Teltow[2].

not far different from the value determined by chemical analysis. The weighed amount of doped cadmium before melting and the chemically analyzed amount in the samples are tabulated in Table II.

It is seen from Table II that the ratio B/A lies between 1 and 1.3, except for the specimen denoted by OCI′Cd 1, and cadmium impurities are more soluble in the crystal than in the melt. It is contrary to the results in the case of potassium chloride. It seems probable that the amount of impurities would increase by recrystalization because the sample denoted by OCII′Cd 1 (R) was recrystalized from the sample denoted by OCII′Cd 1.

Table II.

Specimens	Doped amount of Cd —A—	Chemically analyzed amount of Cd —B—	B/A
	Mol.-%	Mol.-%

(2) *Results of ionic conductivity measurements*

To ascertain whether the intrinsic region can be identified to that determined from the ionic conductivity measurements, the variation of ionic conductivity of each specimen with temperature was measured.

Silver was developed on the two faces to be electrodes of a specimen, which together with silver blocks on its silver-developed faces, was pushed between nickel electrodes fixed in a crucible. The temperature was measured by a copper-constantan thermocouple welded on the nickel electrode. The crucible was set into an electric furnace. The direct current conductivity was measured by a galvanometer in series with the specimen. Their reproducibility was good. The logarithm of specific conductivity is plotted against the reciprocal of absolute temperature of a specimen in Fig. 4.

The curve for each specimen consists of two parts, one of which is steeper than the other, and the steep parts for various specimens overlap each other in higher temperature range. The specific conductivity in the gentle range seems to be nearly proportional to the concentration of the cadmium content, but it is not strictly established. The steep part for undoped specimens lies in the right side of those doped with Cd, and it does not overlap them. Nevertheless, the activation energies of both groups were nearly equal and about 1 eV. The specimens doped with sulpher ions showed the similar behaviour as undoped specimens. The activation energies in each region of the curve are about 1 eV and about 0.4 eV, respectively. It is apparent

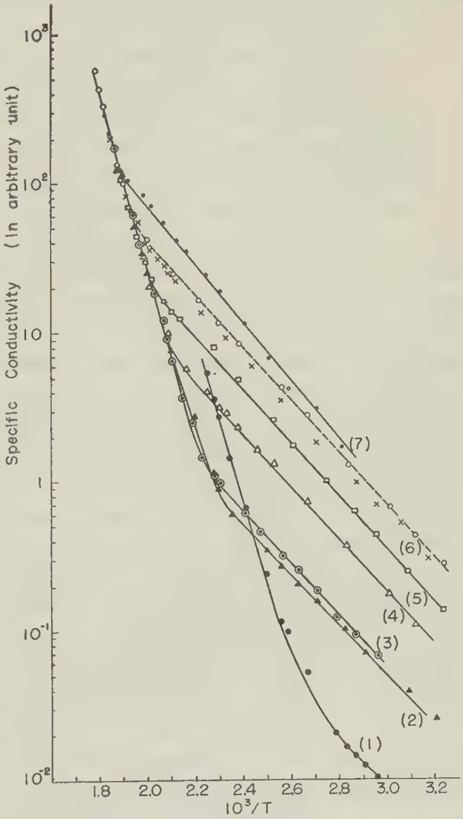

Fig. 4. The specific conductivity of silver chloride crystals doped with cadmium chloride as a function of $10^3/T$. The numbers on the curves refer to 1) the specific conductivity of "pure" AgCl, 2) 0.00125 Mol.-% of $CdCl_2$, 3) 0.0025 Mol.-%, 4) 0.005 Mol.-%, 5) 0.01 Mol.-%, 6) 0.025 Mol.-%, and 7) 0.05 Mol.-%.

that the steep range of the curve corresponds to the intrinsic region and the gentle to the structure-sensitive region. The intrinsic region of specimens seems to begin at a little lower temperature than in the surface potential measurements. The mobility of an interstitial silver ion is larger than a silver vacancy, so that the results are reasonable. The relation between two kinds of knee point temperatures will be discussed later.

§ 4. Discussion

1.6 eV was obtained for the value of the formation energy at 0°K of Frenkel defect in a silver chloride crystals. Considering the errors in the concentration of effective cadmium doped into the crystal and temperature, it may be regarded as agreeing with 1.69 eV obtained by Ebert and Teltow[2]. Taking account of the fluctuation of obtained data from a straight line when $\ln c$ is plotted against $10^3/T$, the value of the formation energy may not be larger than 1.7 eV, and not smaller that 1.5 eV. When the temperature of specimens was elevated above about 330°C, surface potential showed irregular behaviour which was different from specimen to specimen. So, it was difficult to determine accurately the knee point temperature for specimens doped with high concentration of cadmium ions. Below about 140°C, the curves of surface potential plotted against temperature followed various paths, some of which were bent upwards. In such a range of temperature, the association of silver vacancies and cadmium ions may have a role to play and the curve would bend downwards and its slope would become gentler, which is contrary to the present results. It was confirmed that surface potential is higher in lower range of vacuum than in higher range of vacuum, so that gases absorbed on and near the free surface may be contributing to these phenomena, for which we have not a definite interpretation. The logarithm of the concentration of Frenkel defect in silver chloride plotted against $10^3/T$ which was obtained by Ebert and Teltow[2] seems to consist of two lines and the slope of the line below 280°C decreases corresponding to the value of the formation energy, 1.27 eV. According to the present results, the curve seems to retain the same slope down to 170°C.

From the Eq. (1), it is apparent that the concentration of Frenkel defect at knee point temperature is equal to the concentration of impurity cations which replace silver ions at lattice sites. The concentration of Frenkel defect so obtained is several times higher than that obtained by ionic conductivity measurements[2], as was the case in silver bromide crystals. A part of the discrepancy might have been caused by errors in the temperature measurement on the surface of the crystal in our case.

A_1A_2/B_2 may be equal to the square root of $(N_1B_1/N_2B_2)^{1-\alpha}$ under the assumption that the surface potential in the intrinsic region is independent of temperature. In reality, it decreases linearly with temperature, and from Fig. 2, the experimental values of A_1A_2/B_2 fall within the strip bounded by the two curves, $A_1A_2/B_2=(N_1B_1/N_2B_2)^{(1-\alpha)/2}$ and $A_1B_1/B_2=10\times(N_1B_1/N_2B_2)^{(1-\alpha)/2}$. In this temperature range, A_1 and B_2 may be independent of α, and A_1 is nearly equal to unity. We may assume that as temperature is elevated, the work required for taking away an electron on the surface to infinity will decrease and A_2 must be smaller than unity and A_2 is dependent on α. From Fig. 2, the maximum variation might be larger than 10^3 to 1. It follows that B_2 is smaller than unity and B_2

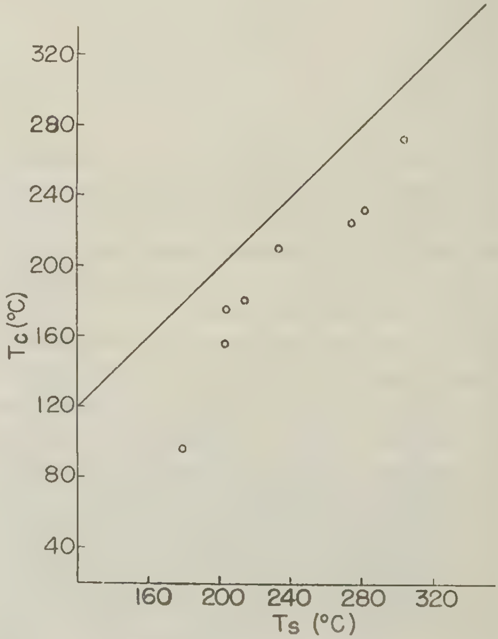

Fig. 5. T_C plotted against T_S. All points lie below the solid line $T_C=T_S$.

is not smaller than 10^{-5} because A_1 may be nearly equal to unity and B_2 may be between $(2\times10^7)^{-1/2}$ and $(2\times10^9)^{-1/2}$ when α is 0. Then B_1 must be larger than one. The energy level for an interstitial silver ion would drop and that for a silver ion at a lattice site would elevate as temperature rises.

By the variation of the ionic conductivity with temperature the intrinsic and the structure-sensitive regions of silver halide crystals can be determined as well as by the variation of surface potential with temperature. The knee point temperature of the surface potential curve will be higher than that of the logarithmic curve of ionic conductivity versus the reciprocal temperature (absolute unit), since an interstitial silver ion has larger mobility than a silver vacancy and the mobility plays the important role only in the latter curve. This point will be ascertained by Fig. 5, in which T_C is plotted against T_S. T_S is always higher than T_C. Suffixes C and S denote measurements of conductivity and surface potential, respectively.

It is apparent under a qualitative view that the intrinsic region determined by surface potential corresponds to that determined by ionic conductivity and the same for the structure-sensitive region.

We will now examine whether this can be established quantitatively. From the Eq. (1), we have:

$$(E_{F0}/k)\times x_S=\ln N_1B_1/N_2B_2-\ln c^2$$

where x_S stands for the reciprocal of T_S, which is the knee point temperature determined from the surface potential measurement. The specific conductivity for silver chloride —σ— is determined by the following equation[3]:

$$\sigma=\sigma_0\left\{\sqrt{\left(\frac{c}{2y_0}\right)^2+1}-\frac{c}{2y_0}\frac{\varphi-1}{\varphi+1}\right\}$$

where σ_0 stands for the intrinsic conductivity which would be displayed by an ideally pure crystal, and we denote the concentration of Frenkel defect in such a crystal by y_0 and the ratio of the mobility of an interstitial silver ion μ_1 to that of a silver vacancy μ_2 by φ.

In the intrinsic region, where $y_0\gg c$

$$\sigma=\sigma_0=Ney_0(\varphi+1)\mu_2$$

where N is the number of silver ion lattice sites per unit volume and $-e$ is electronic charge.

In the structure-sensitive region, where $c\gg y_0$

$$\sigma=\sigma_0\cdot\frac{c}{y_0(\varphi+1)}=cNe\mu_2$$

μ_1, μ_2, and y_0 contain reciprocal temperature only in the exponential function. Then, σ versus $1/T$ curve will be a straight line in each region. The knee point will be determined by extended lines, where extrapolated values of conductivity are equal, and we have

$$N_1B_1/N_2B_2\exp-(E_{F0}/kT_C)\times(\varphi+1)^2=c^2\,. \quad (2)$$

Then, we get

$$x_C=x_S+3.99\times10^{-4}/E_{F0}\log(\varphi+1)$$

where E_{F0} is the formation energy at 0°K in electron volt unit. From this relation we can obtain the mobility ratio φ, which is plotted against $10^3/T$ in Fig. 6.

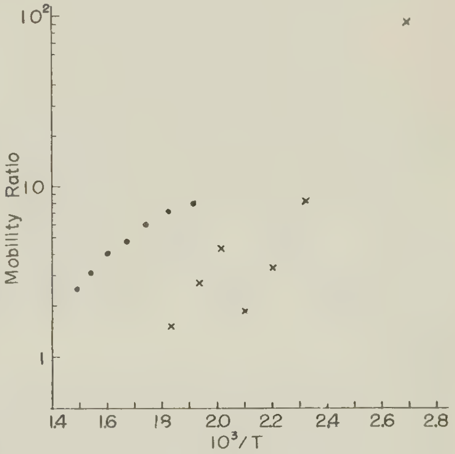

Fig. 6. The logarithm of the ratio of the mobility of an interstitial silver ion to that of a silver vacancy as a function of $10^3/T$. Ebert and Teltow's values[2] are denoted by solid circles and our results are denoted by crosses. Except for "pure" samples, the values of φ are in a resonable range with fluctuation and show a tendency to increase with decreasing temperature.

The values of φ have a tendency that they seem to increase as temperature decreases. The calculated values are subject to great error since they are determined as a small difference between the reciprocal temperatures of two knee points, both of which are determined with some uncertainty on the experimental curves.

With such uncertainty in mind, values of φ may be in a resonable range.

These results showed merely qualitative correctness of our interpretation about surface potential variation with temperature. However, a remarkable difference does appear between φ's for samples doped with a little amount of cadmium ions and undoped samples. The knee point of "pure" samples is at about 180°C in the case of surface potential but is below 100°C in the case of ionic conductivity. The knee point in ionic conductivity of a specimen doped with 1.25 Mol.-% of cadmium is at about 150°C and the value of φ for it is a resonable one. The knee point of an undoped specimen is at about 80°C and φ seems to be large though we have no accurate knowledge of φ at such a low temperature. This difference seems to be attributed to the facts that in higher temperature range the curves for "pure" specimens do not overlap those for doped ones. If the former is displaced to overlap the latter, φ would be reduced from 90 to 20.

In the case of AgBr, the same results were obtained, that is, the knee point temperature obtained from surface potential is higher than that from ionic conductivity, and the ratio of mobilities is smaller than that by Teltow. Also the discontinuity of the knee point temperature between "pure" and a little-doped samples appeared in ionic conductivity measurements.

With increaseing amount of cadmium doped into the crystal, the ionic conductivity decreases and attains to the minimum, and then increases[2]. So, doped cadmium ions make the logarithmic curve of the ionic conductivity versus the reciprocal temperature complex near the knee point. Our experimental temperature range might be in such a peculiar range, and if the range is extended to higher temperature, the discrepancy would disappear and all curves would overlap one another. In suce temperature range, the polarization makes measurement difficult and measurements in such a range did not been carried out.

The size of specimens are about 3×2×2 (mm), and undesirable stress field may remain to change μ_1 and μ_2. It is desirable to use large and well-annealed samples. Stress field may have contributions to both measurements which are not controlled, and make φ fluctuate. The dislocations in a specimen doped with Cd may trap interstitial silver ions and make the conductivity decrease.

The surface potential measurements were carried out in vacuum, and the ionic conductivity measurements in air. To compare the former's knee point temperature with that of the latter, it is necessary to carry out both measurements in the same atmosphere. The specimens for surface potential were thinner than 1 mm, and the electrodes could not been attached to them. We used different specimens for both measurements which were neighbouring parts of the sample.

The above-mentioned three ways involve contradictory characters, but through these ways, more accurate values of φ may be obtained.

Acknowledgements

The author acknowledges with pleasure his debt to Dr. S. Sonoike for his guidance. The author is also grateful to Prof. Dr. H. Takahasi (the University of Tokyo) for helpful suggestions and criticium to manuscript. He wishes to acknowledge the courtesy of Dr. T. Asari and Mr. Y. Watanabe in Japan Analytical Chemistry Research Institute for quantitative analysis of a little amount of cadmium in the crystals. Thanks are extended to the assistance of Mr. H. Motoi throughout the course of this work. The present investigation has been partly supported by this special Research Grant from Chuo University.

On the Magnetic Properties of Cr_2As and Cu_2Sb

By Motoyoshi YUZURI*

The Research Institute for Iron, Steel and Other Matals,
Tohoku University, Sendai, Japan

(Received August 1, 1960)

The thermomagnetic properties of the compound Cr_2As and Cu_2Sb were investigated together with the phase diagram of Cr–As system. From the results of thermal and thermomagnetic measurements for Cr_2As and Cu_2Sb it was found that they show antiferromagnetic behavior with the Néel point at 393°K and at 373°K respectively. Their reciprocal susceptibilities obey the Curie-Weiss law in high temperature range, but a considerable deviation therefrom is seen just above the Néel point. From the Curie constant obtained by the present experiment, the effective magneton number μ_{eff} of the magetic carrier was calculated to be 3.6 and 2.6 for these compounds, Cr_2As and Cu_2Sb, respectively. The total heat absorptions due to the vanishing of antiferromagnetic order in spin arrangement were 50 Cal/mol and 20 Cal/mol. A discussion is given on the origin of the above-mentioned magnetic properties.

§1. Introduction

Various types of spin ordering are expected to be formed[1] for the magnetic compounds with the crystal structure of Cu_2Sb type. Previously the present author reported[1] the antiferromagnetic behavior of the compound Mn_2As with this structure. Now he undertook to study the magnetism of the compounds Cr_2As and Cu_2Sb with the same crystal structure. Since the range of existence of the compound Cr_2As in the phase diagram of Cr–As binary system was not yet clear, X-ray, thermal and magnetic analyses were treid in the composition range near Cr_2As, and, based on the results obtained, the phase diagram near this stoichiometric composition was also established. In the following are given the results of the measurement and the discussion on the spin ordering in Cr_2As and Cu_2Sb.

§2. Preparation of the Specimen

The specimens used were prepared by the usual ceramic method. Chromium (99.3%) and arsenic (99.9%) powder or copper (99.9%) and antimony (99.9%) powder were mixed in the desired ratio, respectively, sealed in evacuated silica tubes and then heated in an electric furnace. To avoid explosion of the tubes during heating, the mixtures were heated up slowly, in 72 hours from room temperature to 900°C in the case of arsenide, and in 96 hours from room temperature to 500°C in the case of antimonide, and they were kept at the terminal temperatures for 48 hours. After the reaction was completed they were cooled down slowly to room temperature. In order to obtain homogeneous specimens, all the reaction products were crushed, mixed well, again heated, to 900°C in the case of Cr_2As and to 500°C in the case of Cu_2Sb, kept at these temperatures for 48 hours and cooled down to room temperature in 72 hours. Such prepared specimens, however, did not show any difference from the original ones in their magnetic properties. Every portion of the specimen thus obtained showed the same thermomagnetic behavior.

§3. Phase-diagramatic Study of Cr–As system

First, the change in crystal structure due to the composition of chromium in Cr–As binary system was investigated by means of X-ray powder method. The diffraction lines in the specimens with the composition CrAs were found to be indexed as those due to the orthorhombic structure with parameters $a=3.48$Å, $b=6.21$Å, $c=5.73$Å; this result almost coincides with that by Nowotny and Arstad[2]. The diffraction lines due to the orthorhombic structure became weak and new lines began appear with an increase of Cr content from $X=1$ in the formula Cr_XAs. The diffraction angles* in the case of $X=1.5$ are shown in Table I. The intensity of the lines became maximum near $X=1.5$ and they disappeared near $X=1.9$. They are indexed as those due to the tetragonal system, in which $a=7.05$Å, $c=9.05$Å, $c/a=1.18$.

On the other hand, the diffraction lines of the compound with the composition Cr_2As could be indexed as those of the crystal structure of Cu_2Sb type and its parameters a and c were 3.58Å and 6.25Å respectively (axial ratio $c/a=1.76$); the results coincide again with those by Nowotny and Arstad. The diffraction lines of Cu_2Sb structure were found for specimens in which $X=1.6$. In intermediate compositions between Cr_2As and Cr, the intensity of diffraction lines due to Cu_2Sb structure became weak with an increase of X beyond $X=2.0$ and new diffraction lines appeared, which could be indexed as those of a tetragonal structure with $a=2.90$Å and $c=6.25$Å. These lines became strong at about $X=5$, but the precise value of X for the compound with this structure was not determined in the present study. In Table II is given the result of analysis of this structure. All the lattice parameters or diffraction angles mentioned above remain unchanged with the change in composition.

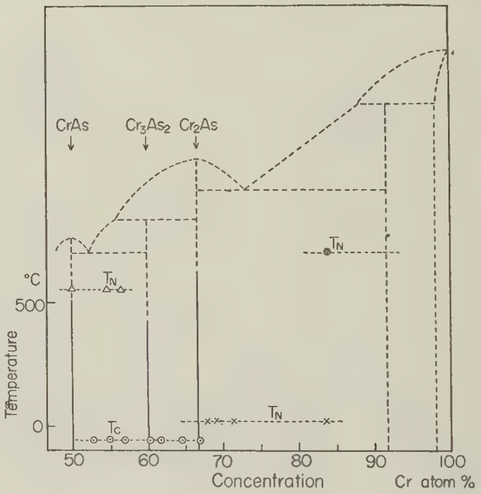

Fig. 1. Phase diagram of Cr–As system.

On the basis of these crystallographic studies, several phases are considered to be existing, that is, orthorhombic phase in a narrow range of composition including $X=1.0$, a phase with Cu_2Sb structure near $X=2.0$, a compound with tetragonal structure near $X=1.5$ and another compound with tetragonal struuture near $X=5.0$. It is conceivable that two phase regions exist between CrAs and Cr_3As_2, Cr_3As_2 and Cr_2As, Cr_2As and Cr_5As, and Cr_5As and Cr. Based on the results of X-ray analysis and the magnetic analysis which will be given in the next section, a tentative phase-diagram of Cr–As system was constructed, as shown in Fig. 1.

---

* Cr-As system was once investigated by Nowotny and Arstad, but they could not ascertain the presence of Cr_3As_2 phase by X-ray analysis, so that their results do not agree with the present ones in Cr_3As_2 phase.

The diffraction lines of the compound Cu_2Sb could be indexed as those of the crystal structure of Cu_2Sb type, its parameters a and c being 3.99Å and 6.07Å respectively (axial ratio $c/a=1.54$). These results coincide also with those by Elander, Hagg and Westgren[3].

§ 4. Thermomagnetic Measurement

The measurement of the magnetic susceptibility was made by means of an automatically recording magnetic balance[4]. First the thermomagnetic curve for CrAs was taken at a field strength of 3500 Oe in the temperature range from the boiling point of liquid nitrogen to 1000°C. The result is shown by a curve in Fig. 2. A peak of susceptibility was observed at 550°C. A similar peak was also observed in $Cr_{1.3}As$.

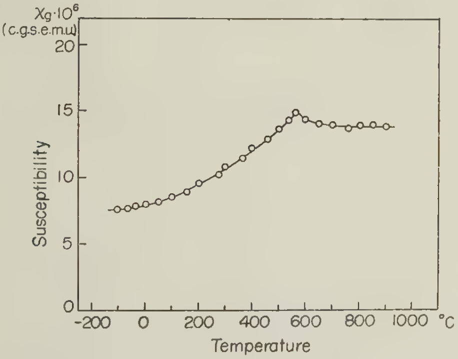

Fig. 2. Thermomagnetic curve of CrAs.

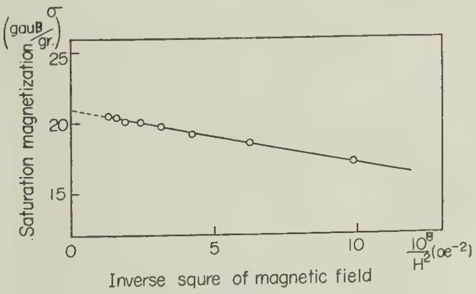

Fig. 3. Specific magnetization of Cr_3As_2 versus inverse square of the magnetic field.

It was also found that the compound Cr_3As_2 shows ferromagnetism. The magnetization curve of the compound Cr_3As_2 was measured to a field strength of 10000 Oe, as shown in Fig. 3. The magnetization varies linearly with inverse of the magnetic field. And the saturation magnetization σ_s was obtained by by extraporation. Now the $\sigma_s - T^{3/2}$ curve (Fig. 4(A)) indicates that the saturation magnetization varies linearly with T below 150°K. The saturation value at absolute zero of temperature obtained by extrapolating the linear part of the $\sigma_s - T^{3/2}$ curve reaches 21.0 gauss/gr, or 0.38 μ_B per Cr atom. Moreover, the molar magnetization obtained by extrapolating to 0°K at a magnetic field of 8000 Oe changes with Cr concentration, as given in Fig. 5, showing that the magnetization increases linearly from the composition of 50% Cr, reaches its maximum at Cr_3As_2, and then decreases again linearly until it vanishes at 67.8% Cr (near Cr_2As). Such an aspect confirm the existance of two phase regions between CrAs and Cr_3As_2 and

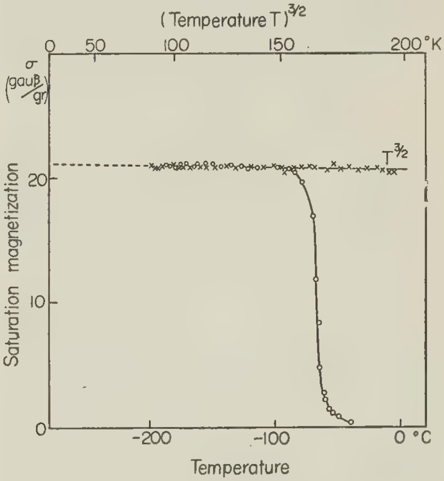

Fig. 4. (A) Thermomagnetic curve (ferromagnetic range) of Cr_3As_2. Where the scale of vertical axis is common for two curves.

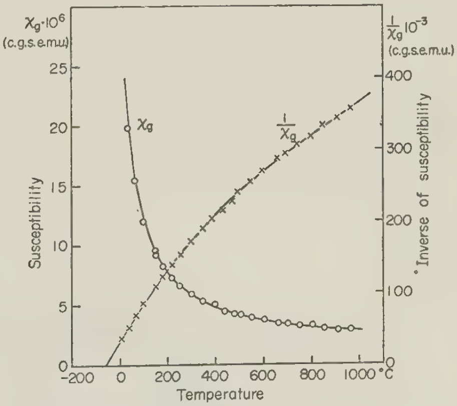

Fig. 4. (B) Thermomagnetic curve (paramagnetic range) of Cr_3As_2.

between Cr_3As_2 and Cr_2As, as shown in Fig. 1.

On the other hand, the thermomagnetic curve of this compound under a magnetizing field of 8000 Oe is shown by the curve in Fig. 4(A), showing that the Curie point lines at −60°C. The susceptibility of the compound above the Curie point was found to change like as a ferrimagnetic compound (Fig. 4(B)). From the Curie constant obtained from the slope of the $1/\chi_g - T$ curve at high temperature, the effective magneton number per Cr ion was calculated to be 2.0. If the Landé factor is assumed to be 2, the mean spin quantum number S will be 1.2/2. According to Haraldsen[5], the saturation value and effective magneton number of Cr_3As_2 were 0.68 μ_B and 2.3 per Cr atom, which are somewht different from the present result.

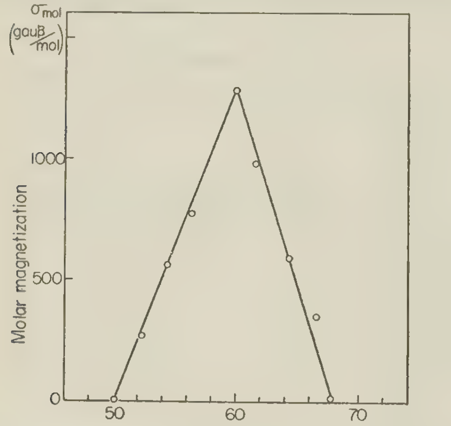

Fig. 5. Saturation magnetization versus Cr concentration.

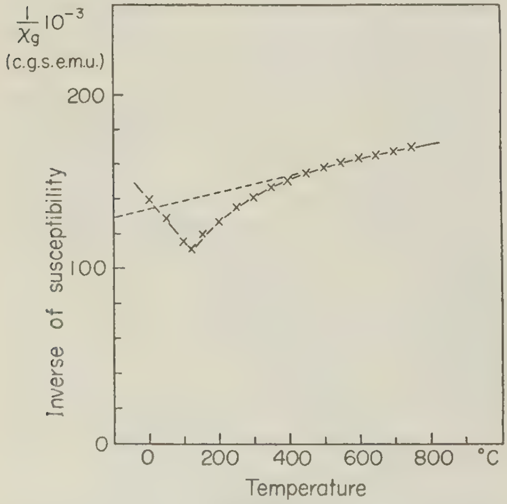

Fig. 6. Reciprocal susceptibility versus temperature of $Cr_{2.1}As$.

The result of thermomagnetic measurement for $Cr_{2.1}As$* at a magnetic field of about 3500 Oe in the temperature range from the boiling point of liquid nitrogen to 1000°C is given in Fig. 6. The peak of susceptibility at 120°C seen from the same figure is attributable to the compound with Cu_2Sb structure (compound Cr_2As). As shown in Fig. 6, the reciprocal susceptibility of $Cr_{2.1}As$ decreases linearly with the lowering of temperature in the high temperature range, but it falls more rapidly just above the point of susceptibility maximum, as in the case of Mn_2As.

The thermomagnetic curve for Cr_5As in the magnetic field of about 3500 Oe in the temperature range from the boiling point of liquid nitrogen to 1000°C is shown in Fig. 7. The magnetic anomaly at 120°C is due to the contamination of the compound Cr_2As, and the magnetic anomaly at 700°C is attributable

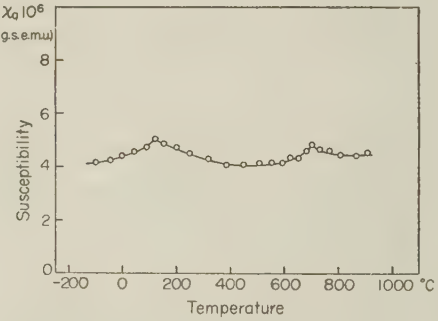

Fig. 7. Thermomagnetic curve of Cr_5As.

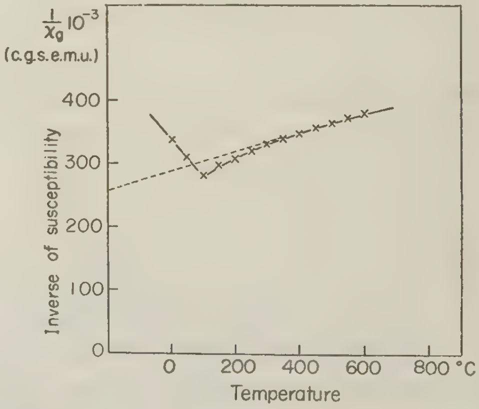

Fig. 8. Reciprocal susceptibility versus temperature of Cu_2Sb.

---

* The composition given here is based not on the chemical analysis but on the charged content, so that we can not attach too much significance to non-stoichiometry of the composition.

to the phase richer in chromium. All these results are considered to confirm the phase diagram mentioned in the previous section.

Next, the thermomagnetic curve for Cu_2Sb under the magnetic field of about 3500 Oe in the temperature range from the boiling point of liquid nitrogen to 1000°C is Fig. 8. It shows a peak of susceptibility at 100°C. Just above the temperature of maximum suceptibility the inverse susceptibility falls rapidly with the lowering of the temperature just as in the case of Cr_2As and Mn_2As.

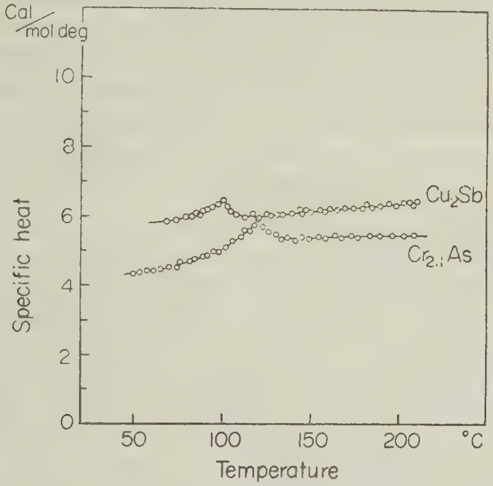

Fig. 9. Specific heats of $Cr_{2.1}As$ and Cu_2Sb versus temperature.

The measurement of the specific heat near the maximum point of susceptibility of the compound $Cr_{2.1}As$ and Cu_2Sb was made by means of an adiabatic caloriemeter, the detailed discription of which is given elsewhere[6]. The results of measurement are shown in Fig. 9. The anomalous peak of the specific heat at about 120°C for $Cr_{2.1}As$ and at about 100°C for Cu_2Sb are considered to correspond to the susceptibility maximum of these compounds respectively, and total heat absorptions at these points are estimated to be 50 and 20 Cal/mol of Cr and Cu, respectively.

§ 5. Discussion on the Antiferromagnetic Behavior of Compounds Cr_2As and Cu_2Sb

Now a suggestion is made here that the peak in susceptibility at 120°C in the case of $Cr_{2.1}As$ and at 100°C in the case of Cu_2Sb can reasonably be attributed to the antiferro-paramagnetic transition in the spin ordering in this type of crystal lattice. The temperature dependence of susceptibility above the maximum point in these substances shown in Fig. 6 and 8 may be expressed as follows:

$$\frac{1}{\chi_M}=\frac{T+2067}{1.61}-\frac{13.6\times10^3}{T-360} \quad \text{for the case of } Cr_2As \qquad (1)$$

and

$$\frac{1}{\chi_M}=\frac{T+1694}{0.85}-\frac{14.5\times10^3}{T-290} \quad \text{for the case of } Cu_2Sb \qquad (2)$$

Now the lattice for cations in Cu_2Sb type crystal is divisible into two sublattices, and if different kinds of cations (s.g. Mn^0 and Mn^{3+} occupy both of these sublattices, respectively, then antiferromagnetic or ferrimagnetic ordering can be expected to occur due to the proper exchange interaction between the ions. In such a case the suceptibility above the Néel or the Curie point is shown[1] to be given by

$$\frac{1}{\chi}=\frac{T+T_a}{\frac{1}{2}(C_A+C_A)}-\frac{\tau}{T-\theta} \qquad (3)$$

where

$$T_a=-\frac{n}{8(C_A+C_B)}(C_B+2C_A+4C_AC_B)$$

$$\theta=\frac{n}{8(C_A+C_B)}(1+2\gamma-4\beta), \quad \beta=\beta_1+\beta_2$$

$$\tau=\frac{n^2\,C_AC_B}{32(C_A+C_B)}\{C_B(1-2\beta)+2C_A(\beta-\gamma)\},$$

and

$$T_A=\frac{1}{16}[n(2C_A-C_B)+|n|\{(C_B+2C_A)^2+16C_AC_B(\beta_1-\beta_2)\}^{\frac{1}{2}}].$$

In these expression T_a is the asymptotic Curie point, C_A and C_B the molar Curie constants of both kinds of cations, respectively, and $n\gamma$, $n\beta_1$, $n\beta_2$ and n represent the intra- as well as inter-layer molecular field coefficients as is defined elsewhere[1]. By comparing expression (3) with the empirical expression (1) and (2), possible values of the molecular field coefficients were determined. If quintet and triplet states for both kinds of Cr ions (2.42 and 0.8 for C_A and C_B) and triplent and doublet states for Cu (1.24 and 0.46 for C_A and C_B) are assumed, then the molecular field coefficient can be determined as shown in Table III.

For the sake of comparison the ferrimagnetic Curie temperature corresponding to the same

Table III. Coefficients of molecular field.

Cr_2As		Cu_2Sb	
$C_A=2.42,\quad C_B=0.80$		$C_A=1.24,\quad C_B=0.46$	
$S_A=4/2,\ g_A=1.80$ (or $S_A=3.5/2,\ g_A=2$)		$S_A=2/2,\ g_A=2.22$ (or $S_A=2.3/2,\ g_A=2$)	
$S_B=2/2,\ g_B=1.79$ (or $S_B=1.7/2,\ g_B=2$)		$S_B=1/2,\ g_B=2.21$ (or $S_B=1.2/2,\ g_B=2$)	
$n=-1.15\times10^3$	$n=-3.71\times10^3$	$n=-2.61\times10^3$	$n=-6.05\times10^3$
$\gamma=2.29$	$\gamma=0.600$	$\gamma=1.56$	$\gamma=0.57$
$\beta_1+\beta_2=2.43$	$\beta_1+\beta_2=0.87$	$\beta_1+\beta_2=1.69$	$\beta_1+\beta_2=0.82$
$\|\beta_1-\beta_2\|=1.86$	$\|\beta_1-\beta_2\|=0.24$	$\|\beta_1-\beta_2\|=1.23$	$\|\beta_1-\beta_2\|=0.17$

values of coefficients was calculated in both cases and it can be shown that the Néel temperature corresponding to these values of coefficients is higher than the ferrimagnetic Curie point, and the antiferromagnetic ordering is, in general, stable, as compared with the case of ferrimagnetic ordering. But the result of calculation for the corresponding internal energy of ferrimagnetic structure, based on the molecular field constants shown above, is lower than that of antiferromagnetic ordering, which predicts a transition from antiferro- to ferrimagnetic state at low temperatures. In the present experiment such a transition was not found in either compound at least above the liquid nitrogen temperature, so that it may be interesting to extend the measuremet to lower temperature. It may be noted, however, that a slight change of molecular field coefficient for the case $C_A>C_B$ in the above Table can make the free energy of the antiferromagnetic state lower than that of the ferrimagnetic state in the whole temperature range, eliminating the possibility of the transition suggested above.

Based on the present theory, the anomalous heat absorption of Cr_2As and Cu_2Sb due to antiferro-para transition is calculated to be 670 and 530 Cal/mol, respectively. The experimental values seem to be smaller than those due to the order-disorder change of spin arrangement. Although, since the estimation of the specific heat due to the thermal vibration of atoms is not rigorous, it might be possible that the exact value of the amount of heat absorption at the Néel point lies far beyond the present value, this is a theoretical problem to be studied in future.

X-ray Studies on the Ferrite-Haematite Solid Solutions

By Chisato OKAZAKI

Research Department, Wireless Division, Matsushita Elect.
Ind. Co. Ltd., Kadoma, Osaka

(Received April 27, 1960)

The variation of the lattice dimension of the solid solution system, $NiFe_2O_4$-Fe_2O_3, and the precipitation process of α-Fe_2O_3 therefrom were investigated by X-ray analysis. These quenched solid solutions possess unstable inhomogeneities originating in the localized oxidization. When annealed at certain temperatures, the solid solution tends to become stabilized by the precipitation of α-Fe_2O_3. The activation energy for the precipitation was found to be ca 1.03 ev.

The solubility of Fe_2O_3 in $NiFe_2O_4$ was determined at various temperatures, and the heat of dissolution was found to be 1.3 ev.

§1. Introduction

It is well known that ferrites can dissolve a considerable amount of ferric oxide at high temperatures.[1), 2)] After a rapid cooling, these soild solutions appear to be homogeneous even at room temperature. However, their electrical conductivity[3)], magnetic field annealing effect[4)] and disaccomodation phenomenon[5)], etc., are dependent not only upon their compositions but also upon the process of preceding heat treatment. These properties should be interpreted in terms of the dissolved ferric oxide in these solid solutions.

Among numerous ferrites, nickel ferrite is known to be the most stable with respect to its atomic arrangement and the valency state, therefore it is a suitable material for the study of examining the behavior of the dissolved ferric oxide. In this paper, a study on the stability of the nickel ferrite-ferric oxide system against the precipitation of ferric oxide will be given.

Some qualitative reports concerning such a precipitation have been published by other investigators[6), 7)], but, no quantitative consideration has been reported.

§2. Preparation of the nickel ferrite-ferric oxide solid solutions

Different proportions of nickel oxide and ferric oxide, both of the c.p. grade were mixed in a steel ball mill. These mixtures were fired at 1300°C in air or in an oxygen atmosphere for four hours, and cooled rapidly (about 100°C/min.) to room temperature.

The products fired in air and quenched were found to be a solid solution having the spinel-type structure if the mole ratio Fe_2O_3/NiO, which we shall designate by x hereafter, was below 2.2. On the other hand, the products fired in an oxygen atmosphere and the quenched are solid soultions if x is below 1.8. Both of these two kinds of preparations contain large amounts of ferrous iron Fe^{2+}. The amounts of Fe^{2+} in these solid solutions were determined by the chemical analysis proposed by Gorter and others[8)], and are shown in Table I.

Table I. Contents of Fe^{2+} ions in $NiFe_2O_4$-Fe_2O_3 solid solutions

Original mole ratios of Fe_2O_3 to NiO x	Atomic ratios of Fe^{2+} to the total Fe ions %		Atomic ratios of Fe^{2+} to the total excess Fe ions %

1.5	5.0	4.8	15.8	14.4
1.75	6.5	6.5	15.2	15.2
2.00	7.6	7.4	15.2	14.8

§3 The lattice constants of the solid solutions, $NiFe_2O_4$-Fe_2O_3, and the role of excess iron ions

In order to find in what manner the excess amounts of ferric oxide are dissolved in the ferrite, the variation of lattice constant with the excess amount of ferric oxide was measured.

Using an automatic recording X-ray diffractometer, X-ray powder patterns of these solid solutions were taken with filtered Co-Kα radiation. Lattice constants were obtained by the extrapolation method against $1/2\,(\cos^2\theta/\sin\theta+\cos^2\theta/\theta)$ using a number of diffraction peaks at high angles, which were calibrated with pure Si (99.99%).

The results are shown in Fig. 1, where the unit cell dimension a_0 is plotted as a function of the excess amount of ferric oxide; curve (1) is for the specimens fired and quenched in the oxygen atmosphere, and curve (2) is for the ones in the air.

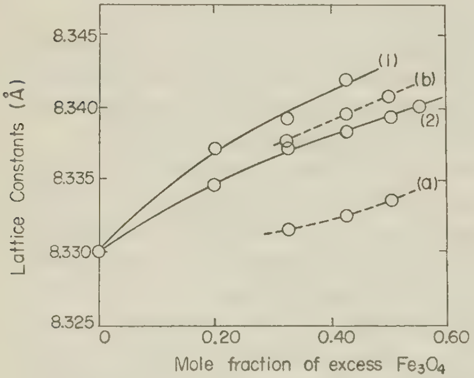

Fig. 1. Lattice constants of quenched $NiFe_2O_4$-Fe_2O_3 soild solutions.
(1) Specimens fired at 1300° C in the oxygen atmosphere
(2) Specimens fired at 1300° C in air
(a) Calculated values using "Vegard's law" -assumtion (a)-
(b) Calculated values using "Vegard's law" -assumption (b)-

In order to accomodate the excess amount of Fe^{3+}, the following there processes may take place:

(1) Soild solution of magnetite phase (reduction of Fe^{3+} to Fe^{2+})

(2) Soild solution of γ-haematite phase

(3) Precipitation of α-Fe_2O_3.

Since the ionic radius of Fe^{2+} ion is larger than those of Ni^{2+} and Fe^{3+} ions, the solid solution of magnetite phase will be followed by an expansion of the lattice ($a_{\text{magnetite}}-a_{\text{nickel-ferrite}}=0.06$Å).[9] The solid solution of γ-haematite phase may lead to a contraction of the lattice ($a_{\text{nickel-ferrite}}-a_{\gamma\text{-haematite}}=0.03$Å)[10]. Using "Vegard's law", and assuming the concentrations of Fe^{2+} ions determined by the chemical analysis, the lattice constants of the air-fired specimens having different x-values were calculated in two ways, based on the following two assumptions (a) and (b). Namely, the lattice dimensions change in proportion to the molar fraction of

(a) both the magnetite and γ-haematite phases,

or

(b) the magnetite phases alone.

Results are shown in Fig. 1, by the curves (a) and (b). Observed values agree fairly well with the calculated values for (b). This suggests that the contraction effect due to the presence of γ-haematite phase is not large in these solid solutions.

On the other hand, the lattice constant of the specimens fired in the oxygen atmosphere is always larger than that of the air-fired specimens with equal amounts of excess ferric oxide. This fact can not be explained by the assumption given above.

Ferric oxide tends to be more reduced at higher temperatures. It is expected that, during the process of rapid cooling, the oxidization of the solid solution localizes on the surface of each individual grain. But, when the localized ferric oxide does not crystallize sufficiently or when its amount is less than 2∼3% of the spinel matrix, it is impossible to detect the precipitate positively by the X-ray analysis. In this case, the observed value of the lattice constant of solid solution may be larger than that calculated by assuming a homogeneous ferrite-magnetite-haematite solid solution, with equal amounts of both the Fe^{2+} ions and the excess ferric oxide. It is expected that, in the oxygen atmosphere, such a formation of localized precipitation on the surface of grain is larger than that in the air. Because of this effect, the lattice constants of the oxygen-fired specimens may tend to be larger than those of the air-fired specimens. Even in the air-fired specimens, their lattice constants may be larger to some extent than the calculated values by this effect.

§ 4 Precipitation of α-ferric oxide from the solid solutions

As stated in the preceding chapter, the quenched solid solution possesses a somewhat unstable inhomogeneity. In order to consider the stability of these solid solutions, precipitation processes of α-ferric oxide therefrom were investigated in various annealing conditions.

4–1 *Temperature dependence*

The solid solutions obtained by quenching were heated in air at temperatures between room temperature and 1300°C, followed by a slow cooling. The rate of heating and cooling were about 1°C/min.[11] in these cases. The amounts of crystalline phases in these powders at different temperatures were measured continually using a high temperature X-ray diffraction camera with Co–Kα ray.

Within a certain definite temperature region, each specimen was found to contain α-ferric oxide, precipitated from the solid solutions. The amount of precipitated ferric oxide was determined from measurements of the intensity ratio of (111) of α-Fe_2O_3 to (220) of the spinel matrix. A calibration curve prepared from the measurements of unheated mixtures of α-ferric oxide and nickel ferrite in various mole ratio was used.

Results obtained can be summarized as follows (see Fig. 2):

(1) It was found that the precipitation of α-ferric oxide first occurs at about 550°C.

(2) Between 800°C and 900°C, the amount of precipitation reaches a maximum value, which is nearly equal to the amount of the excess portion of ferric oxide contained in each solid solution, $NiFe_2O_4$–Fe_2O_3.

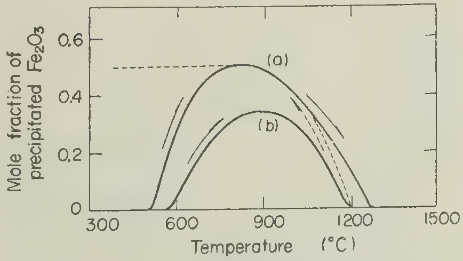

Fig. 2. The temperature dependence of the precipitation of α-Fe_2O_3 from $NiFe_2O_4$–Fe_2O_3 solid solution.
(a) $NiFe_2O_4\cdot Fe_2O_3$
(b) $NiFe_2O_4\cdot(0.5)Fe_2O_3$

(3) As temperature becomes higher than 900°C, the amount of precipitated α-ferric oxide decreases. This means that the α-ferric oxide becomes again soluble in the nickel ferrite at high temperatures. The precipitation disappears completely at about 1250°C.

(4) When a specimen is slowly cooled from higher temperatures, the precipitation of α-ferric oxide begins to occur at about 1200°C. At about 800°C, the precipitation appears to be complete. Below 800°C, the amounts of the precipitates remain constant down to room temperature.

4–2 *Time dependence*

The precipitation of α-ferric oxide from the quenched solid solution depends not only upon the annealing temperature but also upon

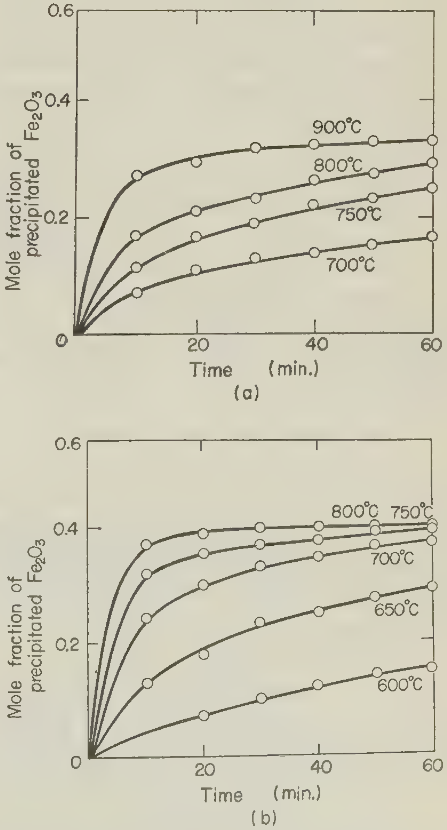

Fig. 3. The time dependence of the precipitation of α-Fe_2O_3 from $NiFe_2O_4$–Fe_2O_3 solid solution.
(a) $NiFe_2O_4\cdot(0.5)Fe_2O_3$
(b) $NiFe_2O_4\cdot(0.75)Fe_2O_3$

the time during which the specimen is annealed.

After various annealing times at certain definite temperatures, the specimens were quenched in air to room temperature in order to stop the precipitation. The rates of precipitation were determined by the same method that was used in the study of the temperature dependence. Results are shown in Fig. 3 (a) and 3 (b). In Fig. 3, the amount of the precipitated α-ferric oxide, expressed in mole fraction in the solid solution, is plotted as a function of reaction time for different annealing temperatures. With a specimen annealed at about 900°C, the precipitation completes after about one hour.

In these cases, end values are always nearly equal to the excess amount of ferric oxide contained in the initial solid solution. But, when the annealing temperature is higher than 1000°C, the amount of precipitate reaches very rapidly a certain saturation value, which is smaller than the amount of excess ferric oxide contained in the initial solid solution. It is likely that the equilibrium take place between the solid solution and the precipitate at these temperatures.

4-3 *Analysis of the experimental results*

The kinetics of the growth of precipitates will be discussed briefly. If each individual grain of the specimen possesses an equal probability for the precipitation and the rate of precipitation is simply proportional to the concentration of dissolved ferric oxide in the solid solution, then we have,

$$\frac{dn}{dt}=K_1(1-n)\,, \qquad (1)$$

where n is the fraction of the precipitated α-ferric oxide to the initial amount of ferric oxide dissolved in the ferrite, and K_1 is the rate constant of precipitation. If K_1 is independent of n, then

$$\ln\frac{1}{1-n}=K_1 t\,. \qquad (2)$$

Regarding K_1 as a constant of reaction for the precipitation, it may be expressed

$$K_1=K_0\,exp(-E_A/kT)\,. \qquad (3)$$

Using these equations, $\log\{1/(1-n\}$ vs. t and $\log K_1$ vs. $1/T$ curves are calculated from the experimental results. They are shown in Figs. 4 and 5, suggesting that equations (2) and

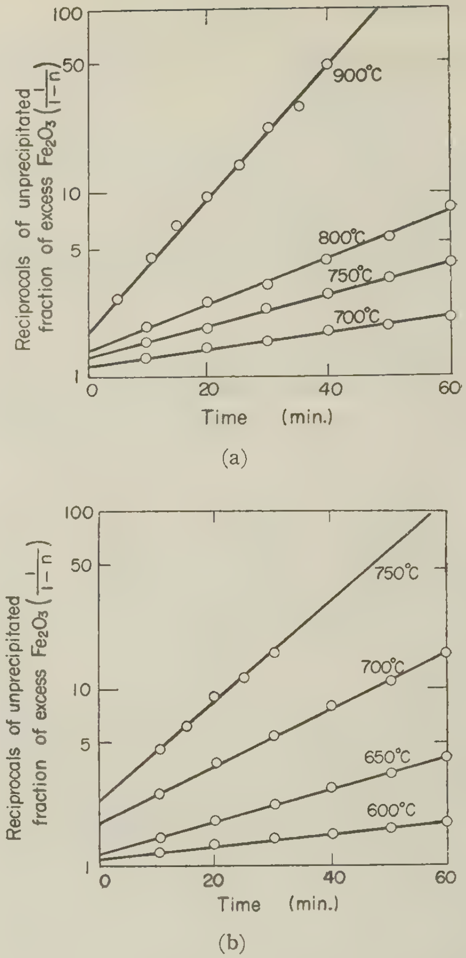

Fig. 4. Ratio of the total amounts to the unprecipitated amounts, of the excessively dissolved Fe_2O_3, versus the time of annealing.
(a) $NiFe_2O_4\cdot(0.5)Fe_2O_3$
(b) $NiFe_2O_4\cdot(0.75)Fe_2O_3$

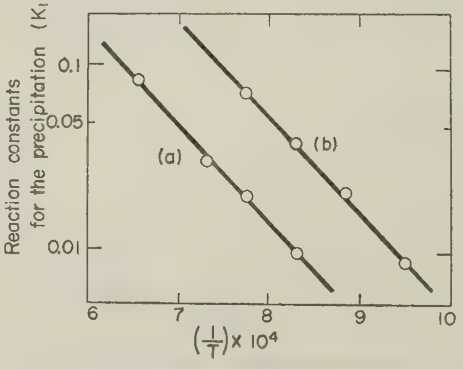

Fig. 5. Reaction rate constants versus the reciprocals of the absolute temperatures.
(a) $NiFe_2O_4\cdot(0.5)Fe_2O_3$
(b) $NiFe_2O_4\cdot(0.75)Fe_2O_3$

(3) are approximately valid for our present experiments. The activation energy, E_A, is found to be about 1.03 ev.

§ 5 Solubility of the *α*-ferric oxide in the nickel ferrite

Let us assume that the solubility of *α*-ferric oxide in a nickel ferrite can be expressed by the same way as that of a solid in a liquid phase. Then, the equilibrium solubility of *α*-ferric oxide in a nickel ferrite as well as its temperature dependency may be expressed by the following equation,

$$(C_{sat})=A\cdot exp\{-(\Delta H_{sat})/RT\}, \qquad (4)$$

where (C_{sat}) is the mole fraction of ferric oxide in a saturated solid solution, and (ΔH_{sat}) is the heat of dissolution of *α*-ferric oxide in the saturated solution of nickel ferrite-haematite.

Using this equation, $\log(C_{sat})$ vs. $1/T$ curve is calculated from the experimental results obtained for a solid solution having the mole ratio 1:1 (i.e., $x=2$), and is shown in Fig. 6. From these results, the heat of dissolution is estimated to be approximately 1.3 ev.

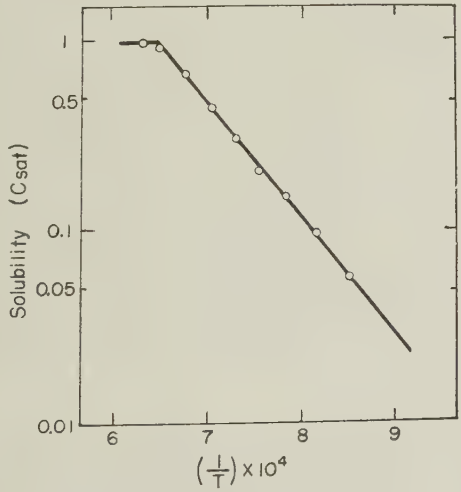

Fig. 6. Solubilities of α-Fe_2O_3 to $NiFe_2O_4$ versus the reciprocals of the absolute temperatures.

§ 6 Conclusion

For the nickel ferrite-haematite solid solution system, the variation of the lattice dimention, the precipitation and redissolution of *α*-ferric oxide were investigated by X-ray analysis. Conclusions drawn from these investigations are as follows:

(1) These solid solution systems, which are obtained by quenching, possess somewhat unstable inhomogeneities originating in the localized oxidixation on the surface of grain.

(2) Above ca. 600°C, these solid solutions tend to become stabilized by the precipitation of *α*-ferric oxide.

(3) At relatively low temperatures, the reaction rate for the precipitation depends upon the amount of the dissolved ferric oxide in the solid solution. The activation energy for the precipitation is about 1.03 ev.

(4) At high temperatures, a definite amount of *α*-ferric oxide is soluble in the ferrite in a state of thermal equilibrium. The heat of dissolution in this process is found to be 1.3 ev.

Acknowledgement

The author wishes to express his sincere thanks to Prof. T. Nagamiya and Prof. T. Watanabe, of Osaka University, for criticizing this manuscript. Thanks are also due to Mr. S. Kisaka, Manager of our department, for his support and to Mr. S. Mori and Mr. F. Kanamaru for their helps throughout the course of this work.

X-Ray Study on the Binding Properties of Cu_2O and Ag_2O Crystals

By Tadasu SUZUKI

Institue of Physics, College of General Education, University of Tokyo, Meguro-ku, Komaba, Tokyo

(Received May 5, 1960)

Crystallographical properties of the chemically prepared powder samples of Ag_2O and Cu_2O were investigated by an X-ray diffractometer, in relation to their bonding characters. The lattice constant is 4.720±0.004A for Ag_2O and 4.268±0.001A for Cu_2O. The thermal expansion coefficient of the lattice is 1.9×10^{-6} for Cu_2O. The root-mean-square amplitude of the thermal lattice vibration is determined as 0.26A for Cu_2O and 0.40A for Ag_2O at room temperature. The mean lattice strain is 1.4% for Ag_2O and 0.15% for Cu_2O, respectively. The thermal decomposition of Ag_2O was also observed. The obtained results suggest that the binding force between metallic and oxygen atoms is much weaker in Ag_2O than in Cu_2O, which can not be expected from the purely ionic model for the present crystals.

§ 1. Introduction

The crystal structure of cuprous oxide (Cu_2O), which is known as of the cuprite type[1], has a cubic symmetry with copper and oxygen atoms in the unit cell at the positions as follows:

oxygen: (1/4, 1/4, 1/4) (3/4, 3/4, 3/4)
copper: (0, 0, 0) (0, 1/2, 1/2) (1/2, 0, 1/2) (1/2, 1/2, 0)

Each oxygen atom is surrounded tetrahedrally by four copper neighbours, while each copper atom has two oxygen neighbours at equal distance.

The nature of the bonding in this crystal structure has been discussed sometimes by ionic model and sometimes by co-valent model. Pauling proposed that the co-valent bonding is more important in the Cu_2O-type structure[2]. In fact, if oxygen atom is a doubly charged *positive* ion, the *sp* bonds in four directions may form the tetrahedral frame-work of the crystal.

On the other hand, there are some experimental facts favouring the ionic model. For instance, spectroscopic analysis[3], quadrupole resonance study[4] and measurement of dielectric dispersion[5] are explained fairly well by the ionic model.

Silver oxide (Ag_2O) is the only substance possessing the cuprite type structure besides cuprous oxide.[*],[**] Like Cu_2O, Ag_2O is known to be semiconductive and show a photoconductivity. However, Ag_2O and Cu_2O are quite different in stability. The melting point of the latter is as high as 1236°C[8], while the former begins to decompose at about 200°C. Such a large difference in stability suggests that the binding energy of the Ag_2O lattice is too smaller than that of the Cu_2O lattice to be explained by assuming the ionic models for both structures.

In the present work, the properties of Ag_2O and Cu_2O were investigated by the X-ray diffraction method in order to clarify their bonding character. In this paper, a study dealing with thermal lattice vibration, thermal expansion, lattice strain of both specimens and thermal decomposition of Ag_2O is reported. The study of the electron distribution in the structure by an accurate intensity measurement will be reported in a subsequent paper.

§ 2. Samples

The red fine powder samples of Cu_2O, supplied from the Furukawa Mining Company, were prepared by dehydration and desiccation of the copper hydrate deposits which were obtained in the course of electrolysis of copper in NaCl solution.

---

[*] It is reported that lead mono-oxide (Pb_2O) also belongs to the cuprite type structure. However, there seems to be some ambiguity about its structure.[6]

[**] Since gold oxide (Au_2O) may exist,[7] an attempt to prepare the mono-oxide of gold by applying some intense oxidizing agents was tried in relation with the present work, but the X-ray diffraction examination showed only a diffuse halo pattern with its first intensity maximum at the scattering angle of 33° and the second small maximum at 60°.

The black powder samples of Ag_2O, supplied from the Tokuriki Noble Metal Company, were prepared by the neutralization of $AgNO_3$ with NaOH. The oxidation of Ag is difficult[9] and the above method is the only known procedure for preparing an appreciable quantity of the sample. In this procedure, too less NaOH produces a mixture of Ag_2O and Ag_2CO_3, while too much NaOH results in the reduction of $AgNO_3$ to Ag. The adequate quantity of NaOH against $AgNO_3$ was controlled by X-ray examination of the prepared specimens.

The diffraction patterns and the X-ray fluorescent analysis of the present samples showed no trace of impurity. The particle size of the samples observed by a microscope is about one micron for Cu_2O and about two microns for Ag_2O. Such a particle size is small enough for a flat specimen of the diffractometer.

§ 3. Instrumentals

For convenience of surveying many samples, the Norelco X-ray diffractometer was used with its rate-meter and scaler. The measurements were performed mainly with the Cu $K\alpha$ radiation filtered by a nickel foil of 0.013 mm thick, although Mo, Fe, Co and Cr $K\alpha$ radiations were also used when necessary. A proportional counter was employed as radiation detector. The study of the thermal expansion and of the lattice vibration were performed with low- and high-temperature attachments. The cooling was achieved by the gas flow generated from liquid nitrogen, by controlling the evaporation rate of nitrogen with an electronic heater immersed in a Dewer flask[10]. For heating, an electronic furnace was set up behind the sample holder. By these attachments the temperature of the samples could be changed from −150°C to 200°C.

§ 4. Lattice Constant and Thermal Expansion

For the determination of the lattice constants, the higher angle reflections (400), (331), (420), (422) and (511)+(333) of Cu_2O and (400), (331) and (420) of Ag_2O were used. The observed value of the lattice constant 4.720±0.004A for Ag_2O and 4.268±0.001A for Cu_2O coincides within the experimental error with the reported values by previous workers, 4.720A for Ag_2O[1] and 4.269A for Cu_2O[11].

The variation of the lattice constant was measured in the temperature range between −150°C and 200°C. The thermal lattice expansion coefficient of Cu_2O estimated by the (511)+(333) reflection is 1.9×10^{-6}.[*] The value for the bulk crystal of Cu_2O was reported as $2.8\sim1.8\times10^{-6}$.[12]

For Ag_2O, the expansion coefficient could not be determined precisely due to the broadening of lines, and was estimated as the same order with that of Cu_2O.

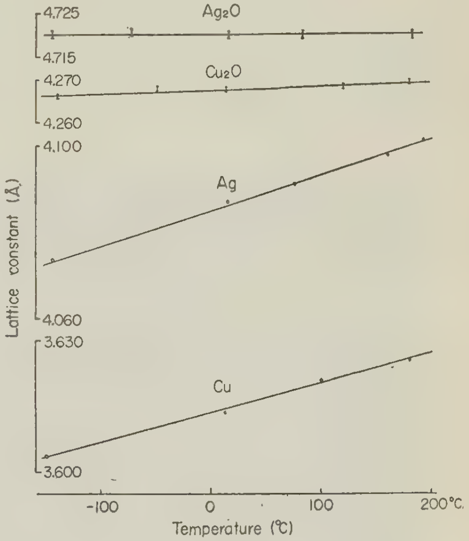

Fig. 1. Thermal expansion of lattice.

The powder samples of Ag and Cu were also measured for instrumental calibration under the same condition. The observed expansion coefficient is 1.0×10^{-5} for Ag and 1.7×10^{-5} for Cu, respectively, and agrees well with the reported values of 0.96×10^{-5} for Ag and 1.71×10^{-5} for Cu[13]. The variation of the lattice constant of the specimens against the covered temperature range is shown in Fig. 1.

§ 5. Thermal Decomposition of Ag_2O

A continuous observation of the thermal decomposition of sputtered Ag_2O by means of the electron diffraction method has been formerly reported[14]. In the present experiment, the decomposition process of Ag_2O was followed quantitatively by X-ray diagram. The powder samples of Ag_2O were packed into a specimen holder and kept at temperatures, say 100°C, 150°C and 200°C, for about 20 hours in an electrical furnace and then the samples were examined by the X-ray diffractometer at room temperature. As shown in Fig. 2(b), the lines of Ag appeared and, at the same time, the intensity of Ag_2O-lines at low angles diminished gradually by the heat treatment. After the heat treatment above 220°C, the pattern showed only the lines of Ag.

---

[*] This value coincides approximately with the unpublished value 2.3×10^{-6}, obtained by T. Takenaka in Prof. S. Miyake's laboratory with the use of the X-ray photographic method.

As is well known, Cu_2O does not decompose but is liable to oxidize by heat treatment.

The observed intensity-decrease of the Ag_2O-lines at low angles can be explained by assuming that the decomposition proceeds from the surface to the interior of the sample. Let x denote the ratio of the Ag_2O quantity in a small volume dV at the depth y from the surface of the samples to its initial quantity. x is considered to be a decreasing function of y, and we assume, for simplicity, the following exponential form,

$$x=1-(1-a)\,e^{-by}\,,$$

where a and b are appropriate constants. Then, the diffracted intensity dI' from Ag_2O in that part is

$$dI'=\{1-(1-a)\,e^{-by}\}e^{-\mu s}\,dV\,,$$

where s denotes the optical path length in the sample and μ the linear absorption coefficient of the sample. The absorption coefficient of the mixture of Ag_2O and Ag is assumed to be equal to that of Ag_2O. Then the integrated intensity I' from a heat-treated sample is given

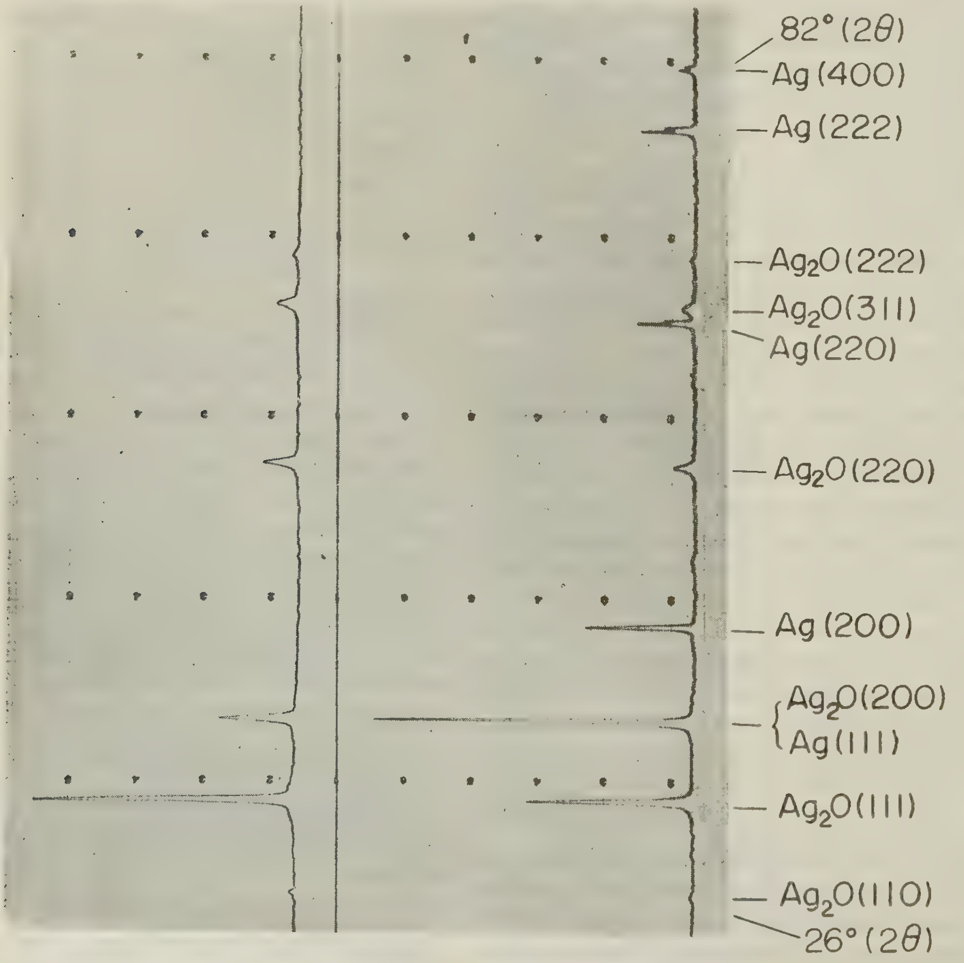

Fig. 2. Debye-Scherrer diagram of Ag_2O: (a) before the heat treatment and (b) after heated at 150°C for 20 hours.

by

$$I'=I\{1+(a-1)\}\frac{2\mu}{b\sin\theta+2\mu},$$

where θ is the Bragg angle and I signifies the integrated intensity for the flat powder sample[15] before the heat treatment. From the above equation we have

$$\frac{I}{I-I'}=\frac{b\sin\theta+2\mu}{2\mu(1-a)},$$

which shows a linear relation of $I/I-I'$ to $\sin\theta$. This relation is confirmed to be the case by Fig. 3. In short, the intensity-diminution of the Ag_2O-lines at low angles is due to the thinness of the decomposed layer of Ag_2O at the surface of the specimen.

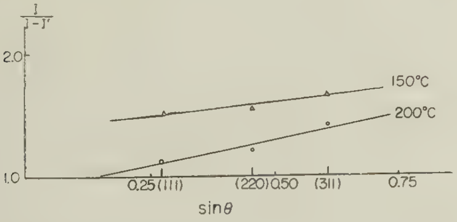

Fig. 3. I/I−I′ against sin θ, I and I′ being the integrated intensity before and after the heat treatment.

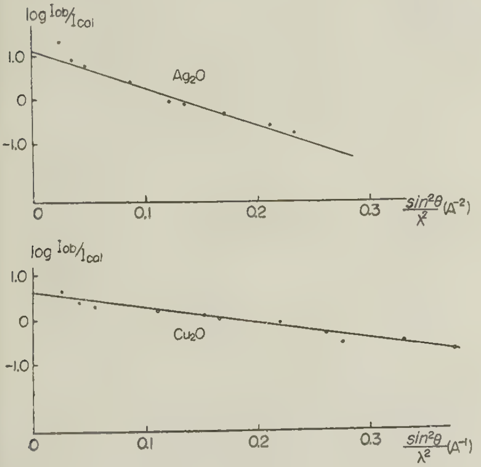

Fig. 4. The logarithmic ratio of the observed intensity to the calculated one plotted against $\sin^2\theta/\lambda^2$.

§ 6. Thermal Lattice Vibration

The root-mean-square amplitude $\sqrt{\bar{u}^2}$ of the thermal lattice vibration was determined by plotting the logarithmic ratio of the observed intensity to the calculated one against $\sin^2\theta/\lambda^2$, as shown in Fig. 4. From the well-known relation

$$I_{ob}/I_{cal}=\text{const}\cdot\exp\left(-2B\frac{\sin^2\theta}{\lambda^2}\right)$$

B can be obtained by the slope of the plot. For cubic crystals B is related to $\bar{u}^2$ as follows:

$$B=\frac{8\pi^2}{3}\bar{u}^2=8\pi\,\bar{u}_s^2\ ,$$

where $\bar{u}_s^2$ signifies the mean square-amplitude of vibration in a particular direction. The theoretical value of the intensity was calculated by the relation

$$I_{c.l}=C\frac{1+\cos^2 2\theta}{\cos\theta\sin^2\theta}\,j\,F^2\ ,$$

where F is the structure factor, j is the multiplicity of the diffraction, θ is the Bragg angle and C is the constant depending on the intensity of the incident X-ray beam. The structure factor F was calculated using the atomic scattering factors of copper and oxygen computed by Berghuis *et al*[16], and that of silver computed by Thomas and Umeda[17]. The dispersion effect of Ag and Cu atoms for

Table I. The calculated and observed values of the integrated intensities and the rms amplitude of the thermal vibration $\sqrt{\bar{u}^2}$ at room temperature. The theoretical values, taking no account of temperature effect, were computed by the relation in § 7. The constant C is put 400 only for the convenience of the calculation. The observed value of (222) is normalized to the theoretical value.

$\sqrt{\bar{u}^2}$	0.26 A		0.40 A	

the Cu Kα radiation was corrected by the tabulation given by Dauben and Templeton[18]. The values of I_{cal}, I_{ob}, B and $\sqrt{\bar{u}^2}$ for room temperature are tabulated in Table I.

The influence of the extinction effect on the observed intensities was studied by using the Kα radiations of Mo, Cu, Fe, Co and Cr. For Cu_2O, the ratio of the F-values of (111) reflection to that of (222) was plotted against the various wave lengths. For Ag_2O, the ratio of (111) to (311) was examined, since its (222) reflection for Cr Kα was too weak. The above ratios were nearly constant within the standard deviation of about 6%, and no dependence on the wave length could not be recognized. It is thus assumed that the effect of primary extinction is not appreciable in the present samples. Secondary extinction was assumed to be negligible for these fine powder samples.

The thermal lattice vibration was observed in the temperature range between −150°C and 200°C. Since, as was described in the previous section, Ag_2O begins to decompose above about 100°C, the surface of the flat specimens was covered with a thin Myler foil of 0.01 mm thick in order to prevent the thermal decomposition. The Myler foil was also used for the measurements on Cu_2O and Cu in order to prevent the oxidation. The absorbing effect of the foil was corrected at low diffraction angles. The rms amplitudes for the various temperatures are shown in Fig. 5, together with those for Ag and Cu obtained by the same procedure. The values of $\sqrt{\bar{u}^2}$, 0.14A for Cu and 0.16A for Ag agree well with the reported values of 0.145A and 0.16A for Cu and Ag, respectively[19]. The observed values of the rms amplitude of Ag_2O is remarkably large, as can be expected from the diffracted pattern shown in Fig. 2(a), in which the intensities at higher angles are strongly reduced.

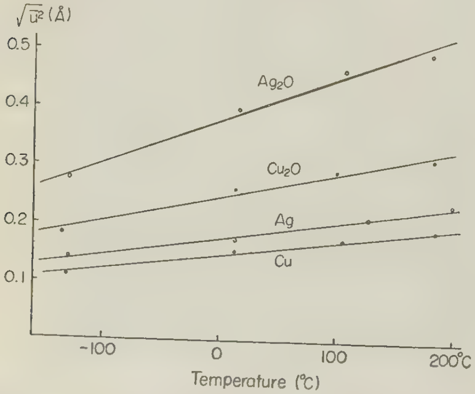

Fig. 5. The change of the rms amplitudes with temperature.

For a crystal containg two kinds of atoms, as is the present case, the mean amplitudes of vibration are to be determined separately to each atom. The above obtained value of $\sqrt{\bar{u}^2}$ should be regarded as an empirical quantity representing an average for metallic and oxygen atoms in the crystals. In a similar sence, the Debye characteristic temperature Θ of an empirical meaning can be determined from the mean-square ampliture $\bar{u}^2$, using the relation

$$\bar{u}^2=\frac{9h^2\,T}{4\pi^2k\,m\Theta^2}\left\{\phi(x)+\frac{x}{4}\right\}^{20)},$$

where $x=T/\Theta$, $\phi(x)$ is a function relating to the frequency distribution of lattice vibration evaluated by Debye, k the Boltzman constant and m the mean atomic weight. The obtained value of Θ are tabulated in Table II. The temperature dependence of $\bar{u}^2$ can be approximately put $\bar{u}^2=aT$, as is known from the above relation. The constant a is related to the elastic constant[21], and determined to be 1.3×10^{-20} for Cu_2O and 6.0×10^{-20} for Ag_2O. The value of a for NaCl is reported to be 5.7×10^{-21} [22].

−130	176	85
17	180	90
190	190	95

§ 7. Lattice Strains

Diffraction lines from Ag_2O were very broad, as an example is shown in Fig. 6. It was, therefore, expected that the chemically prepared samples might contain lattice strain. The strain distribution in the present samples was measured by the line broadening analysis. To obtain the integral breadth, the broadening due to the Kα doublet was corrected by the method of Jones[23]. The instrumental broadening was calibrated by the standard strain-free specimens of silicon.

If both the particle size and the strain effect are present, the line breadth β is in most cases expressed by the following linear equation[24)]

$$\beta\cos\theta=\lambda/\varepsilon+2\eta\sin\theta,$$

where ε, λ, η and θ are the particle size, the X-ray wave length, the effective strain and the Bragg angle, respectively. The line breadth of the present samples, determined by the above procedures, satisfies this relation as shown in Fig. 7. The magnitude of strain may be obtained from slopes of straight lines.

Recently Kuriyama showed[25)] that, if the lattice strain distribution is of a Cauchy type and that of the particle size is of an exponential form, the above relation is strictly correct.

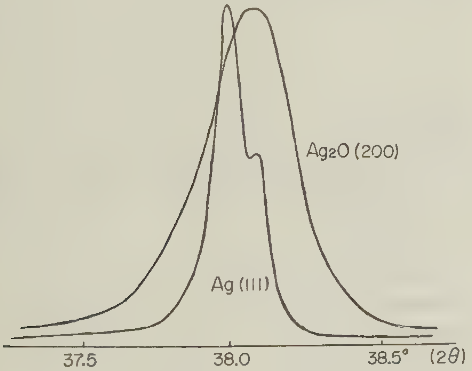

Fig. 6. Line breadth of Ag_2O in comparison with Ag. The maximum values are adjusted to the same level.

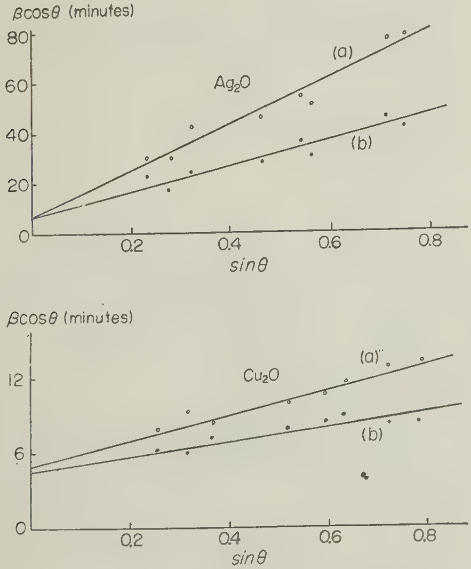

Fig. 7. Angular dependence of the integral line breadth.

The mean strain found in this way was 1.4% for Ag_2O and 0.15% for Cu_2O. By annealing the samples, these strain decreased to about one half of the initial values, but did not disappear. The electrolytically prepared powder samples of Ag and Cu are also measured and both samples showed no lattice strain.

§ 8. Conclusion and Discussion

The experimental results can be summarized as follows. The thermal lattice expansion coefficient of Cu_2O is 1.9×10^{-6} and the same order is estimated for Ag_2O. The rms amplitude of the thermal lattice vibration $\sqrt{\bar{u}^2}$ is 0.40A for Ag_2O and 0.25A for Cu_2O at room temperature. The lattice vibration of Ag_2O is comparatively large even at room temperature and becomes as large as 0.5A at about 200°C, as is shown in Fig. 6. The mean value of lattice strain, so far as the examined samples are concerned, is 1.4% for Ag_2O and 0.15% for Cu_2O, respectively. The former substance decomposes at above 100°C. The decomposition begins from the surface of the specimen and at about 200°C Ag_2O decomposes nearly completely.

The large lattice strain observed in Ag_2O seems to be ascribed to lattice deffects, for instance such as those caused by isolated silver which is formed in the lattice as a result of the instability of the structure. The above results on thermal decomposition, thermal lattice vibration and the lattice strain all suggest that the binding force between the metallic atom and the oxygen atom is much weaker in Ag_2O than in Cu_2O.

As was mentioned in § 1, Cu_2O has been considered in many cases to be ionic from the experimental facts. Taking the purely ionic model for both crystals, the lattice energy can be estimated from the Born theory by the use of Madelung constant for the cuprite type structure. The values are shown in Table III from the tabulation of Seitz[26)]. Calculated values of the lattice energy of some typical ionic oxides are also tabulated for comparison. The Table shows that the difference of the lattice energy between Cu_2O and Ag_2O calculated by the ionic model is not especially large in spite of the marked difference in observed properties of the both substances.

In this connection, it is interesting that the thermal lattice expansion of Ag_2O and Cu_2O

Table III. Crystal structure, lattice constant, melting point and the lattice energy calculated by ionic model of Cu_2O and Ag_2O, and of di-valent oxides.

	Crystal structure	Lattice constant	Melting point	Theoretical lattice energy
MgO	NaCl type	4.20 A	2800°C	940 Kcal/mol
CaO	〃	4.80	2572	842
SrO	〃	5.14	2430	790
BaO	〃	5.52	1923	747
Cu_2O	cuprite type	4.27	1236	682
Ag_2O	〃	4.72	decomposes above 100°C	585

is comparatively small, in spite of the large lattice vibration in them. As the result, the thermal lattice expansion coefficient deviates from Megaw's rule[27] between thermal expansion coefficient and ionicity. Megaw's rule states the following empirical relation. Let q denote the "electronic share", namely the charge number of a ion divided by the number of its nearest neighbour atoms, and α signify the thermal expansion coefficient, then the relation $\alpha q^2 \times 10^6 \doteqdot 1$ holds in typical ionic crystals. For example, the values of $\alpha q^2 \times 10^6$ for NaCl, CsCl and CaF_2 are 1.1, 0.8 and 1.2, respectively. This value for Cu_2O, being 0.48, deviates considerably from unity.

These circumstances seem to suggest that the *purely* ionic model is not adequate for the present crystals. It is probable that the cohesive energy of the cuprite type crystal is partly contributed by an overlap of electron distribution or by atomic polarization[28].

In conclusion the author wishes to express his thanks to Prof. S. Miyake for his kind permission to perform a part of this work in his laboratory in the Institute for Solid State Physics of the University of Tokyo. Thanks are also due to Profs. S. Miyake and S. Takagi and S. Hosoya and to Dr. M. Kuriyama for his kind discussions. This work was partly supported by the Scientific Research Grant of the Ministry of Education.

Dislocation Networks and Moiré Patterns of Molybdenite

By Yoshihiro KAMIYA, Keiichi ANDO, Minoru NONOYAMA
and Ryozi UYEDA

Physical Institute, Nagoya University, Nagoya, Japan

(Received August 2, 1960)

In electron micrographs of molybdenite films, various network-patterns were observed. They are interpreted as images of dislocation networks. Several electron micrographs are reproduced and remarkable features observed in them are explained in terms of dislocations. One of the remarkable observations is that each line of a network sometimes becomes broader and the network changes into a moiré pattern. The gradual change from a sharp image of dislocation to a broad moiré fringe can be explained by a simple consideration. The former implies that the strain accompanying the dislocation is concentrated and the latter, that the strain is spread.

§ 1. Introduction

In the course of an experiment on epitaxy[1], various network-patterns were observed in electron micrographs from molybdenite films evaporated with silver. Similar patterns were also observed for bare molybdenite films and it has become clear that the patterns represent dislocation networks in molybdenite.

In the present paper several of the electron micrographs are reproduced and remarkable features of the patterns are interpreted in terms of dislocations. One of the remarkable observations is that each line of a network sometimes becomes broader and the network changes into a moiré pattern. The gradual change from a sharp image of dislocation to a broad moiré fringe can be explained by a simple consideration. The former implies that the strain accompanying the dislocation is concentrated and the latter, that the strain is spread.

§ 2. Experimental

Thin films of molybdenite were made by pealing good molybdenite of Korean origin. Near peripheries of pealed samples, small transparent areas were usually found which were adequate for observation by electron microscopy. The thickness was not uniform and it could not be measured. In the following sections, thin, medium, and thick may correspond to a few hundred Ångströms, several hundred Ångströms and more than several hundred to a few thousand Ångströms, respectively. These are rough estimates from diffraction patterns. Thin films produce net-patterns while thick films produce mainly Kikuchi-patterns. Electron micrographs were taken at accelerating voltages 75 or 100 kv. Direct magnification was about ×5,000. Exposure time was a few seconds for thin films while for thick films a few ten seconds.

§ 3. Results

Photos. 1–4* were obtained in the course of an experiment on epitaxy[1]. The specimen was a molybdenite film evaporared with silver. Various patterns were obtained from different parts of the specimen. The silver deposit does not form a uniform film and is clearly observed in Photo. 2 as the fine irregular pattern in each cell of the network. In the present paper the silver deposit is not important.

Photos. 5–14 were obtained from bare molybdenite films. Most of molybdenite films produced some network-patterns which were usually irregular and unconspicuous. Sometimes, however, various remarkable patterns were observed. The pictures reproduced in the present paper are some examples from an immense variety.

Photos. 5–8 were obtained from thin films. In these pictures, extinction contours show high contrast. Extinction contours and network-lines usually move when specimens are first irradiated by the electron beam. After several minutes they become gradually stationary. Photos. 9 and 10 were from films of medium thickness, and Photo. 11 from thick

films. Extinction contours are less conspicuous for thicker films. The specimen of Photo. 11 was so thick that it produced only Kikuchi bands and the incident spot was observed only when the anomalous transmission took place[2]. Photos. 12 and 13 were taken at high temperature of about 600°C. So far, only a few pictures were taken at high temperatures and it is not yet clear whether or not this type of patterns is specific

to high temperatures.

§ 4. Interpretations and Discussions

Photo. 1 is very similar to one of the images of dislocations obtained by Hirsch et al[3]. Photos. 9–11 look similar to network-patterns of bismuth tellulide obtained by Geach and Phillips[4]. They have concluded that the patterns are images of dislocations because the majority of the patterns may be interpreted

by dislocation theory. For the same reason, we also conclude that most of the patterns represent dislocations. A few exceptions are surface steps as explained in subsection (f) (SS' in Photos. 8 and 9).

(a) *Distortion of extinction contours*

Pictures similar to Photo. 5 were previously obtained by Hibi[5] in the case of mica. Uyeda[6] reproduced one of them and stated that the line patterns are " without a doubt due to imperfections ". It has now become clear that the line patterns represent dislocations.

Extinction contours are remarkably distorted across each dislocation lines when the films are thin (Photos. 5–8). The same phenomenon was observed by Hashimoto[7] for MoO_3 films. He concluded that the distortion is due to bending of the films. We attribute the cause of the bending to the stress around dislocations. Fig. 1 illustrates a rubber model of a film with two edge dislocations. Regular parts of the model is made merely by pasting two rubber sheets on which parallel lines have been drawn. To make a dislocated part, the lower sheet is stretched normal to the parallel lines so that one edge dislocation is produced between the stretched (lower) and the unstretched (upper) sheets. Keeping the lower sheet stretched, the two sheets are pasted together. When the tension stretching the lower sheet is released, the pasted part buckles as observed in Fig. 1.

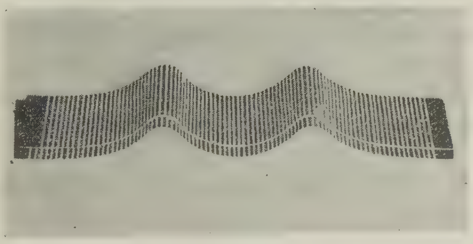

Fig. 1. Rubber model of a thin film with two edge dislocations.

(b) *Moiré fringes and images of dislocations*

It may be worth-while to make clear the relation between moiré fringes and images of dislocations before going into detailed interpretations of reproduced pictures. For the sake of simplicity, the explanation is given by the use of a simple two-dimensional model.

Let us consider two sheets of net as shown in Fig. 2a. Draw an arbitrary curve on one of them and shift the part rightside the curve by a Burgers vector b, resulting in a strain along the curve (Fig. 2b). Then superpose Fig. 2a over Fig. 2b so that the lattices coincide perfectly over the unstrained part (Fig. 2c). A band is observed along the curve, corresponding to an image of dislocation. If the strain is limited in a narrow region along the curve, the band is narrow corresponding to a sharp image of dislocation. If, however, the strain is spread over a broader region, the band becomes broader. The broadened band may adequately be called moiré fringe, because many of moiré fringes observed in

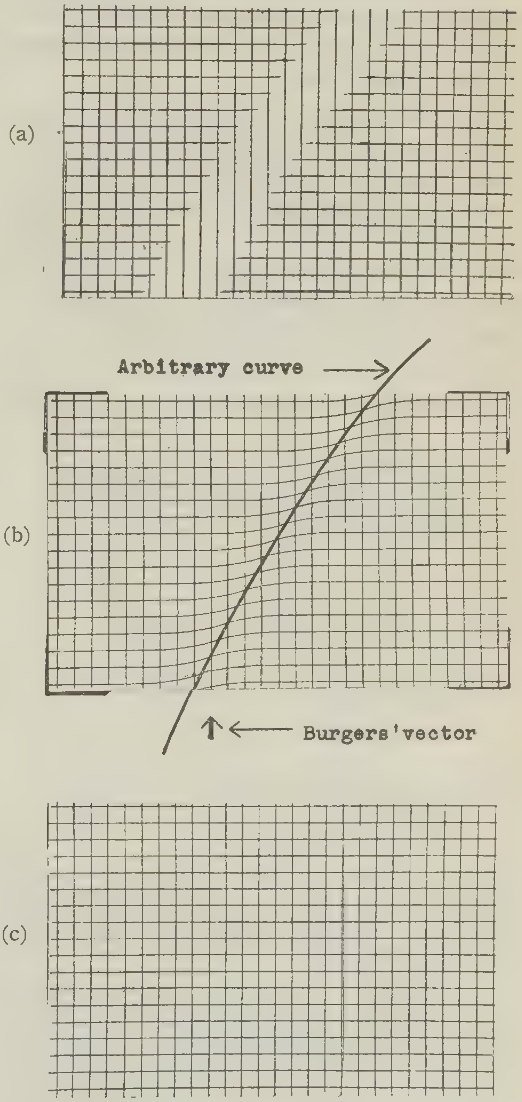

Fig. 2. Illustrating an image of dislocation superposition of (a) over (b) results in (c).

everyday life, *e.g.*, moiré patterns on window curtains, are produced by some kind of strain. Thus it has become clear that there is no discrete difference between a sharp image of dislocation and a broad moiré fringe. It may be said that a sharp image of dislocation is an extreme case of moiré fringes. In the following discussions, however, the term, moiré fringe, is used only for relatively broad bands.

In Photo. 9, the network consists of sharp images of dislocations in most part. Near the curve SS' however, the network looks like moiré pattern. This is understood according to the above discussion. It is often observed that fine networks change to moiré patterns. This change may be caused by the interaction between dislocations.

(c) *Moiré patterns and grid of dislocations*

It is known in dislocation theory that a regular grid of screw dislocations causes a rotation[8]. When, however, the strain accompanying the dislocation is concentrated, the rotation is stepwise (Fig. 3). The steps become gradual as the strain is spread and finally a uniform rotation is obtained*.

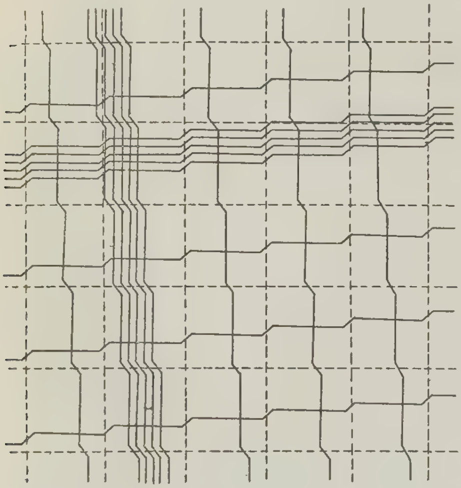

Fig. 3. Stepwise rotation caused by dislocation grid**. Lines indicate the net planes just above the dislocation grid and broken lines indicate screw dislocations.

In part A of Photo. 8 a two-dimensional moiré pattern is observed. It may be a rotation moiré and thus each fringe in part A may correspond to a screw dislocation. The fringes in part A are not perfectly periodic, and the grid is somewhat distorted. The distortion is more remarkable in other parts of Photo. 8. In part B, one set of parallel fringes in part A changes to irregular curves while the other set remains as parallel lines. The structure similar to part B is found also in Photos. 4 and 9. Parallel lines and irregular curves look very different. However, it is sure that both of them represent dislocations with Burgers vectors parallel to the cleavage plane, because in Photo. 8 both of them are extensions of screw dislocations in part A.

Photos. 12 and 13 have also the structure of parallel lines and irregular curves. In Photo. 13 parallel lines are so broad that they may better be called moiré fringes and the irregular curves indicated by BB' etc. are relatively sharp. The broad fringes and sharp curves look so different that they seem to represent different things. However, we conclude that both of them represent dislocations because the structure of parallel lines and irregular curves is similar to that in part B of Photo. 8. This conclusion is supported in the next subsection.

It is supposed that most of the observed dislocations have Burgers vectors parallel to the cleavage plane. Dislocations with Burgers vectors normal to the cleavage plane are also probable. However, they have not yet been identified. Although the mechanism of the formation of dislocations is not clear, it is highly probable that a set of dislocations such as parallel lines is produced from a source by the severe stress applied when the specimen is pealed.

(d) *Parallel lines*

According to dislocation theory, a set of parallel screw dislocations causes a shear[8]. We first considered that parallel lines observed in Photos. 4, 8, 9, and 13 are screw dislocations. Similar to the case of rotation, the shear is stepwise when parallel lines are sharp (Photo. 9) and is uniform* when they are broad (Photo. 13). In part B of Photo. 8, the spacing of parallel lines is only 200Å. This indicates a very strong shear stress. The irregular curves which intersects the parallel lines may cancel the stress more or less. It is often observed that two sets of parallel lines make a grid when the spacings become small. By the formation of a grid, the stress may be released, resulting in a rotation.

---

* It should be noted that the grid of screw dislocations corresponding to a uniform rotation is not unique. For this reason, the dislocation interpretation of rotation moiré includes some ambiguity.

** A better illustration is available in: W. T. Read: *Dislocations is Crystals* (McGraw-Hill, 1953), p. 179.

* Similar to the case of uniform rotation [footnote to subsection (c)], the set of dislocations corresponding to a uniform shear is not unique.

The spacing of the broad fringes in Photo. 13 is as large as 1,000Å. For such a large spacing no spreading of strain has been observed in pictures taken at room temperatures. Thus it is likely that the spreading is an effect of the high temperature (Sec. 3). The fringes refract on boundary XX' and the phase of fringes shifts across the irregular curves BB', CC' etc. (Photo. 13). A tentative interpretation of the refraction and the phase shift is illustrated in Fig. 4. The refraction may imply a discontinuous change of shear on the boundary. If the parallel fringes were rotation moiré, the so-called moiré dislocations[9] should have been observed instead of the refraction. The phase shift implies that the dislocation lines corresponding to the irregular curves have an edge component as predicted by Hashimoto[10]. Similar phenomenon was also observed by Izui[11] for graphite.

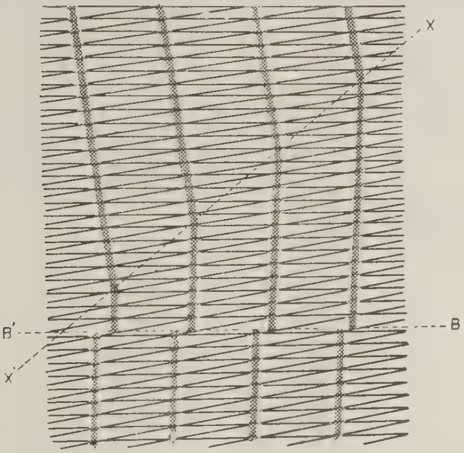

Fig. 4. Illustrating the refraction and phase shift of moiré fringes in Photo. 13.

The above discussions are based upon the assumption that the parallel lines are screw dislocations. On the other hand, Geach and Phillips[4] believed that the parallel lines observed by them are edge dislocations. The parallel fringes observed by us may also be interpreted as edge dislocations. At the present stage, it is not yet decided whether parallel lines are screw or edge. Probably, they are sometimes screw, sometimes edge and sometimes have both components.

(e) *Contrast of dislocations*

Hirsch et al.[3] developed the theory of diffraction contrast which explains images of dislocations. According to them, a Bragg reflection which is weakly excited in the surrounding of a dislocation is enhanced by the strain accompanying the dislocation. The enhancement causes the contrast in the image of dislocation. If two Bragg reflections are simultaneously excited, the image is doubled. Hirsch et al.[3] have proved that the image of a dislocation vanishes under the condition

$$(b \cdot h) = 0 , \qquad (1)$$

where b is the Burgers vector of the dislocation and h is the reciprocal lattice vector corresponding to the Bragg reflection which is weakly excited in the surrounding of the dislocation.

In part C of Photo. 8 only one set of parallel fringes is remarkable and the other set is almost invisible. Since it is certain that there is a grid of dislocations in part C, the vanishing of one set must be due to relation (1).

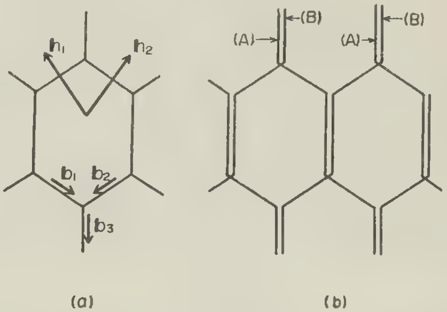

Fig. 5. Explanation of hexagonal network in Photo. 11.

The structure of the hexagonal network in Photo. 11 can also be explained by relation (1). We assume that the network is composed of screw dislocations and that two Bragg reflections h_1 and h_2 are simultaneously excited (Fig. 5a). Since neither $(h_1 \cdot b_3)$ nor $(h_2 \cdot b_3)$ vanishes, the parts of the network with Burgers vector b_3 appear as double lines. On the other hand, since $(h_1 \cdot b_2)$ vanishes but $(h_2 \cdot b_2)$ does not, the parts with Burgers vector b_2 appears as single lines. Similarly, the parts with b_1 are also single. The zigzag lines indicated by (A) are produced by reflection h_1 and those (B) by h_2 (Fig. 5b). The pattern illustrated in Fig. 5b agrees with Photo. 11. It should be noted that the specimen of Photo. 11 is so thick that the incident spot does not appear in the diffraction pattern (Sec. 3). Therefore the simple theory of diffraction contrast must be modified to explain the detail of contrast observed in Photo. 11.

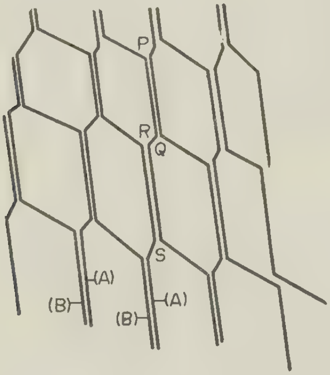

Fig. 6. Network in Photo. 10b.

In Photo. 10b a pattern as illustrated in Fig. 6 is observed. If we assume that the two sets of zigzag lines (A) and (B) in the figure are produced by reflections h_1 and h_2, respectively, we see that (A) is on the left and (B) is on the right along the segment RS, while the relation is reversed along the segment PQ. This cannot be understood if both segments have the same Burgers vector. An alternative interpretation is based upon a conjecture that a single Bragg reflection produces n-ple images according to n given by

$$(h\,b)=n\,. \tag{2}$$

Relation (1) is a special case of this relation. If we assume that the network in the figure is composed of screw dislocations and h is parallel to the segment RS, it is possible that $n=2$ for the segment parallel to RS and $n=1$ for the other segments. Anyway, no conclusion has yet been obtained.

In Photo. 6, hexagonal networks as illustrated in Fig. 7a are observed which are essentially the same as that in Fig. 6. In this case, however, the film is thin and distortion of extinction contours is remarkable. Thus it is probable that a part of the hexagonal network is caused by extinction contours as illustrated in Fig. 7b. A similar tendency is also observed in Photo. 3.

Photo. 12, which was taken at a high temperture, shows lines which are doubled in some parts. This may be interpreted similar to Photo. 7. In Photo. 7, however, images of dislocations are sharply distinguished from extinction contours, while in Photo. 12 they cannot be distinguished. This complicacy may be caused not only by the deformation of the film but also by the spreading of strains accompanying dislocations. In general, images of dislocations, moiré fringes and extinction contours are not sharply distinguished from each other.

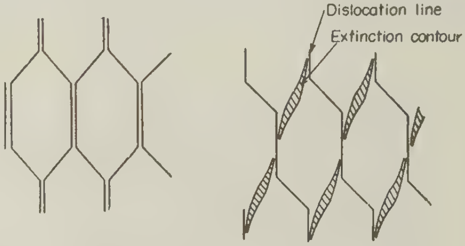

Fig. 7. Schematic illustration of hexagonal network in Photo. 6.

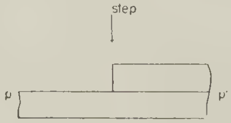

Fig. 8. Surface step.

(f) *Surface steps*

Curves indicated by SS' in Photos. 8 and 9 may be surface steps or grain boundaries. Taking into acccount that molybdenite has a layer structure, surface steps are more probable. In Photo. 8, for example, the upper part is assumed to be thinner than the lower part. Many dislocations in the thicker part stop at the step. This is understood by assuming that the dislocations lie on the plane PP' in Fig. 8. It is also observed in Photos. 8 and 9 that a few dislocations in the thinner part also stop at the steps. This is not yet interpreted.

In Photo. 10a we see a boundary line indicated by S at the top. The line resembles surface step SS' in Photo. 9. However, at the center of the circle (Photo. 10a), the feature of the line changes suddenly and near the left side of the picture the continuation of the line looks like a usual dislocation line rather than a step. It may be possible to interpret that the step running from S terminates at the center of the circle, indicating that there is a bundle of screw dislocations normal to the film at the center. Similar situation is often observed in other pictures and sometimes it is most difficult to distinguish surface steps from usual dislocations.

§ 5. Acknowledgement

We wish to express our sincere thanks to Dr. B. Tadano and the electron microscope group of the Hitachi Central Laboratory for taking many electron micrographs in the preliminary experiment. We also wish to thank to Dr. P. B. Hirsch, Dr. J. W. Menter and their co-workers for showing us many of their unpublished pictures and for valuable comments.

The present work was supported by the Scientific Research Grant of the Japanese Ministry of Education in 1958.

Beam-Type Masers for Radiofrequency Spectroscopy

By Koichi SHIMODA, Hiroshi TAKUMA,* and Tadao SHIMIZU

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received June 28, 1960)

Beam-type masers for radiofrequency spectroscopy of molecules are considered. The theoretical estimate of sensitivity is discussed and a table of minimum detectable beam intensity and estimate of available beam intensity for some of the low frequency transitions is given. A K-type doubling transition, $4_{31}\rightarrow 4_{32}$, of formaldehyde was observed as an emission line at 4.5769 ± 0.0023 Mc, and compared with theories. The observed saturation in focusing is probably due to the non-adiabatic change of rotational states in the focuser. The saturation broadening of the line with increasing rf field shows agreement with theory.

§ 1. Introduction

The radiofrequency molecular spectroscopy using three-level maser action was previously developed by one of the authors.[1] Although it was proved to be useful in detecting low frequency transitions of molecules, the properly spaced third level was necessary in order to perform an effective pumping.

On the other hand, the beam maser can be operated on two levels, between which the transition is allowed, if molecules in either of the two levels are selected by an appropriate method. It is well known that the beam maser spectroscopy has been developed in the microwave frequency range. Although the application of the technique to still higher or much lower frequencies seems promising, very little experimental work has been explored in these ranges.

The energy of a single photon is very small at low frequencies, but the noise figure of an amplifier is much smaller than that for microwaves. Therefore, it is probable that not a few transitions of molecules are detectable by a beam maser even in the megacycle range.

Theoretical considerations on the sensitivity and behavior of the beam-type rf maser are given in this paper. An experimental work on a K-type doubling transition of formaldehyde molecule, $4_{31}\rightarrow 4_{32}$, and the result are also described.

§ 2. Theoretical Considerations

A simplified diagram of the beam-type maser for radiofrequencies is shown in Fig. 1. The beam source and the focuser are essentially the same as those used for microwave masers. Molecules in the beam make transitions inside a parallel-plate condenser, instead of a cavity resonator in a microwave maser. A resonant circuit tuned to the transition frequency is formed with the capacitance of the parallel-plate condenser, C_x, and an external inductance, L. The resonant circuit is excited by a signal generator and the rf voltage across the electrodes is amplified, rectified and displayed on a cathode ray oscilloscope and a recorder. Low frequency Stark modulation and a narrow-band lock-in detector can be used to attain a good sensitivity.

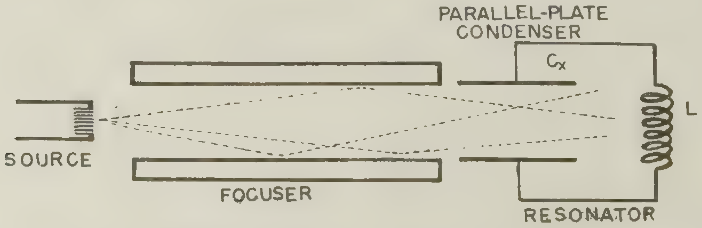

Fig. 1. Simplified diagram of the beam-type rf maser.

---

* Present address: Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo.

(i) Focusing

The Stark energy of a slightly asymmetric rotor can be expressed by

$$W_E=\pm\left[\sqrt{\left(\frac{h\nu_0}{2}\right)^2+\left\{\frac{\mu KME}{J(J+1)}\right\}^2}-\frac{h\nu_0}{2}\right] \quad (1)$$

where E is the intensity of electro-static field, ν_0 the frequency corresponding to the transition between k-type doublets. Because $\frac{\mu KME}{J(J+1)}\gg h\nu_0$ in the focusing field of an rf maser, electro-static focusing seems to be generally more effective compared to the focusing of molecules in doublet levels corresponding to microwave frequencies.

However, the behavior of the rotational state in a focusing field may not be assumed to be adiabatic, when the Stark energy is much larger than the rf photon energy $h\nu_0$ and when the time of flight of the molecules in the focuser, Δt, is not very large compared with $1/\nu_0$. Besides, a rapid change of electric field which the molecules see between the focuser and the parallel-plate condenser must stimulate transitions from focused to unfocused state.

Therefore, the focusing efficiency in the rf maser should show stronger saturation effect with increasing focuser voltage than in a microwave maser. Any further consideration of the theory of saturation character of the focuser is not given in this paper, but an experimental result will be described in the next section.

(ii) Sensitivity

Emission (or absorption) of rf power by the molecules between the parallel electrodes is detected by the increase (or decrease) of rf voltage across the electrodes. It may be expressed by the increase (or decrease) of the quality factor Q of the resonant circuit. The rf electric field between the electrodes of separation d,

$$E(\nu,t)=E\cos 2\pi\nu t=\frac{V}{d}\cos 2\pi\nu t\,,$$

is given by a loosely coupled signal generator. The power emitted form the molecules is written in the form[2)]

$$\Delta P=nh\nu_0\frac{x^2}{(\omega-\omega_0)^2+x^2}\sin^2\{(\omega-\omega_0)^2+x^2\}^{\frac{1}{2}}\frac{t}{2}\,, \quad (2)$$

where n is the number of excited molecules entering the parallel-plate condenser in a unit time, $x=E\bar{\mu}/\hbar$, $\omega_0/2\pi$ the frequency of transition, and L the lengh of the electrodes. Here $\bar{\mu}$ is the average for the component of the molecular dipole matrix element along the direction of rf field in the parallel-plate condenser.

At the center frequency of the line, $\omega=\omega_0$, the emitted power is

$$\Delta P=nh\nu_0\sin^2\frac{xL}{2v}\,, \quad (3)$$

where $v=\frac{2}{\sqrt{\pi}}\alpha=\frac{2}{\sqrt{\pi}}\sqrt{\frac{2kT}{M}}$ is the average velocity of molecules.

The change of the quality factor becomes

$$\Delta\left(\frac{1}{Q}\right)=-\frac{2\Delta P}{\omega_0 CV^2}\,,$$

where $C=C_x+C_s$, C_s being the stray capacitance.

Since the resonant circuit can be assumed to be driven by a constant current generator, the increase of rf voltage is given by

$$\Delta V=-VQ\,\Delta\left(\frac{1}{Q}\right)=\frac{2n\bar{\mu}Q}{Cd}\,\frac{\sin^2\left(\frac{xL}{2v}\right)}{x}\,. \quad (4)$$

The optimum value of rf voltage for maximum ΔV is calculated by differenciating Eq. (4).

$$x_{\rm opt}=2.33\frac{v}{L}\,, \quad (5)$$

$$V_{\rm opt}=2.33\frac{\hbar}{\bar{\mu}}\,\frac{vd}{L}\,. \quad (6)$$

The resonator noise voltage v_n is calculated from

$$\frac{v_n{}^2}{2Z}=FkT\Delta f\,, \quad (7)$$

where F is the over-all noise figure and Δf the bandwidth of the spectrometer, and $Z=\frac{Q}{C\omega}$ the impedance of the resonant circuit.

Then the emission (or absorption) of rf power is detectable, when $\Delta V>v_n$. From Eqs. (4), (5) and (7) the minimum detectable intensity of the beam flux is

$$n_{\rm min}\approx\frac{2vd}{\bar{\mu}L}\sqrt{\frac{C}{\omega_0 Q}FkT\Delta f} \quad (8)$$

in a unit time. Values of $n_{\rm min}$ for rf transitions of some molecules are calculated and shown in Table I, from the assumed values of $F=2$, $C=20$ pF, $T=300$°K, $\Delta f=1$ cps, $Q=100$, $d=0.5$ cm, and $L=10$ cm.

Now the flux of state-selected molecules from the focuser can be evaluated according to the theory by one of the authors.[3] From equation (3.9) in reference (3), the flux of focused molecules is given by

$$n \approx n_0 f \frac{4A}{\pi^2 A_0}\left(\frac{l}{R}\right)^2 \left(\frac{\bar{\mu}E}{kT}\right)^2 , \qquad (9)$$

since

$$\frac{v_0^2}{\alpha^2} \approx \frac{\bar{\mu}E}{kT} , \quad \text{and} \quad N = \frac{\sqrt{\pi}\, n_0 f}{A_0 \alpha} ,$$

where n_0 is the total flux of molecules flowing out from the source of area A_0, f the fraction of molecules in a particular rotational state, l the length of the focuser, R the radius, and E the maximum intensity of electric field in the focuser. The average of dipole matrix element of molecules entering the focuser, $\bar{\mu}$, is given by

$$\bar{\mu}^2 = \mu^2 \frac{K^2 \langle M^2 \rangle_{av}}{J^2(J+1)^2} = \frac{\mu^2 K^2}{3J(J+1)} , \qquad (10)$$

Then for a slightly asymmetric rotor, when $\bar{\mu}E \gg h\nu_0$, the flux of focused molecules can be written by

$$n \approx n_0 f \frac{4A}{3\pi^2 A_0}\left(\frac{l}{R}\right)^2 \frac{\mu^2 K^2 E^2}{J(J+1)k^2 T^2} . \qquad (11)$$

Numerical examples for some molecules are calculated and compared with $n_{\min}$ in Table I. These values have been calculated from Eqs. (8) and (11) with the following values, $n_0 = 10^{17}$ molcules/sec and, $A/A_0 = 1$, $l = 40$cm, $R = 0.5$cm, and the eight-pole focuser voltage of 10 kV corresponding to $E = 40$ kV/cm. The ratio of n to $n_{\min}$ may be considered as a theoretical estimate of signal-to-noise ratio of the line. Table I shows that many of the low frequency

Table I. Rf transistions of some slightly asymmetric molecules for beam-type masers. Transition frequencies, ν_0, are calculated by a rigid rotor approximation. Values of $n_{\min}$ and n are calculated from Eqs. (8) and (11).

rotational transitions of molecules are detectable.

(iii) Line-width

The line-width of the spectrum is determined by the time of flight of the molecules in the parallel-plate condenser. The half-width is[2),4)]

$$2\Delta\nu_0=0.9\,\frac{v}{L}\,,$$

when the amplitude of rf field is sufficiently small.

The saturation broadening of the line can be calculated by taking average of Eq. (2) multiplied by a weight factor, $\bar{e}^{t/\tau}$. The saturation broadened line-width is

$$2\Delta\nu_{\text{sat}}=2\sqrt{(\Delta\nu_0)^2+\left(\frac{x}{2\pi}\right)^2}\,. \qquad (12)$$

For a given rotational transition, there are $2J+1$ different components corresponding to different values of M. The component with larger value of M shows stronger saturation than the component with smaller value of M. It should be noted that the space quantization in the rf field is independent of the space quantization in the focusing field, although the same notation M is used in either field.

§ 3. Experimental Results

A radiofrequency spectral line of formaldehyde, corresponding to the transition between K-type doublets, $4_{31}\rightarrow4_{32}$, was investigated by a beam-type maser. A block diagram of the spectrometer is shown in Fig. 2. The rf electrodes of three parallel plates are 12 cm long with the spacings of 0.4 cm. They are held in a shield box by two sheets of polystyrene at their edges. The state-selected molecular beam enters the rf field through a hole in one side of the shield box.

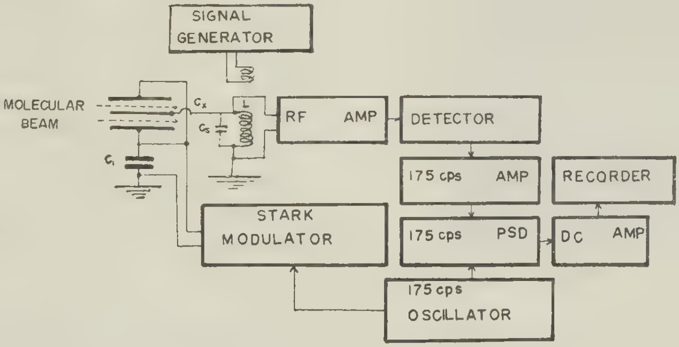

Fig. 2. Block diagram of the maser spectrometer.

A square wave modulation voltage is applied to the outer two electrodes with variable dc bias. The rf by-pass capacitor C_1 is 0.1 μF, C_x=8pF, $C=C_x+C_s=25$ pF. The Q value of the LC resonator is about 70. A signal generator which feeds the rf signal is swept by a small synchronous motor.

The noise figure of the spectrometer was measured to be 3, including the noise of the rf signal generator and of the 175 cps oscillator. The time constant of the dc amplifier used in the following work was $\tau=2.5$ seconds, so that the effective bandwidth Δf is

$$\Delta f=2\times\frac{1}{4\tau}=0.2\,\text{cps}\,,$$

including the 175 cps image noise.

The molecules of formaldehyde were produced by heating powdered paraformaldehyde. A dry ice trap was used in order to remove impurities and polymers of H_2CO. The beam source and the eight-pole focuser are the same ones as used for microwave works.[5)6)] The intensity of the beam flux was estimated to be $10^{17}\sim10^{18}$ molecules per second.

A typical trace of record of the observed spectrum with a focuser voltage of 15 kV and an rf voltage of 3 mV peak is shown in Fig. 3 The observed center frequency is

$$\nu_0=4.5769\pm0.0023\ \text{Mc}\,,$$

where the error is 3 times the standard deviation.

The observed signal-to-noise ratio of the line in Fig. 3 is nearly 40, while the theoretical estimate from Eqs. (8) and (11) gives a value of 1200 for a total beam flux $n_0=5\times10^{17}$ molecules/sec, $V=10$ kV, $v=4.6\times10^4$ cm/sec, $\bar{\mu}=$

0.907 D, ($\mu=2.34$ D), and $L=12$ cm. The difference may be due to the divergence of the beam within the parallel-plate condenser, and to the non-adiabatic behavior of molecules in the focuser region as described before.

The intensity of the emission line was observed as a function of focuser voltage, and the result is plotted in Fig. 4. According to the theoretical estimate given by Eq. (9), the number of focused molecules is proportional to the square of focuser voltage. But Fig. 4 shows strong saturation and confirms violation of adiabatic assumption in the focusing field, as described in § 2 (i). At a focuser voltage of 1 kV for example, the observed signal-to-noise ratio is about 4, while the calculated value of $n/n_{\min}$ is 12, and the discrepancy is smaller.

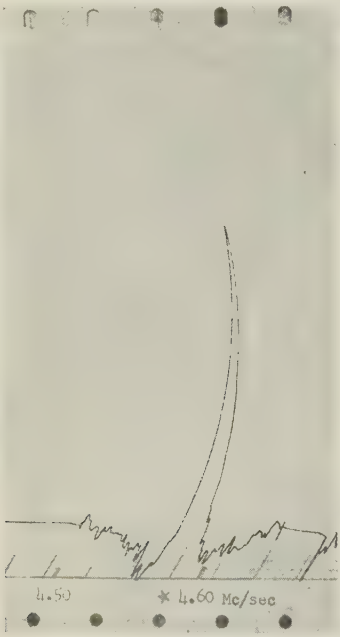

Fig. 3. Typical trace of the $4_{31}\rightarrow 4_{32}$ transition of H_2CO.

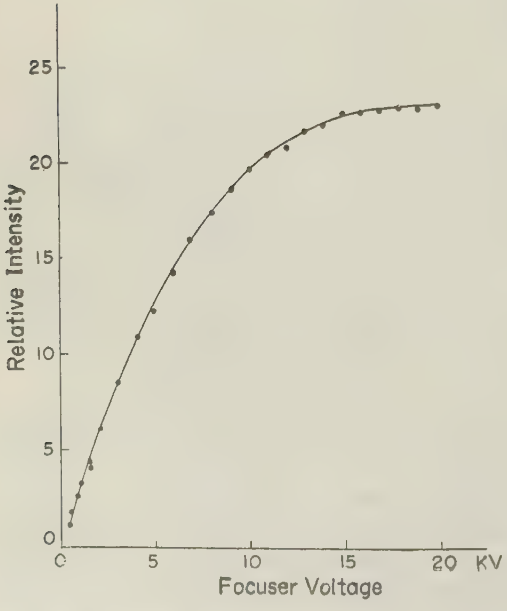

Fig. 4. Observed saturation in focusing.

The half-width of the line was measured as a function of rf valtage on the parallel plate condenser as shown in Fig. 5. A theoretical curve of Eq. (12) for the average value of dipole moment $\bar{\mu}$ is also shown. Agreement between theory and experiment seems good.

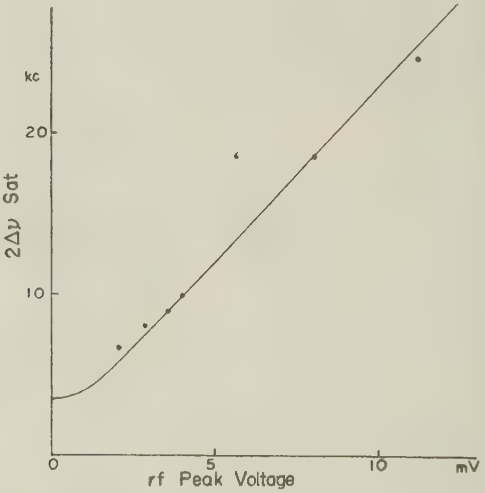

Fig. 5. Half-width of the line as a function of rf voltage.

It may be noted that the Stark shift of an rf transition in a dc field is larger than the shift of a microwave transition in general. Thus the broadening by inhomogeneous dc field becomes large in the rf maser. Even a surface potential difference of the electrodes of the order of some ten millivolts is large enough to somewhat broaden the line. For example, a dc field of 100 mV/cm produces a Stark shift of 2.1 kc for the $M=4$ component in the $4_{31}\rightarrow 4_{32}$ transition of H_2CO.

§ 4. Discussions

The centrifugal distortion of formaldehyde molecule was discussed by Lawrance and Strandberg,[7] and recently by Oka.[8] The calcuated frequencies of the $4_{31}\rightarrow 4_{32}$ transition by these two methods are 4.572 Mc and 4.575 Mc, respectively. They differ from each other, and the value from Oka's theory agrees well with our experimental result. Oka has solved the secular equation based on the Hamiltonian by Kivelson and Wilson.[9] Thus it seems natural that his theory gives more correct value than the semi-empirical calculation according to Lawrance and Strandberg.

According to the theory of the magnetic hyperfine structure of formaldehyde,[6] the $4_{31} \to 4_{32}$ line consists of three strong $\Delta F=0$ transitions and four weak $\Delta F=\pm 1$ transitions. Because the splitting between $\Delta F=0$ components are calculated to be several cycles per second, it is reasonable that the line is observed as a singlet. The $\Delta F=\pm 1$ components are very weak and could not be observed in the present experiment. However, by improving the sensitivity the $\Delta F=\pm 1$ transitions would be observed since the separation is expected to be of the order of 10 kc.

The Stark and Zeeman effects of the rf transition can also be studied by the high resolution beam maser spectrometer. The Stark voltage can be applied to the parallel-plate condenser. The measurement of the Stark pattern of the $4_{31} \to 4_{32}$ line of H_2CO is now in progress.

On the Paramagnetic Susceptibility of Sm^{3+} ion

By Norikiyo URYU
Department of Physics, Faculty of Science, Kyusyu University, Fukuoka, Japan

(Received July 25, 1960)

Synopsis:

The paramagnetic susceptibility of Sm^{3+} ion measured by Borovik-Romanov and Kreines are explained on the basis of crystalline field theory. Postulatiug an appropriate cubic or trigonal potential for two modifications of Sm_2O_3, the magnetic behaviours are well explained with the best choice of the coefficients of each potential. Total separations of the ground manifold $216k$ and $432k$ are obtained for the two cases and are compared with the above author's rough estimations 52 cm^{-1} and 150 cm^{-1}. Further, their erroneous assignment for the lowest state is pointed out.

§1. Introduction

The paramagnetism of the rare earth salts has been investigated in detail both theoretically and experimentally. The $4f$ electrons which contribute to the magnetism are sufficiently screened by outer electrons and the magnetic behaviours, for instance, the effective Bohr magneton number, are well explained as that of free ion. In Sm^{3+} or Eu^{3+}, the excited energy levels which are split by L–S coupling are near the ground level, and the contribution of the high frequency part pointed out by Van Vleck[1] is large. Taking this into account, the paramagnetic susceptibilities of rare earth ion can be explained satisfactorily.

For the ions in crystals, the effects of the crystalline field are not so large and the intra-ionic L–S coupling is the predominant perturbation for the free ion. Accordingly, as the stationary state, we have the Russel-Saunders coupling in which $2S+1$ or $2L+1$ energy levels of different J values are split by above perturbation. The crystalline field affects the energy states of each J values and removes the $2J+1$ degeneracy partially or wholly except for the Kramers doublets. The studies of the rare earth salts which take into account the effect of the crystalline field are that of Pr^{3+} and Nd^{3+} by Penney and Schlapp[2], and that of $Sm_2(SO_4)_3 7H_2O$ crystal by Miss Frank[3]. Her study ranged over the temperature 70°K∼300°K, and she concluded unimportance of the crystalline field for the susceptibility.

Recently, Borovik-Romanov and Kreines[4] investigated the paramagnetic susceptibilities of Eu^{3+} and Sm^{3+} ions over the temperature range of 12°K∼300°K and found that the magnetic properties of Sm^{3+} depend on its crystal structure. The samples investigated are the microcrystalline powder of Sm_2O_3 (Sample I of purity lower than 99.0% and Sample II of purity 99.99%) and $Sm_2(C_2O_4)_3$ $10H_2O$. Ordinary Sm_2O_3 has cubic structure (b. c. c.) and Sample II does not change its crystal structure by heating, whereas Sample I takes an essentially different structure of pseudotrigonal by heating over 720°C. Consequently, as to Sample I, the susceptibility curves for heated and unheated one separate into two, whereas that for Sample II agrees with either one of Sample I in both cases. The results of $Sm_2(C_2O_4)_3$ $10H_2O$ agrees well with Van Vleck's theoretical curve.

In order to explain these result, Borovik-Romanov and Kreines have made a simple estimation of the energy states of the ion in a crystalline field. They take the expression of the susceptibility as follows:

$$\chi=\frac{Ng^2\mu_B{}^2}{kT}\,\frac{M^2{}_{1eff}+M^2{}_{2eff}\exp\{-\varDelta W_1/kT\}+M^2{}_{3eff}\exp\{-\varDelta W_2/kT\}}{1+\exp\{-\varDelta W_1/kT\}+\exp\{-\varDelta W_2/kT\}}+N\alpha,$$

where $\varDelta W_1$, $\varDelta W_2$ are the energy differences between two upper levels and the lowest level which are split from the ground state of six-fold degeneracy, and are of $J_z=\pm 1/2$, $\pm 3/2$, $\pm 5/2$ respectively. They assume that these three doublet states are eigenstates in the presence of crystalline field and take $M_1=\pm 1/2$, $M_2=\pm 3/2$ and $M_3=\pm 5/2$. $N\alpha$ is the high frequency part. Treating $\varDelta W_1$ and $\varDelta W_2$ as the parameter, they determined their values of the best fit for the susceptibility curves, and the values thus determined are $\varDelta W_1=0$, $\varDelta W_2=52\,\mathrm{cm}^{-1}$ (73°K) in the case of cubic modification and $\varDelta W_1=20\,\mathrm{cm}^{-1}$ (29°K), $\varDelta W_2=150\,\mathrm{cm}^{-1}$ (218°K) in the case of pseudotrigonal modification. In fact, they have shown the curves of good agreement with experiments by using these values. However, the eigenstates of ${}^6H_{5/2}$ in cubic or trigonal field are not of $J_z=\pm 1/2$, $\pm 3/2$, $\pm 5/2$ but are their linear combinations, because non-diagonal matrix elements are present. Accordingly, the ground of their arguments to deduce the values of $\varDelta W_1$, $\varDelta W_2$ is meaningless.

Our present purpose is to investigate the energy level splittings by using an appropriate cubic or trigonal potential, and estimate the values of its coefficient in order to explain their experimental results. In this case, the contribution from the excited states can be considered only as the constant susceptibility and may be neglected for the temperature dependent part. Thus we shall consider the effect of crystalline field only in the manifold of $J=5/2$, or of $J=7/2$ if necessary.

§2. Crystalline Potential

We can expand the potential in spherical harmonics by assuming that it satisfies Laplace's equation, thus

$$V=\sum_{n,\,m}A_n{}^m r^n Y_n{}^m(\theta,\,\varphi). \tag{2.1}$$

For our present purpose, the number of terms in (2.1) can be considerably reduced as follows. In evaluating an integral such as $\int\chi^* V\psi d\tau$ where χ and ψ denote f-electron wave function, all terms for which $n>6$ will have zero matrix elements by the orthogonality relations for spherical harmonics and can be omitted. Similarly all terms for which n is odd have zero element because the product

$\chi^*\psi$ is unchanged by the substitution $x, y, z \rightarrow -x, -y, -z$ whereas V reverses its sign. Accordingly, as fas as we consider the f-electron, V takes the form

$$V = \sum_{m=-2}^{2} A_2^m r^2 Y_2^m(\theta, \varphi) + \sum_{m=-4}^{4} A_4^m r^4 Y_4^m(\theta, \varphi)$$
$$+ \sum_{m=-6}^{6} A_6^m r^6 Y_6^m(\theta, \varphi)\ , \tag{2.2}$$

and, being real, $A_2^m = A_2^{-m}$, $A_4^m = A_4^{-m}$ and $A_6^m = A_6^{-m}$.

Now, if we consider the case of cubic potential, the form which V takes is one for a regular octahedron of the six nearest neighbours and we have

$$V_c = A_4^0 r^4 \Big[Y_4^0(\theta, \varphi) + \sqrt{\frac{5}{14}}$$
$$\Big\{ Y_4^4\ \theta, \varphi) + Y_4^{-4}(\theta, \varphi) \Big\} \Big], \tag{2.3}$$

or by changing to Cartesian coordinates

$$V_c = D\left(x^4 + y^4 + z^4 - \frac{3}{5} r^4 \right), \tag{2.3a}$$

where $D = 15\ A_4^0/4\sqrt{\pi}$.

As for the trigonal potential, its three-fold symmetry axis can be considered as (1 1 1) direction of the regular octahedron, and we suppose that the dominant part of the trigonal potential is given as

$$V' = Fr^4 \Big[Y_4^0(\theta, \varphi) - \sqrt{\frac{10}{7}}$$
$$\Big\{ Y_4^3(\theta, \varphi) + Y_4^{-3}(\theta, \varphi) \Big\} \Big], \tag{2.4}$$

which is obtained by the coordinate transformation of (2.3). The general form of V, showing a distortion along (1 1 1) direction is, thus,

$$V_t = A_2^0 r^2 Y_2^0(\theta, \varphi) + A_4^0 r^4 Y_4^0(\theta, \varphi) + V'$$
$$+ \sum_{m=-6}^{6} A_6^m r^6 Y_6^m(\theta, \varphi). \tag{2.5}$$

Now, in the calculation of the matrix elements of these crystalline potentials it is convenient to use the method of operator equivalence by Stevens[5)], according to which we have the following relations

$$\sum A_2^0 r^2 Y_2^0(\theta, \varphi) = \sum B_2^0 (3z^2 - r^2) \equiv B_2^0 \overline{r^2} \alpha \{3J_z^2 - J(J+1)\}$$

$$\sum A_4^0 r^4 Y_4^0(\theta, \varphi) = \sum B_4^0 (35z^4 - 30r^2z^2 + 3r^4)$$
$$\equiv B_4^0 \overline{r^4} \beta \{35J_z^4 - 30J(J+1)J_z^2 + 25J_z^2 - 6J(J+1) + 3J^2(J+1)^2\},$$

$$\sum r^4 \equiv \beta \overline{r^4} \left\{ \{J^2(J+1)^2 - \frac{1}{3} J(J+1) \right\},$$

$$\sum \left(x^4 + y^4 + z^4 - \frac{3}{5} r^4 \right) \equiv \frac{\beta}{20} \overline{r^4} \{35J_z^4 - 30J(J+1)J_z^2 + 25J_z^2 - 6J(J+1)$$
$$+ 3J^2(J+1)^2\} + \frac{\beta}{8} r^4 (J_+^4 + J_-^4),$$

$$\sum A_6^0 r_6 Y_6^0(\theta, \varphi) = \sum B_6^0 (231z^6 - 315r^2z^4 + 105r^4z^2 - 5r^6)$$
$$\equiv B_6^0 \gamma \overline{r^6} [231J_z^6 - 315J(J+1)J_z^4 + 735J_z^4 + 105J^2(J+1)^2J_z^2$$
$$- 525J(J+1)J_z^2 + 294J_z^2 - 5J^3(J+1)^3 + 40J^2(J+1)^2 - 60J(J+1)], \tag{2.6}$$

where the constants α, β and γ are given with regard to the ground manifold ($4f^5\ {}^6H_{5/2}$) by

$$\alpha = \frac{13}{7.45}\ , \qquad \beta = \frac{26}{33.7.\ 45}\ , \quad \gamma = 0. \tag{2.7}$$

For the first excited state ($J = 7/2$),

$$\beta' = -\frac{26}{45.33.\ 7} \frac{8}{99} \tag{2.8}$$

is to be used instead of β. From the relation of (2.7), the last term of (2.5), i. e., the term for $n = 6$ can be neglected as far as the ground state is concerned. The expression of V' in terms of Cartesian coordinates is

$$V'=\frac{3}{16\sqrt{\pi}}F\{35z^4-30r^2z^2+3r^4+60\sqrt{2}\,xz(r^2-z^2)-80\sqrt{2}\,x^3z\}, \tag{2.9}$$

and its equivalent operator is given by

$$\begin{aligned}F'\beta\overline{r^4}[35J_z^4-30J(J+1)J_z^2+25J_z^2-6J(J+1)\\ +3J^2(J+1)^2-5\sqrt{2}\{J_z(J_+^3+J_-^3)+(J_+^3+J_-^3)J_z\}],\end{aligned} \tag{2.10}$$

where the relation $D=-30F'$ holds.

Below, we shall calculate the susceptibility treating the coefficients $D\overline{r^4}$, $B_2^0r^2$, $B_4^0r^4$ and $F'r^4$ as parameters and estimate the values of the best fit with experimental results. The cubic modification causes no trouble, as in this case only one parameter is involved. However, the case of trigonal modification has three unknown parameters and the problem becomes complicated. Now, in view of the susceptibility curves of Sample I and II, the magnitudes of the crystalline potential in each cubic structure can be inferred to be nearly the same. But, as to the change of the crystalline field when Sample I transforms into trigonal phase, nothing is revealed. As stated before, the dominant part of trigonal potential is V' which is obtained by transforming (2.3a) into the direction of (1 1 1), together with the additional field of axial symmetry due to distortion along this direction. But for the essential change, we could expect the relation $D=-30F'$ between the coefficients of crystalline field in the two phases, and it might be possible to diminish the number of parameters in this way. However, there is no definite reason for doing this. We shall take into account only the term of the second degree as the part of axial symmetry and neglect the term of the fourth degree for the time being, and estimate the coefficients of crystalline potential assuming $F\gg B_2^0$.

§ 3. The Energy Eigenvalues and the Susceptibility

The normal state of Sm^{3+} is $^6H_{5/2}$, and from the recent spectroscopic estimation we have the separation 1100 cm^{-1} (1540k) between the states of $J=5/2$ and $J=7/2$ which is caused by the L-S coupling. This almost agrees with the theoretical estimation 1070 cm^{-1} by Van Vleck with the use of shielding constant σ of 33. For our present purpose to calculate the susceptibility below 100°K, the excited states contribute only as the so-called high frequency part. Thus, for the time being, we have only to consider the crystalline field splitting in the manifold of $J=5/2$.

If we take as the perturbation the cubic potential (2.3a) or pseudotrigonal potential (2.5), the secular determinant of sixth degree for the ground state decomposes into three secular determinants of second degree. The necessary matrix elements are given as follows:

$$\begin{aligned}&<J, M|J_+^4+J_-^4|J, M-4>=<J, M-4|J_+^4+J_-^4|J, M>\\ &\quad=\{(J+M)!(J-M+4)!/(J+M-4)!(J-M)!\}^{1/2},\\ &<J, M|J_zJ_+^3|J, M-3>=\frac{M}{M-3}<J, M|J_+^3J_z|J, M-3>\\ &\quad=[(J-M+3)!(J+M)!/(J-M)!(J+M-3)!]^{1/2}M,\\ &<J, M|J_zJ_-^3|J, M+3>=\frac{M}{M+3}<J, M|J_-^3J_z|J, M+3>\\ &\quad=[(J-M)!(J+M+3)!/(J-M-3)!(J+M)!]^{1/2}M.\end{aligned} \tag{3.1}$$

Below, for convenience' sake, we shall consider the cubic or trigonal case separately.

I) The case of cubic modification.

The secular equation in this case can be decomposed into two as follows:

$$\begin{array}{l|cc|l} <\mp\frac{5}{2}| & 3a-W & 3\sqrt{5}\,a & =0 \\ <\pm\frac{3}{2}| & 3\sqrt{5}\,a & -9a-W & , \\ \end{array} \tag{3.2}$$

$$\begin{array}{l|cc|l} <-\frac{1}{2}| & 6a-W & 0 & =0 \\ <+\frac{1}{2}| & 0 & 6a-W & , \\ \end{array}$$

where $a=\beta D\overline{r^4}$. The energy eigenvalues are $W=6a$, $-12a$ and the eigenfunctions corresponding to them are given respectively as

$$\left.\begin{aligned} \psi &=\sqrt{\frac{5}{6}}\left|-\frac{5}{2}\right>+\frac{1}{\sqrt{6}}\left|\frac{3}{2}\right>, \\ \varphi &=\sqrt{\frac{5}{6}}\left|\frac{5}{2}\right>+\frac{1}{\sqrt{6}}\left|-\frac{3}{2}\right>, \\ \phi &=\left|\frac{1}{2}\right>, \qquad \phi'=\left|-\frac{1}{2}\right>, \end{aligned}\right\}\ (W=6a)$$

$$\left.\begin{aligned} \psi' &=\frac{1}{\sqrt{6}}\left|-\frac{5}{2}\right>-\sqrt{\frac{5}{6}}\left|\frac{3}{2}\right> \\ \varphi' &=\frac{1}{\sqrt{6}}\left|\frac{5}{2}\right>-\sqrt{\frac{5}{6}}\left|-\frac{3}{2}\right> \end{aligned}\right\}\ (W=-12a) \tag{3.3}$$

Now, the susceptibility can be calculated by the use of well known formula

$$\begin{aligned} \chi &=\frac{B}{kT}\sum_{jmj'm'}|\mu_B(jm;\,j'm')|^2\,e^{-W^0{}_{nj}/kT} \\ &\quad+2B\sum_{jmn'j'm'(n\neq n)}\frac{|p_B{}^0(njm;\,n'j'm'|^2}{h\nu(n';\,n)}\,e^{-W^0{}_{nj}/kT}, \\ B&=N\sum_{jm}e^{-W^0{}_{njm}/kT} \end{aligned} \tag{3.4}$$

In the present case, we have $\mu_B=g\mu_B J_z$ and $g=2/7$. The second term contains the temperature-independent part which comes from the lowest manifold and the excited state of $J=7/2$. $p^0{}_B$ equals μ_B as regards the lowest manifold. If we abbreviate the part of the second term which comes from the excited state as $N\alpha_J$, we have

$$\begin{aligned} \alpha_J&=\frac{\mu_B{}^2}{6(2J+1)}\left[\frac{F(J+1)}{h\nu(J+1;\,J)}-\frac{F(J)}{h\nu(J\colon J-1)}\right], \\ F(J)&=\frac{1}{J}\,[(S+L+1)^2-J^2]\,[J^2-(S-L)^2]. \end{aligned} \tag{3.5}$$

Thus the result is given as follows:

$$\begin{aligned} \chi_0=\frac{Ng^2\mu_B{}^2}{a}&\left[\frac{40}{81}-\frac{40}{81e}{}^{-18a/kT}+\frac{2a}{kT}\left\{\left(\frac{5}{6}\right)^2+\left(\left(\frac{1}{2}\right)^2+\left(\frac{11}{6}\right)^2\right)e^{-18a/kT}\right\}\right] \\ &+2\{1+2\,e^{-18a/kT}\}+N\alpha_J. \end{aligned} \tag{3.6}$$

$N\alpha_J$ may be replaced by (3.22). See below.

II) The case of trigonal modification.

As stated at the end of the previous section, we shall take the crystalline potential as

$$\begin{aligned} V_t=B_2{}^0\overline{r^2}\alpha\{3J_z{}^2-J(J+1)\}+F'\beta\overline{r^4}[35J_z{}^4-30J(J+1)J_z{}^2 \\ +25J_z{}^2-6J(J+1)+3J^2(J+1)^2-5\sqrt{2}\{J_z(J_+{}^3+J_-{}^3)+(J_+{}^3+J_-{}^3)J_z\}]. \end{aligned} \tag{3.7}$$

If we neglect the term of B_2^0, we have the splitting into two energy levels of four-fold and two fold degeneracy as in the case of cubic potential. However, the secular determinant inclusive of the term B_2^0 is decomposed as

$$\begin{array}{l} \langle -\frac{5}{2}| \\ \langle +\frac{1}{2}| \end{array} \begin{vmatrix} b+5c-W & \sqrt{20}\,b \\ \sqrt{20}\,b & 2b-4c-W \end{vmatrix} =0$$

$$\begin{array}{l} \langle +\frac{5}{2}| \\ \langle -\frac{1}{2}| \end{array} \begin{vmatrix} b+5c-W & -\sqrt{20}\,b \\ -\sqrt{20}\,b & 2b-4c-W \end{vmatrix} =0 \tag{3.8}$$

$$\begin{array}{l} \langle +\frac{3}{2}| \\ \langle -\frac{3}{2}| \end{array} \begin{vmatrix} -3b-c-W & 0 \\ 0 & -3b-c-W \end{vmatrix} =0$$

where $60F'\beta\overline{r^4}=b$, $2B_2^0\alpha\overline{r^2}=c$.

In the approximation of $b \gg c$, we obtain the energy eigenvalues $W_1=b(6+20/9\,\varepsilon^2)$, $W_2=-b(3-\varepsilon+20/9\,\varepsilon^2)$, $W_3=-b(3+\varepsilon)$ by neglecting the higher term than ε^3, and the eigenfunction belonging to them are given by

$$\left.\begin{aligned} \psi_1 &=\alpha_1\left|-\frac{5}{2}\right> +\beta_1\left|\frac{1}{2}\right> \\ \varphi_1 &=\gamma_1\left|\frac{5}{2}\right> +\delta_1\left|-\frac{1}{2}\right> \end{aligned}\right\} \quad (W=W_1)$$

$$\left.\begin{aligned} \psi_1' &=\alpha_2\left|-\frac{5}{2}\right> +\beta_2\left|\frac{1}{2}\right> \\ \varphi_1' &=\gamma_2\left|\frac{5}{2}\right> +\delta_2\left|-\frac{1}{2}\right> \end{aligned}\right\} \quad (W=W_2)$$

$$\phi_1=\left|\frac{3}{2}\right>, \quad \phi_1'=\left|-\frac{3}{2}\right>, \qquad (W=W_3) \tag{3.9}$$

where $\varepsilon=c/b \ll 1$, and each coefficients of (3.9) are obtained as

$$\begin{aligned} \alpha_1 &=\gamma_1=\frac{2}{3}\left(1+\frac{5}{9}\varepsilon-\frac{5}{81}\varepsilon^2\right), \\ \beta_1 &=-\delta_1=\frac{\sqrt{5}}{3}\left(1-\frac{4}{9}\varepsilon-\frac{14}{81}\varepsilon^2\right), \\ \alpha_2 &=\gamma_2=\frac{\sqrt{5}}{3}\left(1-\frac{4}{9}\varepsilon-\frac{14}{81}\varepsilon^2\right), \\ \beta_2 &=-\delta_2=-\frac{2}{3}\left(1+\frac{5}{9}\varepsilon-\frac{5}{81}\varepsilon^2\right). \end{aligned} \tag{3.10}$$

Following (3.4), we consider the contribution from the lowest manifold. As the measurements are made on the microcrystalline powder, it is necessary to compare the experimental result with the mean value of the susceptibilities along x, y, z directions unlike the cubic case. Let us first calculate the low frequency part of the parallel and the perpendicular susceptibilities.

a) Parallel susceptibility

Taking up to ε^2, the necessary matrix elements in (3.4) are given by

$$
\begin{aligned}
|(\psi_1|J_z|\psi_1)|^2 = |(\varphi_1|J_z|\varphi_1)|^2 &= \frac{25}{36}+\frac{200}{81}\varepsilon+\frac{1900}{27^2}\varepsilon^2,\\
|(\psi_1'|J_z|\psi_1')|^2 &= \frac{49}{36}-\frac{280}{81}\varepsilon+\frac{1180}{27^2}\varepsilon^2,\\
|(\varphi_1|J_z|\varphi_1')|^2 = (\psi_1|J_z|\psi_1')|^2 &= \frac{20}{9}+\frac{40}{81}\varepsilon-\frac{1540}{27^2}\varepsilon^2.
\end{aligned}
\tag{3.11}
$$

Then denoting as $W_2-W_1=\Delta E$, $W_3-W_1=\Delta E'$, we have

$$
\begin{aligned}
\chi_{t//} = \frac{2Bg^2\mu_B^2}{kT}&\left\{\left(\frac{25}{36}+\frac{200}{81}\varepsilon+\frac{1900}{27^2}\varepsilon^2\right)+\frac{9}{4}e^{-\Delta E'/kT}\right.\\
&\left.+\left(\frac{49}{36}-\frac{280}{81}\varepsilon+\frac{1180}{27^2}\varepsilon^2\right)e^{-\Delta E/kT}\right\}\\
&+4Bg^2\mu_B^2\,\frac{\dfrac{20}{9}+\dfrac{40}{81}\varepsilon-\dfrac{1540}{27^2}\varepsilon^2}{\Delta E}\{1-e^{-\Delta E/kT}\}.
\end{aligned}
\tag{3.12}
$$

b) Perpendicular susceptibility

Putting $\mu_x=g\mu_BJ_x$ and $J_x=(J_++J_-)/2$ in this case, we can obtain the non vanishing matrix elements which appear in (3.4). Then in the following formula

$$
\begin{aligned}
\chi_{t\perp} = {}&\frac{2Bg^2\mu_B^2}{kT}\{|(\psi_1|J_x|\varphi_1)|^2+|(\psi_1'|J_x|\varphi_1')|^2\,e^{-\Delta E/kT}\}\\
&+2Bg^2\mu_B^2\Big[\{|(\psi_1|J_x|\phi_1)|^2+|(\psi_1|J_x|\phi_1')|^2+|(\varphi_1|J_x|\phi_1)|^2\\
&+|(\varphi_1|J_x|\phi_1')|^2\}/\Delta E'+\{|(\psi_1|J_x|\varphi_1')|^2+|(\varphi_1|J_x|\psi_1')|^2\}/\Delta E\\
&+\left\{\frac{|(\psi_1|J_x|\phi_1)|^2+|(\psi_1|J_x|\phi_1')|^2+|(\varphi_1|J_x|\phi_1)|^2+|(\varphi_1|J_x|\phi_1')|^2}{-\Delta E'}\right.\\
&\left.+\frac{|(\phi_1|J_x|\varphi_1')|^2+|(\phi_1|J_x|\psi_1')|^2+|(\phi_1'|J_x|\varphi_1')|^2+|(\phi_1'|J_x|\psi_1')|^2}{\Delta E-\Delta E'}\right\}\\
&\times e^{-\Delta E/kT}-\left\{\frac{|(\psi_1|J_x|\varphi_1')|^2+|(\varphi_1|J_x|\psi_1')|^2}{\Delta E}\right.\\
&\left.+\frac{(\phi_1|J_x|\varphi_1')|^2+|(\phi_1|J_x|\psi_1')|^2+|(\phi_1'|J_x|\varphi_1')|^2+|(\phi_1'|J_x|\psi_1')|^2}{\Delta E-\Delta E'}\right\}e^{-\Delta E/kT}\Big],
\end{aligned}
\tag{3.13}
$$

each matrix element are obtained up to the term of ε^2 and after tedious calculation, we finally have

$$
\begin{aligned}
\chi_{t\perp} = {}&\frac{g^2\mu_B^2}{kT}B\left\{\frac{25}{18}\left(1-\frac{16}{9}\varepsilon+\frac{40}{81}\varepsilon^2\right)+\frac{8}{9}\left(1+\frac{20}{9}\varepsilon+\frac{130}{81}\varepsilon^2\right)e^{-\Delta E/kT}\right\}\\
&+2g^2\mu_B^2B\Big[-\frac{10}{27}\frac{1}{b}\left(1-\frac{1}{3}\varepsilon-\frac{20}{81}\varepsilon^2\right)-\frac{10}{81}\cdot\frac{1}{b}\left(1+\frac{1}{3}\varepsilon-\frac{114}{81}\varepsilon^2\right)\\
&+\left\{\frac{10}{27}\frac{1}{b}\left(1-\frac{1}{3}\varepsilon-\frac{20}{81}\varepsilon^2\right)+\frac{19}{12}\frac{1}{b\varepsilon}\left(1+\frac{230}{171}\varepsilon+\frac{2480}{19.9^2}\varepsilon^2\right)\right\}e^{-\Delta E/kT}\\
&+\left\{\frac{10}{81}\frac{1}{b}\left(1+\frac{1}{3}\varepsilon-\frac{114}{81}\varepsilon^2\right)-\frac{19}{12}\frac{1}{b\varepsilon}\left(1+\frac{230}{171}\varepsilon+\frac{2480}{19.9^2}\varepsilon^2\right)\right\}e^{-\Delta E/kT}\Big].
\end{aligned}
\tag{3.14}
$$

c) High frequency part.

As in the temperature-dependent part, the temperature-independent part may have different contributions to parallel and perpendicular susceptibilities, and this must be taken into account in the averaging process. However, the anisotropy of this constant susceptibility may be neglected as shown in the following.

Let us consider only the state of $J=7/2$ as the excited one. If the splittings of this level due to crystalline field are neglected, $\chi_{\parallel}$ is given by $N\alpha_J$ of (3.5) and $\chi_{\perp}$ coincides with $\chi_{\parallel}$. In order to show it, we notice that the matrix elements

$$\begin{aligned}
&<\frac{5}{2},\ \pm\frac{1}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \pm\frac{3}{2}>=\pm\sqrt{5}\,f\left(\frac{7}{2}\right),\\
&<\frac{5}{2},\ \mp\frac{1}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \pm\frac{1}{2}>=\pm\sqrt{3}\,f\left(\frac{7}{2}\right),\\
&<\frac{5}{2},\ \pm\frac{3}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \pm\frac{5}{2}>=\pm\frac{\sqrt{30}}{2}f\left(\frac{7}{2}\right),\\
&<\frac{5}{2},\ \mp\frac{3}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \mp\frac{1}{2}>=\pm\frac{\sqrt{6}}{2}f\left(\frac{7}{2}\right),\\
&<\frac{5}{2},\ \pm\frac{5}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \pm\frac{7}{2}>=\pm\frac{\sqrt{42}}{2}f\left(\frac{7}{2}\right),\\
&<\frac{5}{2},\ \pm\frac{5}{2}\Big|L_x+2S_x\Big|\frac{7}{2},\ \pm\frac{3}{2}>=\mp\frac{1}{\sqrt{2}}f\left(\frac{7}{2}\right).
\end{aligned}\tag{3.15}$$

are used for $\chi_{\perp}$, where $f(J)=\sqrt{\frac{\{J^2-(L-S)^2\}\{(L+S+1)^2-J^2\}}{4J^2(2J-1)(2J+1)}}$ and $f\left(\frac{7}{2}\right)=\sqrt{\frac{15}{98}}$.

From (3.5) we have,

$$N\alpha_{5/2}=\frac{20N\mu_B^2}{7h\nu}\tag{3.16}$$

On the other hand, the corresponding perpendicular component

$$\chi_{c\perp}=\frac{2N\mu_B^2}{6}\sum\frac{|(L_x+2S_x)(njm;\,n'j'm')|^2}{h\nu(n':n)},\tag{3.17}$$

turns out to be equal to

$$\frac{2N\mu_B^2}{h\nu}\times 56\times\frac{15}{98}=N\alpha_{5/2},\tag{3.18}$$

if we use (3.15). This result can be seen from another point of view (see, for instance, reference 1). This will provide some suggestion for the consideration of anisotropy.

By taking only (2.10), the secular determinant in the manifold of $J=7/2$ are given by

$$\begin{array}{l}
\begin{array}{l} <\frac{7}{2},\ \pm\frac{7}{2}| \\ <\frac{7}{2},\ \pm\frac{1}{2}| \\ <\frac{7}{2},\ \mp\frac{5}{2}| \end{array}
\begin{vmatrix} 7b'-W & \mp2\sqrt{70}\,b' & 0 \\ \mp2\sqrt{70}\,b' & 9b'-W & \pm4\sqrt{10}\,b' \\ 0 & \pm4\sqrt{10}\,b' & -13b'-W \end{vmatrix}=0\ ,\\[2ex]
\begin{array}{l} <\frac{7}{2},\ \frac{3}{2}| \\ <\frac{7}{2},\ -\frac{3}{2}| \end{array}
\begin{vmatrix} -3b'-W & 0 \\ 0 & -3b'-W \end{vmatrix}=0\ ,
\end{array}\tag{3.19}$$

and the eigenvalues $W_1=-21b'$, $W_2=-3b'$ and $W_3=27b'$ are obtained. Their eigenfunctions are written as

$$\Phi_i=\alpha_i'\Big|-\frac{7}{2}>+\beta_i\Big|-\frac{1}{2}>+\gamma_i\Big|\frac{5}{2}>,$$

$$\begin{aligned}&\Phi_i'=\alpha_i'\left|+\frac{7}{2}\right>+\beta_i'\left|+\frac{1}{2}\right>+\gamma_i'\left|-\frac{5}{2}\right>,\\ &\left|\pm\frac{3}{2}\right> \qquad (W=W_2)\\ &(i=1,\ 2,\ 3)\end{aligned} \tag{3.20}$$

where $b'=60F'\beta'\overline{r^4}$, and the coefficients are determined by the relations

$$\alpha_i^2+\beta_i^2+\gamma_i^2=1,$$

and

$$\frac{\alpha_1}{2\sqrt{70}}=\frac{\beta_1}{30}=-\frac{\gamma_1}{4\sqrt{10}} \qquad \text{etc.}$$

These values α_i, β_i and γ_i are not so different from each other, and the original $|J, M>$ states make roughly equal contribution to the eigenstates except for $|7/2, \pm3/2>$. Moreover, as b' amounts to about one tenth of b, the matrix elements which connect with the lowest state have similar effects as in (3.5) and (3.18) (if we denote the splitting from the unperturbed level by ΔW, the order of error is less than $(\Delta W/h\nu)^2$). This is the reason for neglecting the anisotropy of constant part.

Thus, considering only the splitting of the lowest state, we can take safely the high frequency part as follows:

$$\chi_{tc}=B\mu_B^2\left\{\frac{1}{h\nu-6b}\,\frac{20}{7}+\frac{1}{h\nu+3b}\,\frac{40}{7}\,e^{9b/kT}\right\}, \tag{3.21}$$

and also we calculate $N\alpha_J$ of (3.6) with replacing by

$$\chi_{cc}=\frac{N\mu_B^2}{1+2e^{-18a/kT}}\left\{\frac{1}{h\nu+12a}\,\frac{20}{7}+\frac{1}{h\nu-6a}\,\frac{40}{7}\,e^{-18a/kT}\right\} \tag{3.22}$$

by the same reason.

From (3.21) and (3.14), the final expression of the susceptibility for the powder sample becomes

$$\begin{aligned}\chi_t&=(\chi_{t\parallel}+2\chi_{t\perp})/3\\ &=\frac{0.06125}{\mu T}\Bigg[-\frac{40}{9}+\left(\frac{19}{18}\cdot\frac{1}{\mathcal{E}'}+15+\frac{1180}{9}\mathcal{E}'\right)e^{\mu(1+\mathcal{E}')}\\ &\quad+\left(-\frac{19}{18}\,\frac{1}{\mathcal{E}'}-\frac{95}{9}-\frac{1180}{9}\mathcal{E}'\right)e^{\mu(1-\mathcal{E}')}\\ &\quad+\mu\left\{\frac{25}{36}+\frac{3}{4}e^{\mu(1+\mathcal{E}')}+\left(\frac{3}{4}-\frac{40}{9}\mathcal{E}'\right)e^{\mu(1-\mathcal{E}')}\right\}\Bigg]\\ &\quad\div 2\{1+e^{\mu(1+\mathcal{E}')}+e^{\mu(1-\mathcal{E}')}\}+\chi_{tc},\end{aligned} \tag{3.23}$$

where $9b/kT=\mu$, $\mathcal{E}=9\mathcal{E}'$ and $2Ng^2\mu_B^2/k=0.06125$.

§ 4. Results and Discussion

The experimental values of $1/\chi$ by Borovik-Romanov and Kreines are shown in Fig. 1 and Fig. 2. The experimental points in Fig. 1 are the one for cubic modification of Sm_2O_3 and ○ denotes for Sample I and ● for Sample II. Fig. 2 shows the results for pseudotrigonal modification where ○ denote for Sample I and ● are the results of Leiden group,

In Fig. 1, the theoretical curve 1 is plotted by Eq. (3.6) using the value $a=12\,k$ so as to get the best fit at high temperatures, and for comparison curve 2 is plotted using the value $a=15\,k$. Taking $a<0$, the fitting seems to be impossible in view of the slope of tangential line for $1/\chi$ curve at 0°K; In the limit $T\rightarrow 0$, (3.6) are written asymptotically as

$$a>0\ \ldots.\ 1/\chi\sim 47.05\ T,$$
$$a<0\ \ldots.\ 1/\chi\sim 18.08\ T$$

and we can only give reasonable results when $a>0$.

In Fig. 2, the theoretical curve (a) is plotted by using the values $b=-48k$ and $\mathcal{E}'=-0.1$. In this case, the sign of b is not definite from the comparison of the experiment with asymptotic form of $1/\chi$ in the limit $T\to 0$, ($1/\chi\sim 47.02T$ for negative b and $1/\chi\sim 43.53T$ for positive b), though the fitting at high temperature region can be achieved by taking $b<0$ in agreement with the sign of cubic case. We obtained above value from the intersection of the curves for b and $\mathcal{E}'$ of the best fit at temperatures of 100°K and 60°K respectively. As b depends slightly on $\mathcal{E}'$, the value of $\mathcal{E}'$ has some arbitrariness, but on the value of b we can have fair reliance. For comparison, the curves for $b=-60k$ and $b=-90k$ in the case of $\mathcal{E}'=-0.1$ are shown. In Fig. 3, the anisotropy of the susceptibility for the pseudotrigonal case are also shown.

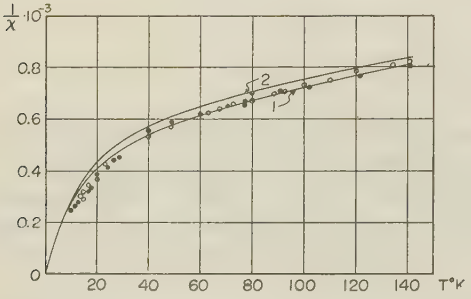

Fig. 1. Experimental points and theoretical curves of $1/\chi$ for cubic modification.

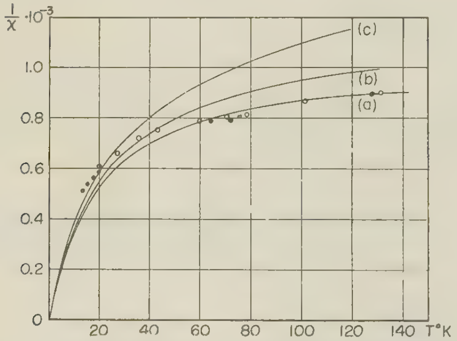

Fig. 2. Experimental points and theoretical curves of $1/\chi$ for pseudotrigonal modification.
(a): curve for $b=-48\,k$ $(\varepsilon'=-0.1)$
(b): curve for $b=-60\,k$ 〃
(c): curve for $b=-90\,k$ 〃

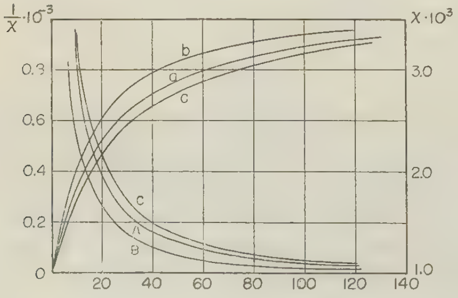

Fig. 3. Anisotropy of susceptibility in the case of pseudotrigonal modification ($b=-48\,k$, $\varepsilon'=-0.1$)
(a): $1/\chi=3/(\chi_{\parallel}+2\chi_{\perp})$ (A): $\chi=(\chi_{\parallel}+2\chi_{\perp})/3$
(b): $1/\chi_{\parallel}$ (B): $\chi_{\parallel}$
(c): $1/\chi_{\perp}$ (C): $\chi_{\perp}$

One of the conclusions of the simple consideration by Borovik-Romanov and Kreines is that if six states of $J_z=\pm 1/2,\ \pm 3/2,\ \pm 5/2$ in the manifold of $J=5/2$ are the eigenstates, the state of small J_z lies as lower one. This means the opposite sign of the coefficient of cubic potential to what is obtained by us, and in the case of trigonal potential the lowest state contains $\pm 5/2$, $\pm 1/2$ states nearly equally. Thus we cannot assent to their conclusion. Rather, our results agrees with the results of Giesekus[6] who estimated the crystalline potential of $Sm(BrO_3)_3 9H_2O$.

The total separation $52\,cm^{-1}$ which they obtained in cubic case may be compared with our $18a=216k$. As for the trigonal case, our result $9b=432k$ is more than twice of their estimation $150\,cm^{-1}$. With respect to these overall splittings in two modifications, their estimations and also our results are not necessary equal. The essential change in the crystalline structure due to thermal treatment of the sample may be a cause of this, but further discussion is not possible at the present stage.

In conclusion, the author wishes to express his cordial thanks to Professor T. Nakamura of Ôsaka University for his valuable discussions and also to members of laboratory for their discussions.

Electroluminescence of Insulated Particles, II

By Keiji Maeda

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki

(Received July 1, 1960)

Lehmann's experimental results on the emission intensity of a single electroluminescent phosphor particle embedded in an insulating dielectric as a function of the applied voltage are analysed on the model proposed in the Part I of this report. In this model the local field enhancement is attributed to the disturbance of the applied field due to the conducting phase of the phosphor particle. The results are reasonable and the validity of the model is confirmed.

§ 1. Introduction

For the origin of the local field enhancement, which is a fundamental problem in the theory of electroluminescence, many workers have adopted the barrier model. However, we have proved in the Part I of this paper[1] (hereafter refered as Part I) that the barrier model is not reasonable for the electroluminescence of phosphor particles dispersed in an insulating dielectric. We have also shown several reasons why the model proposed by Zalm is not suitable for the actual situations[2]. As an alternative mechanism, we have proposed a model that the local field enhancement takes place around the edge of highly conducting phase which is deposited on or segregated within the poorly conducting ZnS phosphor particle. It has been shown that the various experimental facts can be explained consistently by this model.

In Part I it has deen predicted that the voltage dependence of the electroluminescence intensity of an emitting spot is represented by

$$B_s=\alpha_s \exp(-\beta_s/V) \qquad (1)$$

where α_s and β_s are constants depending on the shape and size of the conducting phase which produces the local field enhancement for this emitting spot. Since the values of α_s and β_s differ from spot to spot, the experimental relationship between the applied voltage and the brightness of an electroluminescent cell

$$B_c=\alpha_c \exp(-\beta_c/\sqrt{V}) \qquad (2)$$

should be obtained by summing Eq. (1) over the emitting spots within the cell. However, when Part I was published there were no definite experimental results in support of our model.

§ 2. Analysis of Lehmann's Experiments

Recently Lehmann[3] has measured the voltage dependence of emission intensity of a single phosphor particle on six particles. He has found that the intensity is represented by Eq. (1) for one particle and by the sum of two or more of Eq. (1) for other five particles respectively. The former one particle has a single emitting spot and the latter particles have two or more emitting spots in each of them. Further he has demonstrated that Eq. (2) can be obtained from Eq. (1) by numerical calculations. His experimental results are in complete agreement with our prediction but his numerical calculations have been made on the particle size distribution of the phosphor as he assumed the barrier model.

We shall consider the absolute value of β_s. From Lehmann's measurements which are

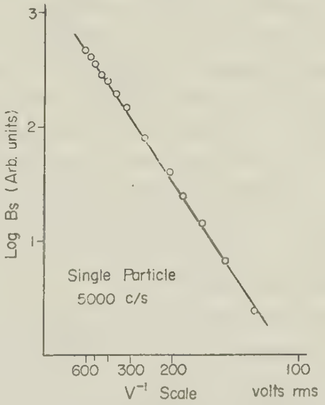

Fig. 1. Voltage dependence of electroluminescence intensity of a single phosphor particle measured by Lehmann.

shown in Fig. 1, we obtain the value of β_s to be 770 V rms and the thickness of the cell is considered to be about 100 μ. On the other hand, we have assumed in Part I that the conductive phase is spheroid in shape as a simple model. The field strength is calculated around the edge of the spheroid when it is placed parallel to the applied field with its major axis. From the probability of carrier multiplication in this local field, the above Eq. (1) is obtained. Using Eqs. (2), (3), (10), (14) and (16) of Part I, we have

$$\beta_s = \frac{\pi C d}{4\sqrt{2}\, r_0 K} \tag{3a}$$

for the oblate spheroid and

$$\beta_s = \frac{C d}{\sqrt{2}\, r_p^2 K} \tag{3b}$$

for the prolate spheroid when V in Eq. (1) is expresed by rms value for a sinusoidal applied voltage. Here, C is the constant in the exponential term of the probability of secondary electron production, d is the thickness of the cell, K is the factor of the field strength in ZnS due to the difference in the dielectric constant between the embedding dielectric and ZnS, and r_0 and r_p are the ratio of the major axis to the minor axis of the oblate and the prolate spheroid respectively. We obtain the values of r_0 or r_p when it is assumed that the field enhancement for the spot is due to either an oblate or a prolate spheroidal conducting phase by inserting the following values in Eqs. (3a) or (3b); $C=8\times 10^5$ V/cm as stated in Part I, $\beta_s=770$ V/cm, $d=100\,\mu$ and $K=2$. Then we have $r_0=2.9$ or $r_p=1.9$. Exactly speaking, Eqs. (3a) and (3b) are derived on the assumption of large axial ratio. But we have made use of them for the sake of simplicity and semi-quantitative nature of our discussion as stated in the next section. When we make exact but complicated calculation, we have $r_0=1.9$ and $r_p=2.0$. It becomes clear that the value of β_s obtained by Lehmann can be explained by our model assuming the plausible shape of the conductive spheroid.

It seems reasonable from Fig. 1 to assume that the minimum applied voltage necessary for the appreciable photon emission in this spot is 100 V rms. Then the average field strength in the cell E_{th} at the peak of this ac voltage cycle is $\sqrt{2}\times 10^4$ V/cm. We have derived the equations for this field strength on the assumption of large axial ratio, i.e. Eqs. (6) and (7) of Part I. However, it becomes clear from Eqs. (4)* and (5) of Part I that these equations are poor approximation for the above values of r_0 and r_p. The exact equations are too complicated to be treated here for our semi-quantitative calculation. Therefore, we shall adopt a simple method. The potential drop in the average field over the distance of the major axis a of the spheroid is concentrated, superposing on the average field, around the edge of the sheroid over the distance of the minor axis. This potential drop should be at least equal to the energy of the forbidden gap of ZnS I_G for the occurrence of appreciable electroluminescence, i.e.

$$I_G = E_{th} K a. \tag{4}$$

Inserting $I_G=3.7$ eV and other values stated above into Eq. (4), we obtain $a=1.3\,\mu$. The obtained value is small compared with the dimension of the phosphor particle, i.e. from 10 to 20 μ in diameter. The presence of the conducting phase of this order of magnitude indimension is reasonable from the various characteristics of the phosphor particle.

§ 3. Discussion

Although we do not know the actual shape of the conducting phase, the assumption of the spheroidal shape may be considered too simple. However, in the first approximation, emphasis should be placed on the shape of the edge in question relative to the whole dimension of the conducting phase. Of course, some actual edges would be more or less sharp than the above spheroidal approximation. Since our discussion is semi-quantitative first approximation in order to demonstrate the consistency of the various quantities, the above approximation is considered to be satisfactory. For instance, even if the dimension of the conducting phase should be multiplied by two in order to avoid the uncertainty of the approximations involved, Lehmann's experiments can be explained reasonably by our model.

As stated before, the derivation of the

---

* Eq. (4) of Part I should be read $\delta=(ac^2/2)^{\frac{1}{3}}$ instead $\delta=(ac^2/2)^{\frac{1}{2}}$.

emission intensity of a cell Eq. (2) from the emission intensity of a spot involves summation of Eq. (1) over the emitting spots. We cannot show the derivation explicitly, since we do not know the distribution of the size and shape of the conducting phase. However, since the number of spots having small values of β_s, i.e. large axial ratio, would be small in a similar way as that of particles having large diameter in the particle size distribution treated by Lehmann, it is expected that the summation of Eq. (1) over emitting spots leads to Eq. (2).

Although the structure of the electroluminescent particle is very complicated and only a little is known on the conducting phase, it is concluded from the above analysis that the validity of our model is further confirmed.

A short explanation will be added for the estimation of efficiency of electroluminescent cell described in Part I in order to avoid misunderstanding. It has been reported to show that the low efficiency of electroluminescent cell can be explained by reasonable estimation on the various processes. It is based on the data by the Philips group and different values would be obtained by analysing other data. Exactly speaking, we should compare the estimated value with the efficiency measured by the Philips group on the same cell, i.e. about 7 lm/W from the efficiency curve shown in Fig. 2 of Part I. Therefore, it does not represent the maximum obtainable efficiency in future.

Note added in proof — Very recently Lehmann has made microscopic observations on ihe electroluminescent phosphor particles (J. Electrochem. Soc. **107** (1960) 657). Within the particles he observed dark segregations, which are frequently thin and elongated, almost needle-like. The emission spots are visibly located directly at the ends of the segregations. Therefore, it seems that our simple assumptions on the shape of the conductive phase are justified. Further, according to his observation the segregations are larger, on the average, in larger particles and vice versa. From this result we can explain the relations between the voltage dependence of emission intensity of a cell, i.e. α_c and β_c, and the particle size distribution (for example, Lehmann: J. Electrochem. Soc. **105** (1958) 585) on our model.

Pseudokinematical Approximation in Electron Diffraction by Crystal

By Mitsuhiko HAYASHI*

Physical Institute, Nagoya University, Nagoya, Japan

(Received August 1, 1960)

The pseudokinematical theory of electron diffraction is considered to be a good approximation for gas molecules. When, the theory is applied to crystals, however, there is an ambiguity concerning the nature of the approximation. In the present paper, the ambiguity is removed by comparing the result of the theory with the exact solution. The higher order Born approximation applied to the entire crystal is used as the exact solution. It is concluded that the pseudokinematical approximation is better than that of the usual kinematical theory and coincides almost with the exact solution under the condition that the crystal is very thin and there is no overlap of atoms when the crystal is seen from the direction of the incident beam.

§1. Introduction

Glauber & Schomaker[1)] pointed out that the kinematical theory of diffraction (KT) is not adequate for the electron diffraction by gas molecules containing heavy atoms. They attributed the cause of this fact to the multiple scatterings of electrons in the heavy atoms. They modified the kinematical theory by substituting the rigorous atomic scattering amplitudes for the usual ones, and succeeded in explaining the electron diffraction patterns from such molecules. The modified theory was called by Hoerni[2)] the pseudokinematical theory (PKT). KT is equivalent to Born approximation in which the multiple scatterings of electrons are entirely neglected. In PKT, the multiple scatterings in individual atoms are taken into account, while those on different atoms are neglected. PKT has been proved to be satisfactory for the electron diffraction by gas molecules.

Hoerni[2)] studied the applicability of PKT to crystals. He compared the result of PKT with that of the dynamical theory (DT) in the case of thin crystals. Based upon numerical calculations, he concluded that the agreement was good for the reflections of low indices, but in general there was no agreement for higher indices. In his calculations of DT, only the systematic interactions* are taken into account. This is not adequate because in the case of thin crystals the accidental interactions** should also be taken into account (Appendix IV).

Recently, Miyake[3)] studied the change of the intensity from DT value to KT value and inferred that PKT would be misleading when applied to crystals. Fujimoto[4)] succeeded in formulating the dynamical theory taking into account many reflected waves. He made numerical calculations[5)] of a number of examples using his formula. According to the result, the exact value does not coincide with PKT value, but it does with KT value when the crystal is thin ($\lesssim$15A). In his calculations, however, only the systematic interactions were taken into account as in Hoerni's[2)].

The purpose of the present paper is to make clear the applicability of PKT to crystals. By comparing the result of PKT with the exact solution, it is concluded that the approximation of PKT is better than that of KT and is very near the exact value in the case of very thin crystals.

---

* Now at Department of Applied Physics, Nagoya University, Nogoya, Japan.

** When the intensity of a given reflection ***h*** is calculated by DT, it is necessary to take into account the coupling of ***h***-reflection with all the other reflections. The reflection ***h*** remains in the Bragg position when the crystal is rotated around the vector ***h***. As the crystal is rotated the amplitudes of other reflections change, except those corresponding to the reciprocal lattice points lying on the rotation axis. Thus some of the dynamical interactions depend on the azimuthal orientation, whereas the others do not. Hoerni[2)] called the latter the systematic interactions and the former the accidental interactions.

§ 2. The pseudokinematical theory and the exact solution of diffraction

(A) *Pseudokinematical theory* (PKT)

When incident wave $\Psi^{(0)}(\mathbf{r})$ with wave vector $\mathbf{K}_0$ falls upon a free atom, a scattered wave $\phi^S(\mathbf{r})$ is produced. $\phi^S(\mathbf{r})$ can be expressed as a series of successive approximations;

$$\phi^S(\mathbf{r})=\phi^{(1)}(\mathbf{r})+\phi^{(2)}(\mathbf{r})+\cdots. \tag{1}$$

If the atom is assumed to have a potential $V_a(\mathbf{r})$, the first approximation $\phi^{(1)}(\mathbf{r})$ is given by[8]

$$\phi^{(1)}(\mathbf{r})=\frac{1}{4\pi}\int\frac{\exp[2\pi iK_0|\mathbf{r}-\mathbf{r}'|]}{|\mathbf{r}-\mathbf{r}'|}\times U_a(\mathbf{r}')\exp[2\pi i\mathbf{K}_0\cdot\mathbf{r}']\,d\mathbf{r}', \tag{2}$$

where

$$U_a(\mathbf{r})=\frac{2me}{\hbar^2}V_a(\mathbf{r}). \tag{3}$$

Using the relations

$$U_a(\mathbf{r})=4\pi\int_\infty f(\mathbf{b})\exp[2\pi i\mathbf{b}\cdot\mathbf{r}]\,d\mathbf{b}, \tag{4}$$

$$\frac{1}{4\pi}\frac{\exp[2\pi iK_0|\mathbf{r}-\mathbf{r}'|]}{|\mathbf{r}-\mathbf{r}'|}=\frac{1}{(2\pi)^2}\times\int\frac{\exp[2\pi i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')]}{\mathbf{k}^2-\mathbf{K}_0^2}\,d\mathbf{k}\,{}^{9)} \tag{5}$$

and

$$\int_\infty\exp[2\pi i(\mathbf{K}_0+\mathbf{b}-\mathbf{k})\cdot\mathbf{r}']\,d\mathbf{r}'=\delta(\mathbf{K}_0+\mathbf{b}-\mathbf{k}),{}^{10)} \tag{6}$$

where $f(\mathbf{b})$ is the usual atomic scattering amplitude for electrons, eq. (2) is rewritten as

$$\phi^{(1)}(\mathbf{r})=\frac{1}{\pi}\int\frac{\exp[2\pi i\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}f(\mathbf{K}-\mathbf{K}_0)\,d\mathbf{K}. \tag{7}$$

Similarly, the second approximation is given by

$$\phi^{(2)}(\mathbf{r})=\frac{1}{\pi^2}\int d\mathbf{K}\frac{\exp[2\pi i\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}\times\int\frac{f(\mathbf{K}-\mathbf{k})f(\mathbf{k}-\mathbf{K}_0)}{\mathbf{k}^2-\mathbf{K}_0^2}\,d\mathbf{k}. \tag{8}$$

PKT wave function $\Psi^P(\mathbf{r})$ for a crystal is given by

$$\Psi^P(\mathbf{r})=\Psi^{(0)}(\mathbf{r})+\sum_n\sum_i\phi^S{}_{n,i}(\mathbf{r}). \tag{9}$$

Here, $\phi^S{}_{n,i}(\mathbf{r})$ is the wave scattered from the i-th atom in the n-th unit cell. $\sum\limits_n$ and $\sum\limits_i$ represent the summations over all lattice points in the crystal and over all atoms in the unit cell, respectively. If the first approximations $\phi^{(1)}{}_{n,i}(\mathbf{r})$ given by (7) are substituted for $\phi^S{}_{n,i}(\mathbf{r})$ in eq. (9), KT wave function is obtained. From eqs. (1), (7), (8) and (9) we have

$$\Psi^P(\mathbf{r})=\Psi^{(0)}(\mathbf{r})+\Psi^{P(1)}(\mathbf{r})+\Psi^{P(2)}(\mathbf{r})+\cdots, \tag{10}$$

where

$$\Psi^{P(1)}(\mathbf{r})=\frac{1}{\pi}\int\frac{\exp[2\pi i\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}\times F(\mathbf{K}-\mathbf{K}_0)L(\mathbf{K}-\mathbf{K}_0)\,d\mathbf{K}, \tag{11}$$

$$\Psi^{P(2)}(\mathbf{r})=\frac{1}{\pi^2}\sum_i\int d\mathbf{K}\frac{\exp[2\pi i\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}\times\exp[-2\pi i(\mathbf{K}-\mathbf{K}_0)\cdot\mathbf{r}_i]\times L(\mathbf{K}-\mathbf{K}_0)\int\frac{f_i(\mathbf{K}-\mathbf{k})f_2(\mathbf{k}-\mathbf{K}_0)}{\mathbf{k}^2-\mathbf{K}_0^2}\,d\mathbf{k}, \tag{12}$$

....

Here $F(\mathbf{b})$ is the usual structure factor for electrons and $L(\mathbf{b})$ the diffraction function of the crystal. They are given by

$$F(\mathbf{b})=\sum_i f_i(\mathbf{b})\exp[-2\pi i\mathbf{b}\cdot\mathbf{r}_i], \tag{13}$$

$$L(\mathbf{b})=\sum_n\exp[-2\pi i\mathbf{b}\cdot\mathbf{R}_n], \tag{14}$$

where $\mathbf{R}_n$ and $\mathbf{r}_i$ represent the position of the n-th lattice point and the i-th atom in the unit cell, respectively.

(B) *Exact solution* (SBAC)

Applying the successive Born approximation to the entire crystal[6] (SBAC), we have for the exact wave function

$$\Psi(\mathbf{r})=\Psi^{(0)}(\mathbf{r})+\Psi^{(1)}(\mathbf{r})+\Psi^{(2)}(\mathbf{r})+\cdots, \tag{15}$$

where

$$\Psi^{(1)}(\mathbf{r})=\frac{1}{\pi}\int\frac{\exp[2\pi i\cdot\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}\times F(\mathbf{K}-\mathbf{K}_0)L(\mathbf{K}-\mathbf{K}_0)\,d\mathbf{K}, \tag{16}$$

$$\Psi^{(2)}(\mathbf{r})=\frac{1}{\pi^2}\int d\mathbf{K}\frac{\exp[2\pi i\cdot\mathbf{K}\cdot\mathbf{r}]}{\mathbf{K}^2-\mathbf{K}_0^2}\times\int\frac{F(\mathbf{K}-\mathbf{k})F(\mathbf{k}-\mathbf{K}_0)}{\mathbf{k}^2-\mathbf{K}_0^2}\times L(\mathbf{K}-\mathbf{k})L(\mathbf{k}-\mathbf{K}_0)\,d\mathbf{k}, \tag{17}$$

....

(C) *Derivation of Fraunhofer formula*

The formulae (10) and (15) are Fresnel formulae. It is desirable to obtain Fraunhofer formulae which correspond to the usual experimental condition of electron diffraction. This is carried out by the following mathematical procedure.

Eqs. (11), (12), (16) and (17) are all of the form

$$\Psi(\boldsymbol{r})=C\int_{\infty}\frac{\exp[2\pi i\boldsymbol{K}\cdot\boldsymbol{r}]}{K^2-K_0{}^2}P(\boldsymbol{K})d\boldsymbol{K}. \tag{18}$$

For eq. (17), for instance, $P(\boldsymbol{K})$ represents

$$P(\boldsymbol{K})=\int\frac{F(\boldsymbol{K}-\boldsymbol{k})F(\boldsymbol{k}-\boldsymbol{K}_0)}{k^2-K_0{}^2}\times L(\boldsymbol{K}-\boldsymbol{k})L(\boldsymbol{k}-\boldsymbol{K}_0)d\boldsymbol{k}.$$

Since for large $|\boldsymbol{r}|$ the function $P(\boldsymbol{K})$ varies slowly compared to $\exp[2\pi i\boldsymbol{K}\cdot\boldsymbol{r}]/(K^2-K_0{}^2)$, eq. (18) is reduced to a surface integral on Ewald sphere.

$$\Psi(\boldsymbol{r})=C\frac{i\pi}{k_0}\int_{\substack{\text{Ewald}\\ \text{sphere}}}\exp[2\pi i\boldsymbol{K}\cdot\boldsymbol{k}]P(\boldsymbol{K})\,d\sigma, \tag{19}$$

where $d\sigma$ is the surface element on Ewald sphere. Taking the direction of $\boldsymbol{r}$ as the polar axis, we can express $P(\boldsymbol{K})$ on Ewald sphere as $P(\theta,\varphi)$, where θ and φ are the polar and the azimuthal angle, respectively. Then, eq.(19) can be rewritten as

$$\Psi(\boldsymbol{r})=Ci\pi K_0\int_0^{2\pi}d\varphi\int_0^{\pi}P(\theta,\varphi)\times\exp[2\pi iK_0r\cos\theta]\sin\theta d\theta. \tag{20}$$

Integrating the inner integral by parts, and taking into account the facts that $P(\pi,\varphi)$ is vanishingly small and that $\partial P/\partial\theta$ changes with θ much more slowly than $\exp[2\pi iK_0r\cos\theta]$, we have finally[11]

$$\Psi(\boldsymbol{r})=C\pi\frac{\exp[2\pi iK_0r]}{r}P(\boldsymbol{K}_r), \tag{21}$$

where $\boldsymbol{K}_r$ is the wave vector in the direction of $\boldsymbol{r}$.

By applying the relation (21) to eqs. (11), (12), (16) and (17), we obtain Fraunhofer formulae.

$$\Psi^P(\boldsymbol{r})=\Psi^{(0)}(\boldsymbol{r})+\frac{\exp[2\pi iK_0r]}{r}\times[\varPhi^{P(1)}(\boldsymbol{K}_r,\boldsymbol{K}_0)+\varPhi^{P(2)}(\boldsymbol{K}_r,\boldsymbol{K}_0)+\cdots], \tag{22}$$

$$\Psi(\boldsymbol{r})=\Psi^{(0)}(\boldsymbol{r})+\frac{\exp[2\pi iK_0r]}{r}\times[\varPhi^{(1)}(\boldsymbol{K}_r,\boldsymbol{K}_0)+\varPhi^{(2)}(\boldsymbol{K}_r,\boldsymbol{K}_0)+\cdots\cdot], \tag{23}$$

where

$$\varPhi^{P(1)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=F(\boldsymbol{K}_r-\boldsymbol{K}_0)L(\boldsymbol{K}_r-\boldsymbol{K}_0), \tag{24}$$

$$\varPhi^{P(2)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=\frac{1}{\pi}\sum_i\exp[-2\pi i(\boldsymbol{K}_r-\boldsymbol{K}_0)\cdot\boldsymbol{r}_i]L(\boldsymbol{K}_r-\boldsymbol{K}_0)\int\frac{f_i(\boldsymbol{K}_r-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)}{k^2-K_0{}^2}d\boldsymbol{k}, \tag{25}$$

.... ,

$$\varPhi^{P(n)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=\frac{1}{\pi^{n-1}}\sum_i\exp[-2\pi i(\boldsymbol{K}_r-\boldsymbol{K}_0)\cdot\boldsymbol{r}_i]L(\boldsymbol{K}_r-\boldsymbol{K}_0)\times\int\cdots\int\frac{f_i(\boldsymbol{K}_r-\boldsymbol{k}_1)f_i(\boldsymbol{k}_1-\boldsymbol{k}_2)\cdots f_i(\boldsymbol{k}_{n-1}-\boldsymbol{K}_0)}{(k_1{}^2-K_0{}^2)(k_2{}^2-K_0)\cdots(k^2{}_{n-1}-K_0{}^2)}d\boldsymbol{k}_1d\boldsymbol{k}_2\cdots d\boldsymbol{k}_{n-1}, \tag{26}$$

.... ;

$$\varPhi^{(1)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=F(\boldsymbol{K}_r-\boldsymbol{K}_0)L(\boldsymbol{K}_r-\boldsymbol{K}_0), \tag{27}$$

$$\varPhi^{(2)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=\frac{1}{\pi}\int\frac{F(\boldsymbol{K}_r-\boldsymbol{k})F(\boldsymbol{k}-\boldsymbol{K}_0)}{k^2-K_0{}^2}L(\boldsymbol{K}_r-\boldsymbol{k})L(\boldsymbol{k}-\boldsymbol{K}_0)d\boldsymbol{k}, \tag{28}$$

.... ,

$$\varPhi^{(n)}(\boldsymbol{K}_r,\boldsymbol{K}_0)=\frac{1}{\pi^{n-1}}\int\cdots\int\frac{F(\boldsymbol{K}_r-\boldsymbol{k}_1)F(\boldsymbol{k}_1-\boldsymbol{k}_2)\cdots F(\boldsymbol{k}_{n-1}-\boldsymbol{K}_0)}{(k_1{}^2-K_0{}^2)(k_2{}^2-K_0{}^2)\cdots(k_{n-1}-K_0{}^2)}\times L(\boldsymbol{K}_r-\boldsymbol{k}_1)L(\boldsymbol{k}_1-\boldsymbol{k}_2)\cdots L(\boldsymbol{k}_{n-1}-\boldsymbol{K}_0)d\boldsymbol{k}_1d\boldsymbol{k}_2\cdots d\boldsymbol{k}_{n-1}, \tag{29}$$

....

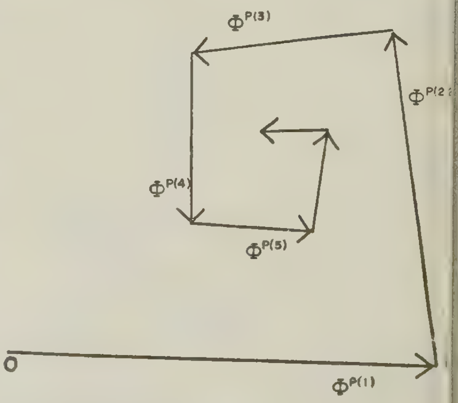

Fig. 1. Illustration of $\varPhi^{P(1)}+\varPhi^{P(2)}+\cdots$ on the complex plane.

Scattering amplitude $\varPhi^{P(1)}+\varPhi^{P(2)}+\cdots$is diagramatically illustrated in Fig. 1. If the crystal is centrosymmetric and the Bragg condition is satisfied, $\varPhi^{P(1)}$ is in the positive direction of the real axis, $\varPhi^{P(2)}$ nearly in the positive direction of the imaginary axis, $\varPhi^{P(3)}$ nearly in the negative direction of the real axis, etc. The same holds also for $\varPhi^{(1)}+\varPhi^{(2)}+\cdots\cdots$.

§ 3. Comparison of PKT with SBAC

In the first approximation, PKT and SBAC coincide with each other [eqs.(24) and (27)], and they coincide also with KT.

The second approximation of PKT (25) can be rewritten for a plane parallel crystal as (Appendix I)

$$\Phi^{P(2)}(\boldsymbol{K},\boldsymbol{K}_0)\approx\frac{1}{\pi S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_i\exp\left[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]$$
$$\times\left[i\pi f_i(\boldsymbol{b}-\boldsymbol{g})f_i(\boldsymbol{g})+\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu}+\boldsymbol{g})f_i(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}d\rho\right]. \tag{30}$$

Here $\boldsymbol{K}_r$ in eq.(25) is simply denoted by $\boldsymbol{K}$ and P represents the principal value. Unit cell vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ lie in the plane of crystal surface and

$$\left.\begin{aligned}&\boldsymbol{b}=\boldsymbol{K}-\boldsymbol{K}_0,\\&\boldsymbol{G}=G_1\boldsymbol{a}_1{}^*+G_2\boldsymbol{a}_2,\\&\boldsymbol{g}=\boldsymbol{G}+\rho_g\boldsymbol{\nu},\\&\boldsymbol{K}_g=\boldsymbol{K}_0+\boldsymbol{g},\\&S_0=|\boldsymbol{a}_1\times\boldsymbol{a}_2|,\end{aligned}\right\} \tag{31}$$

where G_1 and G_2 are integers and ρ_g is the excitation error for $\boldsymbol{G}$ (Fig. 2). The z- axis is taken normal to the crystal surface and $\boldsymbol{\nu}$ is the unit vector in z-direction. In the derivation of (30), the integral over Ewald sphere is replaced by the summation over reciprocal lattice points. This is a good approximation as explained in Appendix I.

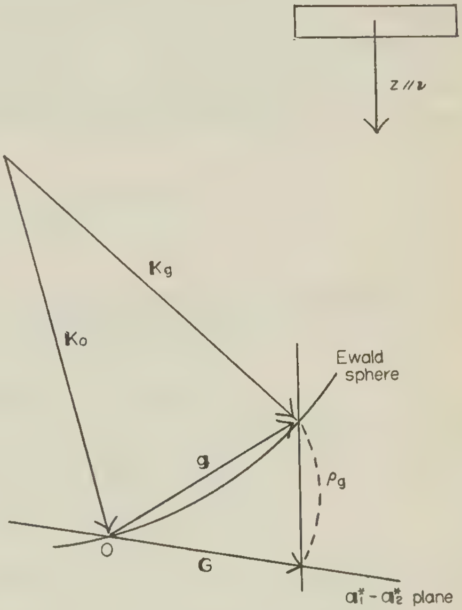

Fig. 2.

For simplicity, we assume a crystal of one unit cell thickness with an area $|M_1\boldsymbol{a}_1\times M_2\boldsymbol{a}_2|$, where M_1 and M_2 are integers. Under this assumption, the second approximation of SBAC (28) becomes (Appendix II)

$$\Phi^{(2)}(\boldsymbol{K},\boldsymbol{K}_0)=\frac{1}{\pi S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_i\sum_j\exp\left[-2\pi i(\boldsymbol{b}-\boldsymbol{g})\cdot\boldsymbol{k}_i\right]\exp\left[-2\pi i\boldsymbol{g}\cdot\boldsymbol{r}_j\right]$$
$$\times\left[i\pi f_i(\boldsymbol{b}-\boldsymbol{g})f_j(\boldsymbol{g})+\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}\cos 2\pi(z_i-z_j)\,\rho d\rho\right.$$
$$\left.+i\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}\sin 2\pi(z_i-z_j)\,\rho d\rho\right], \tag{32}$$

where z_i is the z-component of $\boldsymbol{r}_i$.

Eqs.(30) and (32) can be written as

$$\left.\begin{aligned}&\Phi^{P(2)}(\boldsymbol{K},\boldsymbol{K}_0)=A+B,\\&\Phi^{(2)}(\boldsymbol{K},\boldsymbol{K}_0)=A+A'+B+B'+B''.\end{aligned}\right\} \tag{33}$$

The expressions of A, B, A' etc. are given in Appendix III. Terms A and B come from double scatterings within the same atom, whereas terms A', B' and B'' come from double scatterings on different atoms. In reciprocal space, a double scattering is a successive transition of state from $\boldsymbol{K}_0$ to $\boldsymbol{k}$ and then to $\boldsymbol{K}$. $\Phi^{P(2)}(\boldsymbol{K}, \boldsymbol{K}_0)$ and $\Phi^{(2)}(\boldsymbol{K}, \boldsymbol{K}_0)$ are made up of such transitions with all possible intermediate states $\boldsymbol{k}$'s. Thus every point in the reciprocal space contributes to $\Phi^{P(2)}$ and $\Phi^{(2)}$ as an intermediate state. Terms A and A' are the contribution from the points on Ewald sphere, while terms B, B' and B'' from all the points of the reciprocal space except those on Ewald sphere.

It is easily seen that terms B' and B'' are quite negligible in comparison to B for the usual wave length of electrons (10 KV~500 KV). Terms A' is negligible in comparison to A, provided that the central parts of atoms where the atmic potential has considerable value do not overlap when the crystal is seen from the direction of $\boldsymbol{K}_0$ (Appendix IV). Thus it is concluded that PKT is a better approximation than KT, and particularly when the condition of non-overlap is satisfied, PKT is almost equal to the exact solution i.e. $|\Phi^{P(2)}-\Phi^{(2)}|\ll|\Phi^{(2)}|$.

Under the condition of non-overlap, it is also found that $|\Phi^{P(3)}-\Phi^{(3)}|\ll|\Phi^{(3)}|$, $|\Phi^{P(4)}-\Phi^{(4)}|\ll|\Phi^{(4)}|$ etc.

The conclusion reached above applies to crystals of any size and also to amorphous substances as shown in the following. If we assume an amorphous scatterer, we obtain from eqs.(25) and (28) for the second approximations of PKT and SBAC

$$\Phi^{P(2)}(\boldsymbol{K},\boldsymbol{K}_0)=\frac{1}{\pi}\frac{1}{2K_0}\sum_i \exp\left[-2\pi i(\boldsymbol{K}-\boldsymbol{K}_0)\cdot\boldsymbol{r}_i\right]\int_{\substack{\text{Ewald}\\\text{sphere}}}\left[i\pi f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)\right.$$
$$\left.+\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{K}-\boldsymbol{k}-\rho\boldsymbol{\nu})f_i(\rho\boldsymbol{\nu}+\boldsymbol{k}-\boldsymbol{K}_0)}{\rho}d\rho\right]d\sigma, \tag{34}$$

$$\Phi^{(2)}(\boldsymbol{K},\boldsymbol{K}_0)=\frac{1}{\pi}\frac{1}{2K_0}\sum_i\sum_j\int_{\substack{\text{Ewald}\\\text{sphere}}}\exp\left[-2\pi i(\boldsymbol{K}-\boldsymbol{k})\cdot\boldsymbol{r}_i\right]\exp\left[-2\pi i(\boldsymbol{k}-\boldsymbol{K}_0)\cdot\boldsymbol{r}_j\right]$$
$$\times\left[i\pi f_i(\boldsymbol{K}-\boldsymbol{k})f_j(\boldsymbol{k}-\boldsymbol{K}_0)+\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{K}-\boldsymbol{k}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{k}-\boldsymbol{K}_0)}{\rho}\cos 2\pi(z_i-z_j)\rho d\rho\right.$$
$$\left.+i\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{K}-\boldsymbol{k}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{k}-\boldsymbol{K}_0)}{\rho}\sin 2\pi(z_i-z_j)\rho d\rho\right]d\sigma, \tag{35}$$

Here $L(\boldsymbol{b})$ is taken as unity, and $\sum_i$ and $\sum_j$ are extended over all atoms in the scatterer. The derivation of (34) from (25) is exact and any approximation as used in that of (30) from (25) is not necessary. Eqs. (34) and (35) are compared in the same way as in the case of eqs.(30) and (32). Then it is found that PKT approximation almost coincides with the exact solution provided that the number of atoms which overlap one another when the scatter is seen from the directon of $\boldsymbol{K}_0$ is negligibly small compared to the number of atoms which do not overlap any other (Appendix V).

In Appendixes (IV) and (V), the atomic numbers of the atoms in the crystal are assumed to be nearly the same. If the crystal cotains heavy and light atoms, the overlap of two heavy atoms are important and that of a heavy atom and a light atom or of two light atoms can be neglected. This is verified because S_{ij} given by (A8) and (A12) predominates only when both the i-th and the j-th atom are heavy.

§ 4. Discussions

It is concluded in the previous section that the result of PKT coincides with that of the exact theory under the condition that there is no overlap of atoms when the crystal is seem from the direction of the incident beam. This conclusion may be physically interpreted as follows. The scattering of electrons by an atom is considerable only for small scattering angles for the usual accelerating voltages (≳10 KV). Therefore, when the condition of non-overlap is satisfied, the multipe scatterings on different atoms are negligible compared to those in individual atoms. The reason that PKT is satisfactory for gas molecules may be understood as follows. Since gas molecules take random orientations, the probability that two atoms in a molecule arrange themselves along the direction of the incident beam is very small. Thus the condition of non-overlap is satisfied for most molecules.

Our result that PKT gives more exact value than KT for very thin crystals does not contradict the conclusion by Miyake,[3] Fujimoto[4] and Fujiwara[6] that the exact value approaches KT value in the limit $\lambda D \to 0$, where λ is the wave length of electrons and D the crystal thickness.

First, we consider the variation of I_h with D fixing λ to a definite value, where I_h is the intensity* of a given reflection $\boldsymbol{h}$. It is well known[2] that, according to KT and PKT, the curve $\sqrt{I_h}$ vs. D is a straight line if Bragg condition is exactly satisfied. This can be seen also from eqs. (22), (24), (25) etc. The curve for the exact value is tangent to the straight line for KT at the origin (Miyake, Fujimoto and Fujiwara) and it may cross the straight line for PKT at $D=D_0$ (Present theory), where D_0 is the one unit cell thickness. Thus the curves $\sqrt{I_h}$ vs. D for a definite value of λ may be as illustrated in Fig. 3.

Next, we consider the variation of $\sqrt{I_h}$ with λ for a fixed value of D. KT intensity is independent of λ. From eqs. (22) to (29) it is found that PKT intensity and the exact intensity approaches KT value in the limit $\lambda \to 0$. Thus the intensity may change with λ for a fixed D as illustrated in Fig. 4.

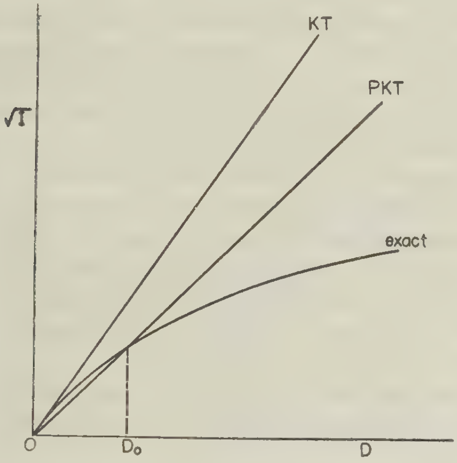

Fig. 3. Dependence of $\sqrt{I}$ on D for fixed λ.

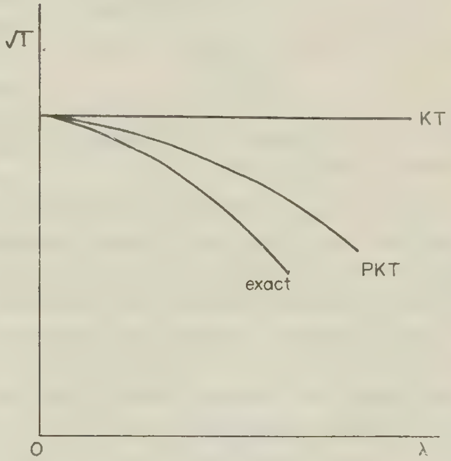

Fig. 4. Dependence of $\sqrt{I}$ on λ for fixed D.

From Fig. 3 and Fig. 4, it is clear that the three intensities all coincide with each other in the limit $\lambda D \to 0$. It is noted that the structure factor of PKT $F^P(\boldsymbol{K}, \boldsymbol{K}_o)=\sum_i f^P{}_i(\boldsymbol{K}, \boldsymbol{K}_o) \times \exp[-2\pi i(\boldsymbol{K}-\boldsymbol{K}_o)\cdot \boldsymbol{r}_i]$ depends upon λ and approaches the structure factor of KT $F(\boldsymbol{K}-\boldsymbol{K}_o)$ in the limit $\lambda \to 0$. Here f^P is the rigorous atomic scattering amplitude in which the multiple scatterings within the atom are taken into account.

Ibers & Hoerni[13] calculated f^P for 40 KV by the method of partial waves for selected atoms of the atomic numbers ranging from 1 to 98 using the Thomas-Fermi potential in the approximate from the Rozental.[14] According to the result, the value of $|f^P|$ differs for heavy atoms considerably from the Born approximation value f calculated for the same potential (Fig. 5). Thus, at the usual voltages the discrepancy between the exact and KT value may be considerable for thicknesses around D_0 when heavy atoms are contained. This is supported by the fact[1] that the electron diffraction by gas molecules can be explained by PKT but it can not by KT at the voltages 10 -80 KV. Thus, when we say that the exact value approaches KT value in the limit $\lambda D \to 0$, it implies that D must be reduced to a value smaller than the atomic diameter if the voltage is fixed to say 80 KV, or that the voltage must be increased much higher than 80 KV if D is fixed to a physically possible value.

According to the numerical calculation by Fujimoto,[5] the exact intensity coincides with

---

* Peak intensity. The conclusion of this section holds also for the integrated intensity.

KT value within the error of 3% for 111-reflection from Au of the thicknesses smaller than 15 A at $2\pi/\lambda=100$ A^{-1} (37 KV). On the other hand, from the value of $|f^{P}{}_{An}|$ calculated by Ibers & Hoerni, it is found that $I^{P}{}_{111}/I^{K}{}_{111}=0.784$ for 40 KV for the same crystal, where $I^{P}{}_{111}$ and $I^{K}{}_{111}$ are the intensity of 111-reflection given by PKT and by KT, respectively. Thus the exact intensity must differ from that of KT by about 20% for $D\approx D_0=4.07$ A. The conflicting result of the two calculations may be caused by the neglecting of the accidental interactions in Fujimoto's calculation.

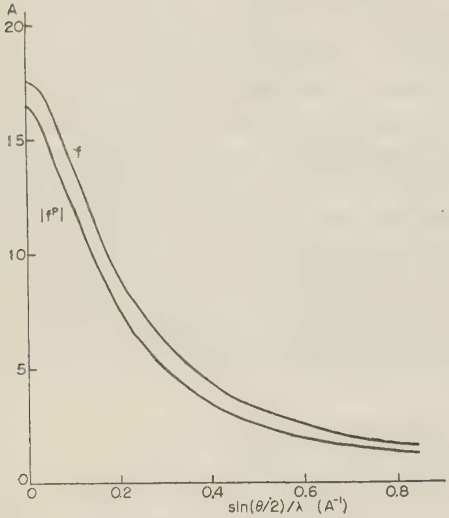

Fig. 5. Comparison of $|f^P|$ for 40KV and f for Tl. Thomas-Fermi potential (Rozental form) is used.

For usually available values of λ and D, the exact intensity can neither be approximated by KT value nor by PKT value. Therefore, the method of extrapolation is needed in order to obtain the intensity of KT or PKT. If we extrapolate the observed (exact) intensity to $\lambda=0$ at a fixed value of D, KT intensity will be obtained, In the method proposed by Honjo & Kitamura[7] the diffraction patterns are taken for various λ and the intensity in the limit $\lambda\to 0$ is obtained. It is also possible in principle to extrapolate the intensity to $D=D_0$ at a fixed value of λ and obtain PKT intensity. But the reflections for which the procedure is valid are limited on account of the condition of non-overlap. Moreover the procedure is experimentally impossible even for the reflections for which the condition of non-overlap is satisfied. Thus, PKT is not applicable to the structure analysis of crystals, while KT is convenient for the purpose. Theories by Miyake,[3] Fujimoto[4] and Fujiwara[6] provide the theoretical basis for the method by Honjo & Kitamura.

The present problem was suggested to the author by Prof. Ryozi Uyeda.

In conclusion, the author wishes to express his sincere thanks to Prof. Ryozi Uyeda for his kind guidance throughout this work. The author's thanks are also due to Dr. Y. Kainuma for his valuable suggestions and discussions.

Appendix

(I) Derivation of (30)

The integral in eq. (25) is calculated as follows.[12]

$$\int\frac{f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)}{\boldsymbol{k}^2-\boldsymbol{K}_0{}^2}\,d\boldsymbol{k}=\mathrm{P}\int d\boldsymbol{k}+\int\limits_{\text{singular}}d\boldsymbol{k}\qquad.$$

Taking the polar and the azimuthal angle θ,φ and writing $f_i(\boldsymbol{K}-\boldsymbol{k})\,f_i(\boldsymbol{k}-\boldsymbol{K}_0)\equiv g(k,\,\theta,\,\varphi)$,

$$\int\limits_{\text{singular}}d\boldsymbol{k}=\iiint\limits_{\text{singular}}\frac{g(k,\theta,\varphi)}{k^2-K_0{}^2}k^2\sin\theta dkd\theta d\varphi=\iint\sin\theta d\theta d\varphi\int\limits_{\text{singular}}\frac{g(k,\theta,\varphi)}{(k-K_0)(k+K_0)}k^2dk$$

$$=\iint\sin\theta d\theta d\varphi\pi i\frac{g(K_0,\theta,\varphi)}{2K_0}K_0{}^2=\frac{i\pi}{2K_0}\int\limits_{\substack{\text{Ewald}\\\text{sphere}}}f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)d\sigma.$$

Thus eq.(25) can be written as

$$\Phi^{P(2)}(\boldsymbol{K},\boldsymbol{K}_0)=\frac{1}{\pi}L(\boldsymbol{b})\sum_i\exp\left[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]\left[\frac{i\pi}{2K_0}\int\limits_{\substack{\text{Ewald}\\\text{sphere}}}f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)d\sigma\right.$$

$$\left.+\mathrm{P}\int\frac{f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)}{\boldsymbol{k}^2-\boldsymbol{K}_0{}^2}d\boldsymbol{k}\right].\qquad\text{(A1)}$$

Taking into account that $f(\boldsymbol{b})$ changes only a little when $\boldsymbol{b}$ changes by an amount of the order of a^*, we have

$$\left.\begin{aligned}&\int\limits_{\substack{\text{Ewald}\\\text{sphese}}} f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)d\sigma \approx \frac{1}{S_0}\sum_G \frac{K_0}{K_{gz}} f_i(\boldsymbol{K}-\boldsymbol{K}_g)f_i(\boldsymbol{K}_g-\boldsymbol{K}_0),\\ &\mathrm{P}\int \frac{f_i(\boldsymbol{K}-\boldsymbol{k})f_i(\boldsymbol{k}-\boldsymbol{K}_0)}{\boldsymbol{k}^2-\boldsymbol{K}_0^2}d\boldsymbol{k} \approx \frac{1}{S_0}\sum_G \frac{1}{2K_{gz}}\,\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{K}-\boldsymbol{K}_g-\rho\boldsymbol{\nu})f_i(\rho\boldsymbol{\nu}+\boldsymbol{K}_g-\boldsymbol{K}_0)}{\rho}d\rho.\end{aligned}\right\} \tag{A2}$$

Substituting (A2) into (A1), we obtain eq. (30)

(II) Derivation of (32)

For a crystal plate of one unit cell thickness with an area $|M_1\boldsymbol{a}_1\times M_2\boldsymbol{a}_2|$, we have from (14), for large M_1 and M_2,

$$L(\boldsymbol{b})\approx\sum_{G1}\sum_{G2}\delta(\xi-G_1)\,\delta(\eta-G_2), \tag{A3}$$

where G_1 and G_2 are integers and $\boldsymbol{b}=\xi\boldsymbol{a}_1^*+\eta\boldsymbol{a}_2^*+\zeta\boldsymbol{a}_3^*$. Eq. (32) is obtained from eq. (28) by the help of eqs. (13) and (A3).

(III) Expressions of A, B, A', B' and B''

$$A=\frac{i}{S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_i\exp[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i]f_i(\boldsymbol{b}-\boldsymbol{g})f_i(\boldsymbol{g}), \tag{A4}$$

$$B=\frac{1}{\pi S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_i\exp[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i]\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu})f_i(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}d\rho,$$

$$A'=\frac{i}{S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_{i\neq j}\sum\exp[-2\pi i(\boldsymbol{b}-\boldsymbol{g})\cdot\boldsymbol{r}_i]\exp[-2\pi i\boldsymbol{g}\cdot\boldsymbol{r}_j]f_i(\boldsymbol{b}-\boldsymbol{g})f_j(\boldsymbol{g}), \tag{A5}$$

$$\begin{aligned}B'=\frac{1}{\pi S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum_{i\neq j}\sum\exp[-2\pi i(\boldsymbol{b}-\boldsymbol{g})\cdot\boldsymbol{r}_i]\exp[-2\pi i\boldsymbol{g}\cdot\boldsymbol{r}_j]\\ \times\mathrm{P}\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}\cos 2\pi(z_i-z_j)\,\rho d\rho,\end{aligned}$$

$$\begin{aligned}B''=\frac{i}{\pi S_0}L(\boldsymbol{b})\sum_G\frac{1}{2K_{gz}}\sum\sum_j\exp[-2\pi i(\boldsymbol{b}-\boldsymbol{g})\cdot\boldsymbol{r}_i]\exp[-2\pi i\boldsymbol{g}\cdot\boldsymbol{r}_j]\\ \times\int_{-\infty}^{\infty}\frac{f_i(\boldsymbol{b}-\boldsymbol{g}-\rho\boldsymbol{\nu})f_j(\rho\boldsymbol{\nu}+\boldsymbol{g})}{\rho}\sin 2\pi(z_i-z_j)\rho d\rho\ .\end{aligned}$$

(IV) Comparison of A' with A

Eqs. (A4) and (A5) can be approximately written as

$$A\approx\frac{i}{S_o}L(\boldsymbol{b})\ \frac{1}{2K_{oz}}\sum_i\exp[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i]\ S_{ii}(\boldsymbol{b}), \tag{A6}$$

$$A'\approx\frac{i}{S_o}L(\boldsymbol{b})\ \frac{1}{2K_{oz}}\sum_i\exp[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i]\sum_j{}'\ S_{ij}(\boldsymbol{b}), \tag{A7}$$

where $\sum_j{}'$ represents the summation over j excluding $j=i$. $S_{ij}(\boldsymbol{b})$ is given by

$$S_{ij}(\boldsymbol{b})=\sum_G f_i(\boldsymbol{b}-\boldsymbol{g})f_j(\boldsymbol{g})\exp[-2\pi i\boldsymbol{g}\cdot(\boldsymbol{r}_j-\boldsymbol{r}_i)]. \tag{A8}$$

In the case where the number of atoms in the unit cell is small and their atomic numbers are nearly equal,

$$\frac{A'}{A}\sim\frac{\sum_j{}'\ S_{ij}(\boldsymbol{b})}{S_{ii}(\boldsymbol{b})}\equiv\sum_j{}'\ Q_{ij}\ . \tag{A9}$$

For the reflections of low indices, $|Q_{ij}|$ is determined almost solely by s_{ij}, where s_{ij} is the smallest distance between i-atom and j-atom projected on the plane perpendicular to $\boldsymbol{K}_o$ (Fig. 6.). $|Q_{ij}|$ decreases monotonously from unity to zero when s_{ij} increases from zero to infinity. $|Q_{ij}|$ is negligibly small in comparison to unity when s_{ij} is larger than the sum of the screening distances (a_i+a_j) of the atomic potentials of i-atom and j-atom. Here the screening distance a_i is such a distance that $\phi_i(r)\ll 1$ for $r>a_i$, where $\phi_i(r)$ is the screening function of the atomic potential of i-atom. An example of curve $Q_{ij}(s_{ij})$ is given in Fig. 7.

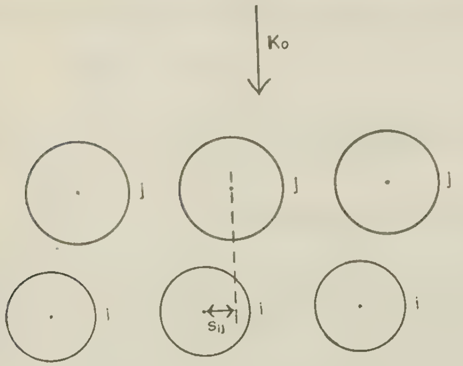

Fig. 6. Illustration of overlap of atom.

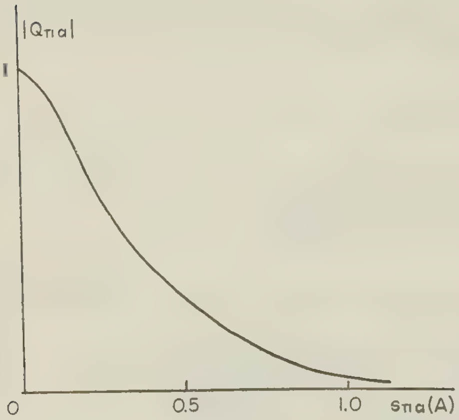

Fig. 7.

Thus we see that A' is small in comparison to A when s_{ij} is larger than (a_i+a_j) for every pair of atoms i, j. This is the condition of non-overlap mentioned in § 3.

The rapid decrease of $|Q_{ij}(s_{ij})|$ with increasing s_{ij} is due to the summation over all $\boldsymbol{G}$'s in (A8). The summation means that the accidental interactions as well as the systematic interactions are taken into account. If the summation is made only over the systematic interactions, $|Q_{ij}(s_{ij})|$ does not decrease so rapidly.

(V) Comparison between (34) and (35)

Eqs. (34) and (35) are written in the form of (33). The expressions of A, B, A' etc. in this case are easily found by comparing (34) and (35) with (30) and (32). An order estimation of these quantities shows that also in this case B' and B'' are negligible compared to B. A, A', S_{ij} and Q_{ij} are given by

$$A=\frac{i}{2K_o}\sum_i \exp\left[2\pi i(\boldsymbol{K}-\boldsymbol{K}_o)\cdot\boldsymbol{r}_i\right] S_{ii}(\boldsymbol{K}-\boldsymbol{K}_o), \tag{A10}$$

$$A'=\frac{i}{2K_o}\sum_i \exp\left[2\pi i(\boldsymbol{K}-\boldsymbol{K}_o)\cdot\boldsymbol{r}_i\right]\sum_j{}' S_{ij}(\boldsymbol{K}-\boldsymbol{K}_o), \tag{A11}$$

$$S_{ij}(\boldsymbol{K}-\boldsymbol{K}_o)=\int_{\substack{\text{Ewald}\\ \text{sphere}}}\exp\left[-2\pi i(\boldsymbol{k}-\boldsymbol{K}_o)\cdot(\boldsymbol{r}_j-\boldsymbol{r}_i)\right] \times f_i(\boldsymbol{K}-\boldsymbol{k})f_j(\boldsymbol{k}-\boldsymbol{K}_o)d\sigma, \tag{A12}$$

$$Q_{ij}=S_{ij}/S_{ii}$$

Q_{ij} is found to decrease rapidly with increasing s_{ij} as in the case of Appendix (IV). In the summation over j in $\sum_j{}' S_{ij}(\boldsymbol{K}-\boldsymbol{K}_o)$ of (A11), only the atoms in the neighbourhood of the i-th atom must be taken into account. If non of those atoms overlap the i-th atom, then $\sum_j{}' S_{ij}\ll S_{ii}$. When the condition $\sum_j{}' S_{ij}\ll S_{ii}$ holds for most of the i-th atom, we have $A'\ll A$ from (A10) and (A11) assuming the randomness of the phases $\exp\left[2\pi i(\boldsymbol{K}-\boldsymbol{K}_o)\cdot\boldsymbol{r}_i\right]$.

Magnetic Properties of Potassium Iron Group Fluorides KMF_3

By Kinshiro HIRAKAWA*, Kazuyoshi HIRAKAWA** and
Takasu HASHIMOTO*

**Department of Physics, **General Education Department, Kyusyu University, Fukuoka*

(Received August 5, 1960)

Evidence of antiferromagnetism in perovskite-type potassium iron group fluoride KMF_3 was found through the susceptibility measurements made between 80°K and 700°K. The obtained results are as follows:

Compounds	T_N(°K)	θ(°K)	C_M	p
$KMnF_3$	88	158	4.73_5	6.15
$KFeF_3$	113	—	—	—
$KCoF_3$	114	125	3.07_5	4.95
$KNiF_3$	275	843	2.41_5	4.39
$KCuF_3$	243	355	0.58_7	2.16

T_N: Néel point, θ: paramagnetic Curie temperature,
C_M: Curie constant, p: effective Bohr-magneton number.

Additional thermal analysis was also made in order to confirm the Néel points. The magnetic properties of these compounds are reviewed and brief discussions of our results are given.

§ 1. Introduction

Recently, the magnetic properties of compounds with relatively simple structures, for example, MO, MF_2, MF_3, $LaMO_3$, etc.,[1] have been investigated experimentally and theoretically in detail. We have been interested in the magnetic properties of the series of KMF_3, which has the perovskite structure. Although $LaMO_3$[2] and MF_3[3] are similar to KMF_3 as regards crystal structure, the M ions in the former two series are trivalent and it is not always easy to obtain the compounds with ideal composition or to prepare the specimens in the form of single crystals. On the other hand, the M ions in the latter are divalent and cover all of the more-than-half transition metal ions ranging from Mn^{2+} to Cu^{2+}, and it is possible to obtain their single crystals. In these materials, we may expect to obtain plenty of information about the superexchange and anisotropy mechanisms, since the M ions are arranged on the simple cubic lattice with a F^- ion in the center of each two adjacent M^{2+} ions. A detailed X-ray investigation on the crystals prepared by us have been performed by Okazaki et al.,[4] whose results are shown in Table I.

Table I. Lattice parameters of KMF_3

Compounds	values at 298°K (Å)
$KMnF_3$	a; 4.191 ± 0.001
$KFeF_3$	a; 4.122 ± 0.001
$KCoF_3$	a; 4.069 ± 0.001
$KNiF_3$	a; 4.015 ± 0.001
$KCuF_3$	$A(=\sqrt{2}a)$; 5.855 ± 0.002 $C(=2c)$; 7.852 ± 0.004 (Tetragonal)

On the course of our studies, we came to know the results of investigation made by Martin et al.[5] They have found the Néel points of this series to be $KMnF_3$(incomplete), $KFeF_3$(115°K), $KCoF_3$(135.3°K), $KNiF_3$(275°K), $KCuF_3$(<100°K) respectively. Recently, Shulman et al observed the N.M.R. shift of F^{19} and Co^{59}, F^{19} in $KMnF_3$[6] and $KCoF_3$[7] respectively. Ogawa[8] measured the susceptibility of $KMnF_3$. Their results are not always in agreement with our results. In this paper, our measurements of the powder susceptibility will be described and the magnetic properties of this series will be reviewed.

§2. Preparation of the Specimens

All specimens were prepared from the reagent grade of chemicals. The employed methods of preparation will be described for each compound.

$KMnF_3$:

We obtained $KMnF_3$ in the precipitated form from the aqueous solutions of the weighted 3KF and $MnCl_2 \cdot 4H_2O$. The precipitates packed in the carbon crucible were dried in vacuum and melt in the argon atmosphere to crystallize. Another method is to melt the precipitates in the nitrogen atmosphere with KCl or KI as a flux. Thus we obtained white transparent (with a dash of pink) crystals. The specimens obtained by these two methods showed completely the same magnetic properties.

$KFeF_3$:

The preparation of $KFeF_3$ is the most difficult. The precipitates obtained from $FeCl_2$ and KF reaction have a pseudo-perovskite structure and are ferrimagnetic below ~110°K. This ferrimagnetism may perhaps arise from the Fe^{3+} contamination in the starting material $FeCl_2$. By melting there precipitates in the argon atmosphere, we could obtain rectangular brown crystals of $KFeF_3$, which were proved to be cubic by X-ray analysis. As these crystals are mixed with a little amount of magnetite, we could not obtain a quantitative results; they are however not ferrimagnetic but antiferromagnetic below 113°K.

$KCoF_3$ and $KNiF_3$:

The concentrated aqueous solutions of $CoCl_2$ and $KF \cdot HF$ were mixed and the water was evapolated at 90°C. When a proper amount of $KCoF_3$ precipitated, the remained KCl and HF were fully washed out by boiled water. The powder was then dried in vacuum at about 200°C. $KNiF_3$ was also prepared by the same method.

$KCuF_3$:

At first, $CuCO_3$ was dissolved into an excess equeous solution of HF, then an adequate composition of KF was added. This dilute solution was kept in the temperature controlled (90°C) drying furnace, then excess water and HF were evaporated. By using this method we could obtain crystals of $KCuF_3$ slightly with coloured violet and about 2×2×1 m/m in size.

Because of the difficulty of the chemical analysis of F^-, we could not know the precise composition of these compounds. Only comparison between the diffracted intensity and density gave information or regards the composition.

§3. Susceptibility measurements

Susceptibility was measured in the nitrogen atmosphere by the use of the automatic recording magnetic balance of Hirone type.[9] For the determination of the absolute value, Gouy's method was employed. Temperatures were measured by a fine copper-constantan thermocouple (~0.1 mmϕ). The correction for the exerted force due to the constantan wire becomes considerably significant at temperatures below ~150°K, especially in the measurements of the low susceptibility compounds such as $KNiF_3$ and $KCuF_3$. The errors of the susceptibility measurements are estimated to be less than one percent.

§4. Results and discussions

$KMnF_3$*: Fig. 1 shows the measured, gram susceptibility χ in the case of heating run. The Néel point is estimated to be 88°K, below which the susceptibility strongly depends upon the field strength, suggesting that the crystal has a weak ferromagnetic component. Under field strengths higher than 5,000 gauss the susceptibility in the antiferromagnetic region does not depend on temperature showing that the spin moment is flopped into a plane perpendicular to the field direction. Such an easy flopping is convincing if we consider that Mn^{2+} is in ^{6}S state and is on the simple cubic lattice points for which there should be no dipole-dipole interaction. At a temperature a little above the Néel point the susceptibility curve shows a kink. The origin of the occurrence of this kink is not understood at present, but the observed curve for KMnF$_3$ is very similar to that for MnCO$_3$.[12] The susceptibility follows the Curie-Weiss law above about 200°K but not below it. X-ray determination of our sample shows that, below about 200°K, the crystal becomes tetragonally deformed. The observed paramagnetic Curie temperature θ is 158° and the effective Bohr-magneton number p is 6.15, which is somewhat larger than the free spin value 5.92 for Mn^{2+}.

---

* Dr. Portis et al have made torque[10], X-ray[11] and microwave[10] measurements on $KMnF_3$. Their results are consistent to our results. We would like to express our thanks to Dr. Portis for kindly supplying their preprints.

KFeF$_3$: As the preparation of this specimen is difficult, the measured susceptibility will be reported very briefly. Fig. 2 shows the measured results. This specimen contains evidently a trace of magnetite, but it may be pointed out that below 113°K KFeF$_3$ becomes antiferromagnetic.

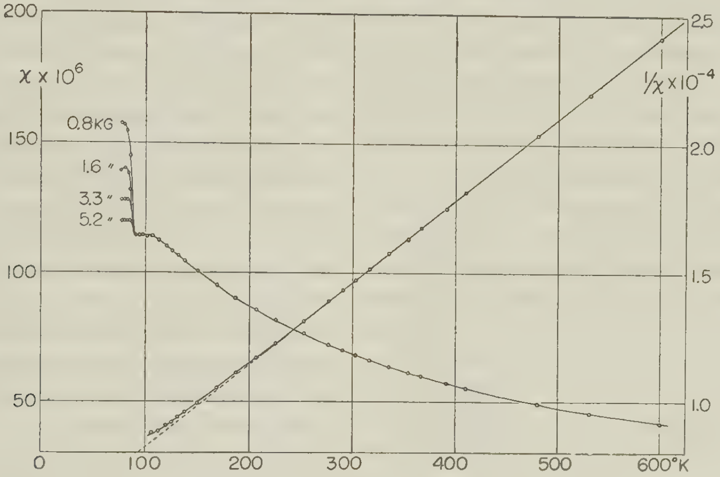

Fig. 1. Gram susceptibility (inverse susceptibility) versus temperature curve for KM$_n$F$_3$.

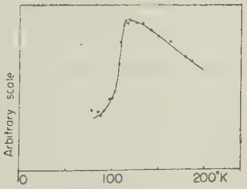

Fig. 2. The susceptibility-temperature curve for KF$_e$F$_3$, which contains a trace of magnetite.

KCoF$_3$: Fig. 3 shows the measured susceptibility of KCoF$_3$. Below 114°K χ decreases monotonically with falling temperature, thus 114°K is thought to be the Néel point. In some specimens the $\chi_{\max}$ point was about 20 degrees higher than 114°K. But the results

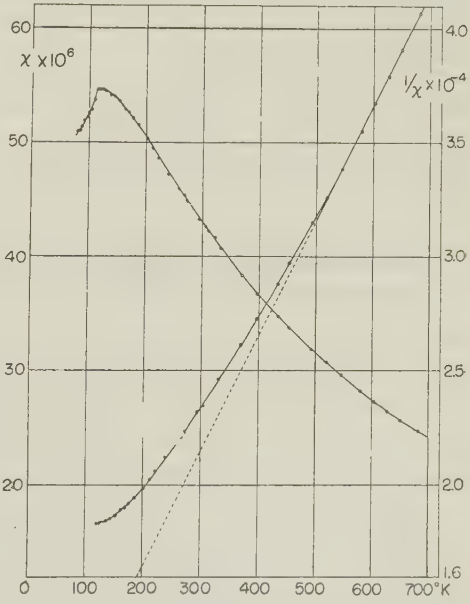

Fig. 3. Gram susceptibility (inverse susceptibility) versus temperature curve for KC$_0$E$_3$.

of X-ray and calorimetric measurements suggest that 114°K is more preferrable*. The paramagnetic susceptibility follows the Curie-Weiss law above~500°K, but deviates below it. The values of θ, C_M and p obtained in the region between~500°K and 700°K are 125°, 3.07 and 4.95, respectively.

θ/T_N is 1.09 which is the smallest in this series. As the θ/T_N value of $KMnF_3$ is 1.80, the lower θ/T_N value in $KCoF_3$ may be, as pointed out by Kanamori[13] for CoO, the effect of the residual orbital moment of Co^{2+} in the cubic field. The temperature dependence of χ, the value of C_M and p are very similar to those of CoO measured by La' Blanchetais[14]. As is well known, the lowest orbital triplet of Co^{2+} in the cubic field is split into three levels with $j=1/2$, $3/2$ and $5/2$ by the L-S coupling. As these level separations are of the order of kT which corresponds to the temperatures of measurements, one may be able to expect a considerable deviation of χ from the Curie-Weiss law. An analysis of such a case has been made with success by Kanamori[13] for CoO.

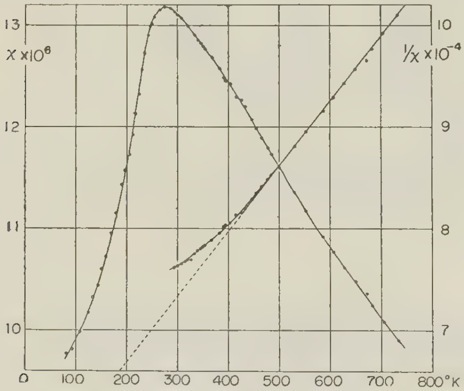

Fig. 4. Gram susceptibility (inverse susceptibility) versus temperature curve for KN_iF_3.

$KNiF_3$: The measured susceptibilities of $KNiF_3$ are shown in Fig. 4. A fairly broad maximum was found at 275°K, below which χ decreases in the usual manner and the ratio $\chi_{T=0}/\chi_{max}$ is 9.0/13.2=0.68 which is very nearly 2/3. We examined further the field dependence of susceptibility below the Néel point, but no change was detected at all. Thus we suggest that the spin moment of Ni^{2+} in $KNiF_3$ is fixed to the crystal axis. In the paramagnetic region χ obeys the Curie-Weiss law with $\theta=840°$ and $p=4.39_4$, but again deviates from it below~400°K. This deviation may be the effect of short range order still remaining above the Néel point. It is noted, however, that the observed θ and p are unusually large compared with $T_N=275°K$ and $p=2\sqrt{S(S+1)}=2.82$ for the free spin value of Ni^{2+}. Such a high p has also been observed in NiO (p=4.6) by Singer.[15]

In order to interpret this, we subtract tentatively a temperature independent susceptibility $\chi_c=3.5\times10^{-6}$ (or $\chi_{mol\ c}=5.6=10^{-4}$) from the observed paramagnetic susceptibilities and get the corrected value of θ and p as 300° and 2.80, respectively, both of which are reasonable value. In the cubic field the orbital levels of Ni^{2+} consist of higher two triplets and the lowest singlet and the separations are usually fairly large compared with kT. Thus the temperature independent term χ_c may be the Van Vleck paramagnetism plus a small part of diamagnetism due to the constituent nonmagnetic ion cores.

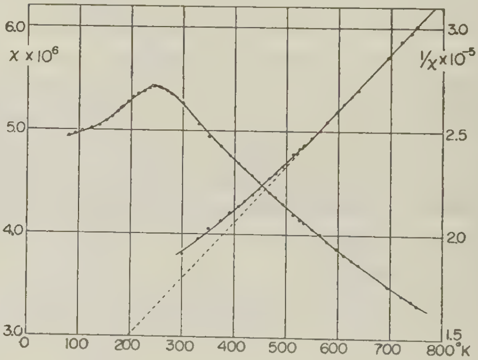

Fig. 5. Gram susceptibility (inverse susceptibility) versus temperature curve for $KCuF_3$.

$KCuF_3$: Fig. 5 shows the susceptibility of $KCuF_3$. A broad maximum in $\chi-T$ curve was observed at 243°K, below which χ decreases slowly with falling temperature. The Curie-Weiss law is applicable at temperatures higher than 500°K. Because of the small susceptibility, the magnetic properties of $KCuF_3$ are very sensitive to diamagnetic corrections or contamination of other paramagnetic salts. From the observed data, without any diamagnetic corrections for K^+ and F^-, we obtained $\theta=355°$ and p=2.16. As the lowest orbital state for Cu^{2+} in the cubic field is $d\gamma$, p should be very nearly 1.73, which is the free spin value of Cu^{2+}. The experimentally obtained p=2.16 is considerably higher than 1.73, and if suitable diamagnetic corrections are made p will become still larger. As in the case of $KNiF_3$, we may be able to consider the Van Vleck paramagnetism due to the upper $d\varepsilon$ orbits, but no reasonable explanation for θ and p has been found at present. It may possible that $KCuF_3$ has an A-type[16] antiferromagnetic spin structure as in $LaMnO_3$ and MnF_3 because the Cu^{2+} has, like Mn^{3+}, an unpaired electron in $d\gamma$ orbits and by X-ray studies[17] it has been confirmed that the crystal has a large Jahn-Teller distortion very similar to that in $LaMO_3$ or MF_3. Thus, $KCuF_3$ would might have an A-type structure, and one might expect a small or rather negative θ/T_N, because in the A-type structure there exists ferromagnetic nearest neighbour coupling within the {001} planes. This is the case for MnF_3 studied by Bozorth and Nielson[18]. In our case, however, θ/T_N is positive and not so small compared to unity. Thus at present we are not certain whether or not $KCuF_3$ has an A-type structure.

---

* T_N for $KCoF_3$ has been reported to be 135.3°K after Martin et al[5] and 137°K in the paper of Schulman.[7]

§ 5. Thermal analysis

In order to ascertain in another way the antiferromagnetic transition of the substances thermal analysis was made by a simple method (a type of conduction calorimeter). Measurements were made on $KCoF_3$, $KNiF_3$ and $KCuF_3$. A typical sharp anomalous hump in specific heat curve was observed at 109°K for $KCoF_3$, 253°K for $KNiF_3$ and 220°K for $KCuF_3$. These temperatures are all somewhat lower than the corresponding temperatures T_N, found by susceptibility measurements. Although any marked changes of the crystal symmetry of $KNiF_3$ and $KCuF_3$ have not been observed by X-ray, we believe that the antiferromagnetic transition was comfirmed. The fact that T_N determined from susceptibility measurements are higher than those from thermal analysis is a common fact, and it has been explained by Nakamura[19] as due to statistical effects.

§ 6. Conclusion

The details of the present experiment and discussions of the results were already des-

** Tetragonally deformed perovskite structure.

cribed for each compound KMF_3. In Table II the characteristic magnetic properties of this series are summarized.

It is interesting to compare the T_N of the KMF_3 series to those of other cubic compounds such as MF_3, $LaMO_3$ and MO, because in the crystal of perovskite structure T_N may be a direct measure of the superexchange among the M ions. This is shown in Table III. Unfortunately, full comparison with other perovskite type compounds can not be made. But it may be pointed out that in the MO series T_N becomes successively higher toward high d electron compounds, while in the KMF_3 series it may be classified into high T_N group of more than $d\varepsilon^6 d\gamma^2$($KNiF_3$ and $KCuF_3$) and low T_N group of less than $d\varepsilon^6 d\gamma^2$ ($KMnF_3$, $KFeF_3$, and $KCoF_3$).

Lastly it is pointed out that the susceptibilities of this series show not necessarily a sharp maximum at their Néel point and the Curie-Weiss law is applicable only at higher temperatures than twice as large as their Néel temperatures. As a matter of fact, we observed in some of the crystallized specimen of KMF_3, a temperature independent susceptibility in a wide range immediately above the Néel temperature, like in the case of $ZnFe_2O_4$.[20] It is not certain at present whether this result is due to the effect of some special properties of short range order in such a type of crystal or to a certain incompleteness of their crystals.

We wish to express our hearty thanks to Prof. Nagamiya and Dr. Nakamura of Osaka University for their kind interests and encouragements, to Mr. Okazaki for showing us his unpublished X-ray data and to Osaka Oxygen Company for kindly supplying us liquid nitrogen. A part of this research was supported by the scientific expenditure of Ministry of Education.

The Perturbation Method due to the Small Change in the Shape of the Boundary*

By Tomoyuki SAITO*

*Tokyo University of Agriculture and Technology***
Koganei, Tokyo

(Received April 25, 1960)

A general method is presented for estimating the effect caused by a small change in the boundary shape (or the hypersurface shape in the many-dimensional space, the time-coordinate being included) upon the solutions or eigenvalues of linear partial differential equations (elliptic, parabolic or hyperbolic). When the given boundary is slightly deformed from a shape favorable for obtaining the solutions, this method gives the approximate solutions or eigenvalues based upon the exact or unperturbed ones for the case of the favorable shape, where many solutions can be obtained easier. The following illustrative examples are given, showing the validity of the method presented: (1) The eigenfrequencies of the lateral vibration of a uniform membrane fixed at its boundary close to a circle in shape, e.g. elliptic, oval, cinquefoil-shaped, etc. (2) The eigenvalue problem concerning the heat conduction of a "corned-beef-can"-shaped uniform matter, close to a rectangular parallelepiped in shape and with its temperature being kept constant on the boundary surface. (3) Three boundary-value problems representing the parabolic, hyperbolic and elliptic cases, respectively.

§ 1. Introduction

Generally speaking, the partial differential equations in physics are laid to be solved, not alone, but always together with boundary-conditions. For boundaries of favorable shapes (or "favorable boundaries" for short), such as circle, sphere, rectangular parallelepiped, etc., many have been solved analytically. For boundaries of rather irregular or unfavorable shapes (or "unfavorable boundaries"), however, it is generally difficult to solve the equations analytically, except in some special cases. But, when the deviation of the given boundary from a favorable one is small, the very situation makes a method for approximate solutions possible.

Two ways of approach have been presented; the one commenced by Brillouin(1) consists in expanding the perturbed solution by the eigenfunctions of the unperturbed, exactly solvable problem. It needs to solve a secular equation of infinite order, the solution obtained diverges in most cases, and so only a few problems have been solved by this method.

The other method, introduced by Oshida et al.,(2) seems more promising, for it surmounts the difficulty by the use of an appropriate transformation of the variables, changing the shape of the boundary to a favorable one. In general, this transformation makes the original equation more complicated, but, if the transformation is small, the transformed equation can be treated by a method similar to the one familiar in the ordinary theory of perturbation.

The latter method is not generally known, nor to be said well-established, in spite of its applicability to the wide field of mathematical physics. In this paper, the present author generalizes the method extensively, giving the formulae in a form immediately applicable to the vast field of mathematical physics. These formulae are sufficiently compact and are as easily handled as those in the ordinary perturbation method.

Concerning the extension of the method, a new technique is presented in boundary-value problems (in the broader sense, including so-called initial-value problems), which makes the problems with time-dependent boundary-conditions solvable, by admitting the time-coordinate into the method.

Although the practical terminology, "unfavorable" and "favorable", is used from the point of view of contributing to the intimate connection between the theory and its practical application, the discussion concerns only the two categories of boundaries, "given or deformed" and "undeformed", and so it is not necessary that the former should be always "unfavorable" and the latter "favorable", since the present paper aims originally at the effect which a slight deformation of the boundary has upon the solutions or eigenvalues.

---

* Read at the 15th Annual Meeting of the Physical Society of Japan, on April 5, 1960.

§2. General Principles

1. *The introduction of the one-to-one mapping between the two boundaries, given and favorable.*

A linear partial differential equation (or simply "equation" for short, when there is no fear of confusion)

$$L\Psi(x) = -h(x) \tag{1}$$

is given with some specified boundary-condition on its specified boundary

$$C: \quad S(x)=0 \quad \text{or} \quad x=X(\lambda) \tag{2}$$

in the N-dimensional space (including the time-axis, as the case may be). **L** is a linear partial differential operator, $\Psi(x)$ the solution to be sought for, $h(x)$, $S(x)$ and $X(\lambda)$ the given functions of x and λ, respectively, continuously differentiable with respect to their arguments up to the requested order, x and λ representing symbolically the independent variables x^α and the independent parameters λ^i, with the indices α and i obeying the following rule:

Any index is assumed (unless any special mention is made) to vary from 1 to N, or from 1 to N–1, according as it is Greek or Latin, respectively. Also, any index appearing twice in one term should be regarded as a "summation-index", as is familiar in tensor calculus.

If the given boundary C is slightly deviated from the favorable one

$$C: \quad S^{(0)}(x)=0 \quad \text{or} \quad x=X^{(0)}(\lambda) \tag{3}$$

the functions S and X in Eq. (2) will be expanded in power series of a small quantity ϵ ($|\epsilon| \ll 1$), respectively, as follows:

$$S(x)=S^{(0)}(x)+\epsilon S^{(1)}(x)+\epsilon^2 S^{(2)}(x)+\dots$$
$$X(\lambda)=X^{(0)}(\lambda)+\epsilon X^{(1)}(\lambda)+\epsilon^2 X^{(2)}(\lambda)+\dots \tag{4}$$

where $S^{(n)}(x)$ and $X^{(n)}(\lambda)$, $n=0, 1, 2, \dots$, are the known functions of x and λ, respectively, sufficiently qualified concerning their differentiability with respect to their arguments, etc.

Now, suppose that the following transformations (5) and (6) are one-to-one mappings, of the given domain D (together with the surrounding boundary C) onto the favorable domain D_0 (together with the surrounding boundary C_0), and merely of the given boundary C onto the favorable one C_0, respectively:

$$x^\alpha=\bar{x}^\alpha+\epsilon\varphi^{(1)\alpha}(\bar{x})+\epsilon^2\varphi^{(2)\alpha}(\bar{x})+\dots$$

or, symbolically,

$$x=\bar{x}+\epsilon\varphi^{(1)}(\bar{x})+\epsilon^2\varphi^{(2)}(\bar{x})+\dots \tag{5}$$

and

$$\lambda^i=\bar{\lambda}^i+\epsilon\Lambda^{(1)i}(\bar{\lambda})+\epsilon^2\Lambda^{(2)i}(\bar{\lambda})+\dots$$

or, symbolically,

$$\lambda=\bar{\lambda}+\epsilon\Lambda^{(1)}(\bar{\lambda})+\epsilon^2\Lambda^{(2)}(\bar{\lambda})+\dots \tag{6}$$

where $\varphi^{(1)\alpha}(x)$, $\varphi^{(2)\alpha}(x)$, ... and $\Lambda^{(1)i}(\lambda)$, $\Lambda^{(2)i}(\lambda)$, ... are the functions of x and λ, respectively, the former ("domain-to-domain deviation functions", so to speak) being defined in and in the neighborhood of D_0, and the latter ("boundary-to-boundary deviation functions", so to speak) being defined on C_0, both qualifying the geometrical deviation of the given boundary from the favorable one. not independent of each other as a matter of course, as is shown in Eq. (13), and being, of course, assumed to be continuously differentiable with respect to their arguments up to the requested order.

Here, ϵ is assumed to be sufficiently small to make the Jacobian to be positive, therefore permitting the following "inverse" transformations (writing symbolically):

$$\bar{x}=x-\epsilon\varphi^{(1)}(x)-\epsilon^2\{\varphi^{(2)}(x)-\boldsymbol{D}^{(1)}\varphi^{(1)}(x)\}-\cdots \tag{7}$$

and

$$\bar{\lambda}=\lambda-\epsilon\Lambda^{(1)}(\lambda)-\epsilon^2\{\Lambda^{(2)}(\lambda)-\boldsymbol{D}^{(1)}{}_{(\lambda)}\Lambda^{(1)}(\lambda)\}-\cdots \tag{8}$$

respectively, with $\boldsymbol{D}^{(1)}$ and $\boldsymbol{D}^{(1)}{}_{(\lambda)}$ being defined in Eq. (11).

Eqs. (4) are rewritten in terms of $\bar{x}$ and $\bar{\lambda}$, respectively, by means of Eqs. (5) and (6), as follows:

$$\begin{aligned}S(x)=S^{(0)}(\bar{x})&+\epsilon\{S^{(1)}(\bar{x})+\boldsymbol{D}^{(1)}S^{(0)}(\bar{x})\}\\&+\epsilon^2\{S^{(2)}(\bar{x})+\boldsymbol{D}^{(1)}S^{(1)}(\bar{x})+\boldsymbol{D}^{(2)}S^{(0)}(\bar{x})\}+\cdots\end{aligned} \tag{9}$$

and

$$X(\lambda)=X^{(0)}(\bar{\lambda})+\in\{X^{(1)}(\bar{\lambda})+\boldsymbol{D}^{(1)}{}_{(\lambda)}X^{(0)}(\bar{\lambda})\}$$
$$+\in^2\{X^{(2)}(\bar{\lambda})+\boldsymbol{D}^{(1)}{}_{(\lambda)}X^{(1)}(\bar{\lambda})+\boldsymbol{D}^{(2)}{}_{(\lambda)}X^{(0)}(\bar{\lambda})\}+\cdots \tag{10}$$

where

$$\boldsymbol{D}^{(1)}\equiv\varphi^{(1)\alpha}\frac{\partial}{\partial x^{\alpha}},$$
$$\boldsymbol{D}^{(2)}\equiv\frac{1}{2}\varphi^{(1)\alpha}\varphi^{(1)\beta}\frac{\partial^2}{\partial x^{\alpha}\partial x^{\beta}}+\varphi^{(2)\alpha}\frac{\partial}{\partial x^{\alpha}}$$
$$\boldsymbol{D}^{(1)}{}_{(\lambda)}\equiv\Lambda^{(1)i}\frac{\partial}{\partial\lambda^{i}},$$
$$\boldsymbol{D}^{(2)}{}_{(\lambda)}\equiv\frac{1}{2}\Lambda^{(1)i}\Lambda^{(1)k}\frac{\partial^2}{\partial\lambda^{i}\partial\lambda^{k}}+\Lambda^{(2)i}\frac{\partial}{\partial\lambda^{i}}. \tag{11}$$

Therefore, the above-adopted mappings or transformations (5) and (6) should be such ones as transform the equation of the given boundary (2) to the following series of equations, respectively:

$$S^{(0)}=0,\ (S^{(1)}+\boldsymbol{D}^{(1)}S^{(0)})_{S^{(0)}=0}=0,$$
$$(S^{(2)}+\boldsymbol{D}^{(1)}S^{(1)}+\boldsymbol{D}^{(2)}S^{(0)})_{S^{(0)}=0}=0,\cdots \tag{12}$$

and

$$x=X^{(0)}(\lambda),\ (\varphi^{(1)})_{x=X^{(0)}}=X^{(1)}+\boldsymbol{D}_{(\lambda)}{}^{(1)}X^{(0)},$$
$$(\varphi^{(2)})_{x=X^{(0)}}=X^{(2)}+\boldsymbol{D}^{(1)}{}_{(\lambda)}X^{(1)}+\boldsymbol{D}^{(2)}{}_{(\lambda)}X^{(0)},\cdots \tag{13}$$

as are easily verified.

2. *Introduction of "virtual" scalar functions.*

Corresponding to an arbitrary scalar function $u(x)$, a new or "virtual" function $\bar{u}(x)$ is defined by the following relation:

$$\bar{u}(\bar{x})=u(x) \tag{14}$$

where $\bar{x}$ and x are related to each other through Eq. (5), and, just because of Eq. (5) being one-to-one mapping, $\bar{u}$ and u are defined by each other in such a way as $\bar{u}$ is defined in D_0 by means of u defined in D, and vice versa.

By making use of Eq. (5), the relation between $\bar{u}$ and u is obtained as follows:

$$\bar{u}(x)=\bar{u}(\bar{x}+\in\varphi^{(1)}(\bar{x})+\in^2\varphi^{(2)}(\bar{x})+\ \ldots)$$
$$=\bar{u}(\bar{x})+\in\boldsymbol{D}^{(1)}\bar{u}(\bar{x})+\in^2\boldsymbol{D}^{(2)}\bar{u}(\bar{x})+\ \ldots$$
$$=u(x)+\in\boldsymbol{D}^{(1)}u(x)+\in^2\boldsymbol{D}^{(2)}u(x)+\ \ldots$$

i.e.

$$\bar{u}=(1+\in\boldsymbol{D}^{(1)}+\in^2\boldsymbol{D}^{(2)}+\ \ldots)\,u \tag{15}$$

or, inversely,

$$u=[1-\in\boldsymbol{D}^{(1)}-\in^2(\boldsymbol{D}^{(2)}-\boldsymbol{D}^{(1)}\boldsymbol{D}^{(1)})-\ldots]\bar{u} \tag{16}$$

as is easily verified.

For instance, by making use of Eqs. (12),

$$\bar{S}=S^{(0)}$$

which shows that the virtual expression of the given boundary C is the favorable boundary C_0.

3. *Introduction of "virtual" tensor functions.*

Corresponding to an arbitrary covariant or contravariant tensor function, $u_{\alpha_1\alpha_2\cdots\alpha_n}(x)$ or $u^{\alpha_1\alpha_2\cdots\alpha_n}(x)$, a new or "virtual" covariant or contravariant tensor function, $\bar{u}_{\alpha_1\alpha_2\cdots\alpha_n}(x)$ or $\bar{u}^{\alpha_1\alpha_2\cdots\alpha_n}(x)$, is defined by the following relations, respectively:

$$\bar{u}_{\alpha_1\alpha_2\cdots\alpha_n}(\bar{x})=\frac{\partial x^{\beta_1}}{\partial\bar{x}^{\alpha_1}}\cdot\frac{\partial x^{\beta_2}}{\partial\bar{x}^{\alpha_2}}\cdots\frac{\partial x^{\beta_n}}{\partial\bar{x}^{\alpha_n}}u_{\beta_1\beta_2\cdots\beta_n}(x)$$

and

$$\bar{u}^{\alpha_1\alpha_2\cdots\alpha_n}(\bar{x})=\frac{\partial\bar{x}^{\alpha_1}}{\partial x^{\beta_1}}\cdot\frac{\partial\bar{x}^{\alpha_2}}{\partial x^{\beta_2}}\cdot\cdot\frac{\partial\bar{x}^{\alpha_n}}{\partial x^{\beta_n}}u^{\beta_1\beta_2\cdots\beta_n}(x) \tag{17}$$

where $\bar{x}$ and x are related to each other through Eq. (5) and the correspondence between the tensors, given and virtual, is also one-to-one.

By making use of Eqs. (5), (7), (15) and (16), the relations between the original and the virtual tensors are obtained as follows:

$$\bar{u}_{\alpha_1\cdot\cdot\alpha_n}=u_{\alpha_1\cdot\cdot\alpha_n}+\in[\sum_{s=1}^{n}\varphi^{(1)\beta_s}{}_{,\alpha_s}u_{\alpha_1\cdot\cdot\alpha_{s-1}\beta_s\alpha_{s+1}\cdot\cdot\alpha_n}$$
$$+\boldsymbol{D}^{(1)}u_{\alpha_1\cdot\cdot\alpha_n}]+\ldots$$

and

$$\bar{u}^{\alpha_1\cdot\cdot\alpha_n}=u^{\alpha_1\cdot\cdot\alpha_n}-\in[\sum_{s=1}^{n}\varphi^{(1)\alpha_s}{}_{,\beta_s}u^{\alpha_1\cdot\cdot\alpha_{s-1}.\beta_s\cdot\alpha_{s+1}\cdot\cdot\alpha_n}$$
$$-\boldsymbol{D}^{(1)}u^{\alpha_1\cdot\cdot\alpha_n}]-\ldots \tag{18}$$

or, inversely,

$$u_{\alpha_1\cdot\cdot\alpha_n}=\bar{u}_{\alpha_1\cdot\cdot\alpha_n}-\in[\sum_{s=1}^{n}\varphi^{(1)\beta_s}{}_{,\alpha_s}\bar{u}_{\alpha_1\cdot\cdot\alpha_{s-1}\beta_s\alpha_{s+1}\cdot\cdot\alpha_n}$$
$$+\boldsymbol{D}^{(1)}\bar{u}_{\alpha_1\cdot\cdot\alpha_n}]-\ \ldots$$

and

$$u^{\alpha_1\cdot\cdot\alpha_n}=\bar{u}^{\alpha_1\cdot\cdot\alpha_n}+\in[\sum_{s=1}^{n}\varphi^{(1)\alpha_s}{}_{,\beta_s}\bar{u}^{\alpha_1\cdot\cdot\alpha_{s-1}\cdot\beta_s.\alpha_{s+1}\cdot\cdot\alpha_n}$$
$$-\boldsymbol{D}^{(1)}\bar{u}^{\alpha_1\cdot\cdot\alpha_n}]+\ldots \tag{19}$$

where the indices attached to the right-hand foot of any function, with a comma ahead of them, mean its differentiation with respect to the coordinates or arguments denoted by them as follows:

$$f_{,\alpha}\equiv\frac{\partial f}{\partial x^{\alpha}},\ f_{,\alpha_1\alpha_2\cdot\cdot\alpha_n}\equiv\frac{\partial^n f}{\partial x^{\alpha_1}\partial x^{\alpha_2}\cdot\cdot\partial x^{\alpha_n}}\ \text{etc.},$$

as is usual in differential geometry.

Especially, as regards the fundamental metrical tensors, covariant and contravariant,

$$\bar{g}_{\alpha\beta}=g_{\alpha\beta}+\in g^{(1)}{}_{\alpha\beta}+\ \ldots$$

and

$$\bar{g}^{\alpha\beta}=g^{\alpha\beta}-\in g^{(1)\alpha\beta}-\ \dots \qquad (20)$$

where

$$g^{(1)}{}_{\alpha\beta}\equiv\varphi^{(1)\gamma}{}_{,\alpha}g_{\gamma\beta}+\varphi^{(1)\gamma}{}_{,\beta}g_{\alpha\gamma}+\boldsymbol{D}^{(1)}g_{\alpha\beta}$$
$$=g_{\alpha\rho}g_{\beta\sigma}g^{(1)\rho\sigma}$$
$$g^{(1)\alpha\beta}\equiv\varphi^{(1)\alpha}{}_{,\gamma}g^{\gamma\beta}+\varphi^{(1)\beta}{}_{,\gamma}g^{\alpha\gamma}-\boldsymbol{D}^{(1)}g^{\alpha\beta}$$
$$=g^{\alpha\rho}g^{\beta\sigma}g^{(1)}{}_{\rho\sigma}$$

which will be used later in the transformation of boundary-conditions, etc.

4. *Introduction of "virtual" functions corresponding to the functions defined on the given boundary C.*

Corresponding to an arbitrary scalar function $F(\lambda)$ defined on the boundary C, a virtual function $\bar{F}(\lambda)$ is defined by the following relation:

$$\bar{F}(\bar{\lambda})=F(\lambda) \qquad (21)$$

where $\bar{\lambda}$ and λ are related to each other through Eq. (6) and, just because of Eq. (6) being one-to-one mapping, the correspondence between $\bar{F}$ and F is one-to-one.

The relation between $\bar{F}$ and F is obtained as follows:

$$\bar{F}(\lambda)=\bar{F}(\bar{\lambda}+\in \Lambda^{(1)}(\bar{\lambda})+\in^2\Lambda^{(2)}(\bar{\lambda})+\dots)$$
$$=\bar{F}(\bar{\lambda})+\in \boldsymbol{D}^{(1)}{}_{(\lambda)}\bar{F}(\bar{\lambda})+\in^2\boldsymbol{D}^{(2)}{}_{(\lambda)}\bar{F}(\bar{\lambda})+\ \dots$$
$$=F(\lambda)+\in \boldsymbol{D}^{(1)}{}_{(\lambda)}F(\lambda)+\in^2\boldsymbol{D}^{(2)}{}_{(\lambda)}F(\lambda)+\ \dots$$

i.e.

$$\bar{F}=(1+\in \boldsymbol{D}^{(1)}{}_{(\lambda)}+\in^2\boldsymbol{D}^{(2)}{}_{(\lambda)}+\ \dots)F \qquad (22)$$

or, inversely,

$$F=[1-\in \boldsymbol{D}^{(1)}{}_{(\lambda)}$$
$$-\in^2(\boldsymbol{D}^{(2)}{}_{(\lambda)}-\boldsymbol{D}^{(1)}{}_{(\lambda)}\boldsymbol{D}^{(1)}{}_{(\lambda)})-\dots]\,\bar{F} \qquad (23)$$

as is easily verified.

It is easily shown by making use of Eqs. (4), (13), (15) and (22), that, corresponding to the equation of the given boundary C: $x=X(\lambda)$, its virtual expression is $x=X^{(0)}(\lambda)$, the equation of the favorable boundary C_0 (which might be, therefore, referred to as the "virtual" boundary).

5. *Introduction of "virtual" linear partial differential operators.*

Corresponding to an arbitrary linear partial differential operator L (or merely "operator" for short, when there is no fear of confusion), a new or "virtual" operator $\bar{L}$ is defined as follows:

$$\bar{L}\bar{u}=\overline{Lu} \qquad (24)$$

where the correspondence between $\bar{L}$ and L is also one-to-one.

By making use of Eqs. (15) and (16), the relation between the operators, given and virtual, is obtained as follows:

$$\bar{L}\bar{u}=\overline{Lu}=(1+\in \boldsymbol{D}^{(1)}+\in^2\boldsymbol{D}^{(2)}+\ \dots)Lu$$
$$=(1+\in \boldsymbol{D}^{(1)}+\in^2\boldsymbol{D}^{(2)}+\dots)L$$
$$[1-\in \boldsymbol{D}^{(1)}-\in^2(\boldsymbol{D}^{(2)}-\boldsymbol{D}^{(1)}\boldsymbol{D}^{(1)})-\ \dots]\bar{u}$$

therefore

$$\bar{L}=L+\in L^{(1)}+\in L^{(2)}+\ \dots \qquad (25)$$

where

$$L^{(1)}\equiv \boldsymbol{D}^{(1)}L-L\boldsymbol{D}^{(1)}$$
$$L^{(2)}\equiv \boldsymbol{D}^{(2)}L-L\boldsymbol{D}^{(2)}-L^{(1)}\boldsymbol{D}^{(1)}$$

or, inversely,

$$L=\bar{L}-\in \bar{L}^{(1)}-\in^2\bar{L}^{(2)}-\ \dots \qquad (26)$$

where

$$\bar{L}^{(1)}\equiv \boldsymbol{D}^{(1)}\bar{L}-\bar{L}\boldsymbol{D}^{(1)}$$
$$\bar{L}^{(2)}\equiv \boldsymbol{D}^{(2)}\bar{L}-\bar{L}\boldsymbol{D}^{(2)}-\boldsymbol{D}^{(1)}\bar{L}^{(1)} \quad .$$

The virtual expressions or "transformations" of several important operators are given in explicit forms, convenient to use, to the first order of approximation here, where the chief aim is to have the extensive scope of the subject rather than the elevation of the order of approximation, as follows:

[1] Laplacian operator

$$\bar{\Delta}=\Delta+\in L^{(1)}{}_{\triangle}+\ \dots \qquad (27)$$

where

$$\Delta\equiv\frac{1}{\sqrt{g}}\frac{\partial}{\partial x^\alpha}\sqrt{g}\,g^{\alpha\beta}\frac{\partial}{\partial x^\beta}$$
$$L^{(1)}{}_{\triangle}\equiv-\left[\frac{1}{\sqrt{g}}\frac{\partial(\sqrt{g}\,\varphi^{(1)\gamma})}{\partial x^\gamma}\Delta\right.$$
$$\left.+\frac{1}{\sqrt{g}}\frac{\partial}{\partial x^\alpha}\sqrt{g}\,\Phi^{\alpha\beta}\frac{\partial}{\partial x^\beta}\right]$$
$$\Phi^{\alpha\beta}\equiv g^{(1)\alpha\beta}-\frac{g^{\alpha\beta}}{\sqrt{g}}\frac{\partial(\sqrt{g}\,\varphi^{(1)\gamma})}{\partial x^\gamma}=\Phi^{\beta\alpha}$$
$$g\equiv|g_{\alpha\beta}|$$

the time-coordinate being here assumed to be not included among x or to be a mere parameter at most, if it appears.

[2] The "heat-conduction" operator

$$\bar{L}_{h.c.}=L_{h.c.}+\in L^{(1)}{}_{h.c.}+\ \dots \tag{28}$$

where

$$L_{h.c.}\equiv\kappa^2\Delta-\frac{\partial}{\partial t}$$

$$L^{(1)}{}_{h.c.}\equiv\kappa^2(L^{(1)}{}_{\triangle}+L^{(1)}{}_{t\triangle})+L^{(1)}{}_{\partial/\partial t}$$

$$L^{(1)}{}_{\triangle}\equiv[L^{(1)}{}_{\triangle}\text{ of Eq.(27)}]_{\alpha=i,\beta=k,\gamma=l}$$

$$L^{(1)}{}_{t\triangle}\equiv-\Big[2g^{kl}\varphi^{(1)N}{}_{,k}\frac{\partial^2}{\partial x^l\partial x^N}$$

$$+\frac{1}{\sqrt{g}}\frac{\partial(\sqrt{g}g^{kl}\varphi^{(1)N}{}_{,k})}{\partial x^l}\frac{\partial}{\partial x^N}\Big]$$

$$L^{(1)}{}_{\partial/\partial t}\equiv\varphi^{(1)N}{}_{,N}\frac{\partial}{\partial x^N}+\varphi^{(1)l}{}_{,N}\frac{\partial}{\partial x^l}$$

$$g\equiv|g_{ik}|,\quad x^N\equiv t.$$

[3] D'Alembertian operator

$$\bar{\Box}=\Box+\in L^{(1)}{}_{\Box}+\ \dots \tag{29}$$

where

$$\Box\equiv\frac{1}{\sqrt{g}}\frac{\partial}{\partial x^\alpha}\sqrt{g}g^{\alpha\beta}\frac{\partial}{\partial x^\beta}$$

$$L^{(1)}{}_{\Box}\equiv-\Big[\frac{1}{\sqrt{g}}\frac{\partial(\sqrt{g}\varphi^{(1)\gamma})}{\partial x^\gamma}\Box$$

$$+\frac{1}{\sqrt{g}}\frac{\partial}{\partial x^\alpha}\sqrt{g}\Phi^{\alpha\beta}\frac{\partial}{\partial x^\beta}\Big]$$

$$g\equiv|g_{\alpha\beta}|,\quad x^N\equiv ct\text{ or }t.$$

Especially, when $x^N=ct$, $g_{NN}=g^{NN}=-1$ and $g_{Nk}=g^{Nk}=0$, the above expression is reduced to the following:

$$\overline{\left(\Delta-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)}=\left(\Delta-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)$$

$$+\in L^{(1)}{}_{\Box}+\dots \tag{30}$$

where

$$L^{(1)}{}_{\Box}\equiv L^{(1)}{}_{\triangle}+L^{(1)}{}_{(\Box-\triangle)}$$

$$L^{(1)}{}_{\triangle}\equiv[L^{(1)}{}_{\triangle}\text{ of Eq.(27)}]_{\alpha=i,\beta=k,\gamma=l}$$

$$L^{(1)}{}_{\Box-\triangle}\equiv2\varphi^{(1)N}{}_{,N}\frac{\partial^2}{\partial(x^N)^2}$$

$$+2(\varphi^{(1)l}{}_{,N}-g^{kl}\varphi^{(1)N}{}_{,k})\frac{\partial^2}{\partial x^l\partial x^N}+\varphi^{(1)l}{}_{,NN}\frac{\partial}{\partial x^l}$$

$$+\left\{\varphi^{(1)N}{}_{,NN}-\frac{1}{\sqrt{g}}\frac{\partial(\sqrt{g}g^{kl}\varphi^{(1)N}{}_{,k})}{\partial x^l}\right\}\frac{\partial}{\partial x^N}$$

$g\equiv|g_{ik}|.$

[4] The operator $\partial/\partial x^\alpha$

$$\overline{\frac{\partial}{\partial x^\alpha}}=\frac{\partial}{\partial x^\alpha}-\in D^{(1)}{}_\alpha-\in^2D^{(2)}{}_\alpha-\ \dots \tag{31}$$

where

$$D^{(1)}{}_\alpha\equiv\frac{\partial}{\partial x^\alpha}D^{(1)}-D^{(1)}\frac{\partial}{\partial x^\alpha}=\varphi^{(1)\gamma}{}_{,\alpha}\frac{\partial}{\partial x^\gamma}$$

$$D^{(2)}{}_\alpha\equiv\frac{\partial}{\partial x^\alpha}D^{(2)}-D^{(2)}\frac{\partial}{\partial x^\alpha}-D^{(1)}{}_\alpha D^{(1)}$$

$$=\varphi^{(2)\gamma}{}_{,\alpha}\frac{\partial}{\partial x^\gamma}-(D^{(1)}{}_\alpha\varphi^{(1)\gamma})\cdot\frac{\partial}{\partial x^\gamma}\ .$$

[5] The operator $L_n\equiv\partial/\partial n$, differentiating to a direction normal to the given boundary C

$$\bar{L}_n=L_n-\in L^{(1)}{}_n-\in^2L^{(2)}{}_n-\ \dots \tag{32}$$

where

$$L_n\equiv\frac{g^{\alpha\beta}S_{,\alpha}}{\sqrt{g^{\rho\sigma}S_{,\rho}S_{,\sigma}}}\frac{\partial}{\partial x^\beta}\text{ or }\frac{g^{\alpha\beta}\Delta_\alpha}{\sqrt{g^{\rho\sigma}\Delta_\rho\Delta_\sigma}}\frac{\partial}{\partial x^\beta}$$

$$L^{(1)}{}_n\equiv L_nD^{(1)}-D^{(1)}L_n$$

$$L^{(2)}{}_n\equiv L_nD^{(2)}-D^{(2)}L_n-L^{(1)}{}_nD^{(1)}$$

Δ_α being the cofactor of c^α in the following determinant of the order N, consisting of the derivatives $X^\alpha{}_{,i}(\equiv\partial X^\alpha/\partial\lambda^i)$ and of the mere letters c^α introduced only to specify their own cofactors, respectively:

$$\begin{array}{ccccccc}
c^1 & c^2 & \cdots\cdots & c^\alpha & \cdots\cdots & c^N \\
X^1{}_{,1} & X^2{}_{,1} & \cdots\cdots & X^\alpha{}_{,1} & \cdots\cdots & X^N{}_{,1} \\
\vdots & \vdots & & \vdots & & \vdots \\
X^1{}_{,i} & X^2{}_{,i} & \cdots\cdots & X^\alpha{}_{,i} & \cdots\cdots & X^N{}_{,i} \\
\vdots & \vdots & & \vdots & & \vdots \\
X^1{}_{,N-1} & X^2{}_{,N-1} & \cdots\cdots & X^\alpha{}_{,N-1} & \cdots\cdots & X^N{}_{,N-1}
\end{array}$$

or

$$\Delta_\alpha=(-1)^{\alpha-1}\varepsilon^{i_1\cdots i_{\alpha-1}i_{\alpha+1}\cdots i_N}$$

$$X^1{}_{,i_1}X^2{}_{,i_2}\cdots X^{\alpha-1}{}_{,i_{\alpha-1}}X^{\alpha+1}{}_{,i_{\alpha+1}}\cdots X^N{}_{,i_N}$$

with $\varepsilon^{i_1\cdots i_{\alpha-1},i_{\alpha+1}\cdots i_N}$ being $+1$ or -1 according as the permutation

$$\begin{pmatrix}1,\cdots,\alpha-1,\alpha,\cdots,N-1\\ i_1,\cdots,i_{\alpha-1},i_{\alpha+1},\cdots\cdots,i_N\end{pmatrix}$$

is even or odd and being zero otherwise.

Eq.(32) is rewritten by means of Eqs.(4) and (12) as follows:

$$\bar{L}_n=L^{(0)}{}_n-\in N^{(1)}-\ \dots \tag{33}$$

where

$$L^{(0)}{}_n\equiv\frac{g^{\alpha\beta}S^{(0)}{}_{,\alpha}}{\sqrt{g^{\rho\sigma}S^{(0)}{}_{,\rho}S^{(0)}{}_{,\sigma}}}\frac{\partial}{\partial x^\beta}$$

$$\text{or }\frac{g^{\alpha\beta}\Delta^{(0)}{}_\alpha}{\sqrt{g^{\rho\sigma}\Delta^{(0)}{}_\rho\Delta^{(0)}{}_\sigma}}\frac{\partial}{\partial x^\beta}$$

$$N^{(1)}\equiv\frac{g^{(1)\alpha\beta}S^{(0)}{}_{,\alpha}}{\sqrt{g^{\rho\sigma}S^{(0)}{}_{,\rho}S^{(0)}{}_{,\sigma}}}\frac{\partial}{\partial x^\beta}$$

$$-\frac{1}{2}\frac{(g^{(1)\alpha\beta}S^{(0)}{}_{,\alpha}S^{(0)}{}_{,\beta})}{(g^{\rho\sigma}S^{(0)}{}_{,\rho}S^{(0)}{}_{,\sigma})}L^{(0)}{}_n$$

or $$\frac{g^{(1)\alpha\beta}\Delta^{(0)}{}_\alpha}{\sqrt{g^{\rho\sigma}\Delta^{(0)}{}_\rho\Delta^{(0)}{}_\sigma}}\frac{\partial}{\partial x^\beta}$$

$$-\frac{1}{2}\frac{(g^{(1)\alpha\beta}\Delta^{(0)}{}_\alpha\Delta^{(0)}{}_\beta)}{(g^{\rho\sigma}\Delta^{(0)}{}_\rho\Delta^{(0)}{}_\sigma)}L^{(0)}{}_n$$

$$\Delta^{(0)}\equiv(\Delta)_{X=X^{(0)}}$$

6. *The Dirichlet condition (or the question, what value the virtual function $\bar{\Psi}$ should take on the boundary C_0 of the domain D_0, when a scalar function $\Psi(x)$ takes the given value $f(x)$ or $F(\lambda)$ on the boundary C of the domain D).*

If the given function $f(x)$ is assumed to be defined in some neighborhood of C_0, the answer is obtained by making use of Eqs.(14) and (15), as follows:

$$\bar{\Psi}(\bar{x})=\Psi(x)=f(x)=\bar{f}(x)$$
$$=(1+\in D^{(1)}+\in^2 D^{(2)}+\ .\ .\ .)f(\bar{x}) \text{ on } C_0$$

i.e.

$$(\bar{\Psi})_{C_0}=[(1+\in D^{(1)}+\in^2 D^{(2)}+\ .\ .\ .)f\,]_{C_0} \quad (34)$$

Or, if the boundaries, C and C_0, are represented in terms of their respective parameters (related to each other through Eq.(6)), like Eqs.(2) and (3), what value should the virtual function $\bar{\Psi}$ take on C_0, when the boundary-value of the scalar function Ψ on C is $F(\lambda)$?

Making use of Eqs.(14), (21) and (22), the answer is obtained as follows:

$$\bar{\Psi}(X^{(0)}(\bar{\lambda}))=\bar{\Psi}(\bar{x})=\Psi(x)=\Psi(X(\lambda))=F(\lambda)=\bar{F}(\bar{\lambda})$$
$$=(1+\in D^{(1)}{}_{(\lambda)}+\in D^{(2)}{}_{(\lambda)}+\cdots)F(\bar{\lambda})$$

i.e.

$$(\bar{\Psi})_{C_0}=(1+\in D^{(1)}{}_{(\lambda)}+\in^2 D^{(2)}{}_{(\lambda)}+\cdots)F \quad (35)$$

Eqs.(34) and (35) are the virtual expressions, respectively, of the inhomogeneous Dirichlet condition

$$(\Psi)_C=(f(x))_C \text{ or } (\Psi)_C=F(\lambda)$$

given on the boundary C. Also, by combining the above results, Eqs. (34) and (35), when the following identity holds on the boundary C:

$$(f(x))_C=F(\lambda) \quad ,$$

then

$$[(1+\in D^{(1)}+\in^2 D^{(2)}+\ .\ .\ .\ )f]_{C_0}$$
$$=(1+\in D^{(1)}{}_{(\lambda)}+\in^2 D^{(2)}{}_{(\lambda)}+\ .\ .\ .\ )F$$

where the function $f(x)$ is required only to be equal to $F(\lambda)$ on the boundary C, and free elsewhere, as far as it is continuated "smoothly" from the value on the boundary.

Eq.(35) tells that, when F is a constant, the virtual function $\bar{\Psi}$ should take the same constant value on the boundary C_0, too.

7. *The Neumann condition.*

The given function $f(x)$ is assumed to be defined smoothly in the neighborhood of C_0 (therefore, also of C).

For the Neumann condition

$$L_n\Psi=f(x) \quad \text{on } C,$$

making use of Eqs.(24) and (33),

$$(L^{(0)}{}_n-\in N^{(1)}-\ .\ .\ .\ )\bar{\Psi}=\bar{L}_n\bar{\Psi}=\overline{L_n\Psi}$$
$$=(1+\in D^{(1)}+\ .\ .\ .\ )L_n\Psi=(1+\in D^{(1)}+\ .\ .\ .\ )f$$

or, carrying the perturbed part on the first side to the last side and assuming the expression

$$\bar{\Psi}\equiv\bar{\Psi}^{(0)}+\in\bar{\Psi}^{(1)}+\in^2\bar{\Psi}^{(2)}+\ .\ .\ . \quad (36)$$

the "virtual" Neumann condition is

$$(L^{(0)}{}_n\bar{\Psi})_{C_0}=[\,f+\in(N^{(1)}\bar{\Psi}^{(0)}+D^{(1)}f)+\ .\ .\ .\ ]_{C_0} \quad (37)$$

Or, when the boundaries, C and C_0, are represented in terms of the parameters, like Eqs.(2) and (3), and the Neumann condition is given as follows:

$$(L_n\Psi)_C=F(\lambda) \quad ,$$

then, by making use of Eqs.(14), (22), (24) and (33),

$$[L^{(0)}{}_n-\in N^{(1)}-\ .\ .\ .\ )\bar{\Psi}(\bar{x})]_{\bar{x}=X^{(0)}(\bar{\lambda})}$$
$$=[\bar{L}_n\bar{\Psi}(\bar{x})]_{\bar{x}=X^{(0)}(\bar{\lambda})}=[\overline{L_n\Psi}(\bar{x})]_{\bar{x}=X^{(0)}(\bar{\lambda})}$$
$$=[L_n\Psi(x)]_{x=X(\lambda)}=F(\lambda)=\bar{F}(\bar{\lambda})$$
$$=(1+\in D^{(1)}{}_{(\lambda)}+\ .\ .\ .)F(\bar{\lambda})$$

therefore, from the first and the last sides, and also assuming the expression (36), the corresponding virtual Neumann condition is obtained as follows:

$$(L^{(0)}{}_n\bar{\Psi})_{C_0}=F+\in\{(N^{(1)}\bar{\Psi}^{(0)})_{C_0}+D^{(1)}{}_{(\lambda)}F\}+\ .\ .\ . \quad (38)$$

8. *The mixed boundary-condition.*

The corresponding virtual expression is derived by combining the results already obtained. In the following, the given functions $p(x)$, $q(x)$ and $f(x)$ are assumed to be defined smoothly in the neighborhood of the boundary C therefore of C_0, and their values on the boundary C are assumed to be expressed in terms of the parameters as follows:

$$[p(x)]_{x=X(\lambda)}\equiv P(\lambda),\quad [q(x)]_{x=X(\lambda)}\equiv Q(\lambda),$$
$$[f(x)]_{x=X(\lambda)}\equiv F(\lambda).$$

Now, a mixed bondary-condition

$$[p(x)\boldsymbol{L}_n\Psi+q(x)\Psi]_C=[f(x)]_C$$

or

$$P(\lambda)(\boldsymbol{L}_n\Psi)_C+Q(\lambda)(\Psi)_C=F(\lambda)$$

is expressed "virtually" as follows:

$$[p\boldsymbol{L}^{(0)}{}_n\bar{\Psi}+q\bar{\Psi}]_{C_0}=[f+\in f^{(1)}+\ .\ .\ .]_{C_0}$$

or

$$P(\boldsymbol{L}^{(0)}{}_n\bar{\Psi})_{C_0}+Q(\bar{\Psi})_{C_0}=F+\in F^{(1)}+\ .\ .\ . \tag{39}$$

where

$$(f^{(1)})_{C_0}\equiv[\boldsymbol{D}^{(1)}f$$
$$+\{p\boldsymbol{N}^{(1)}-(\boldsymbol{D}^{(1)}p)\cdot\boldsymbol{L}^{(0)}{}_n-(\boldsymbol{D}^{(1)}q\}\bar{\Psi}^{(0)}]_{C_0}$$

or

$$=[p\{\boldsymbol{N}^{(1)}\bar{\Psi}^{(0)}+\boldsymbol{D}^{(1)}\boldsymbol{L}^{(0)}{}_n\bar{\Psi}^{(0)}\}+q\boldsymbol{D}^{(1)}\bar{\Psi}^{(0)}]_{C_0}$$

with $\boldsymbol{L}^{(0)}{}_n\bar{\Psi}^{(0)}$ in the last side being, of course, considered to be given in the neighborhood of the bondary C_0 before being acted on by the operator $\boldsymbol{D}^{(1)}$, and

$$F^{(1)}\equiv\boldsymbol{D}^{(1)}{}_{(\lambda)}F$$
$$+[\{P\boldsymbol{N}^{(1)}-(\boldsymbol{D}^{(1)}{}_{(\lambda)}P)\boldsymbol{L}^{(0)}{}_n-(\boldsymbol{D}^{(1)}{}_{(\lambda)}Q)\}\bar{\Psi}^{(0)}]_{C_0}$$

or

$$=P[(\boldsymbol{N}^{(1)}\bar{\Psi}^{(0)})_{C_0}+\boldsymbol{D}^{(1)}{}_{(\lambda)}(\boldsymbol{L}^{(0)}{}_n\bar{\Psi}^{(0)})_{C_0}]$$
$$+Q\boldsymbol{D}^{(1)}{}_{(\lambda)}(\bar{\Psi}^{(0)})_{C_0}$$

[Example] *The virtual expression of a mixed boundary-condition* $p_0\dfrac{\partial\Psi}{\partial n}+q_0\Psi=F(\theta,\varphi)$, *with* p_0 *and* q_0 *being constants, on the boundary* $r=a(1+\in\phi)$, *with* ϕ *being a function of* θ *and* φ, *which is close to the spherical surface* $r=a$ *in shape.*

The equations of the two boundaries are rewritten as follows:

$$S\equiv r-a-\in a\phi=0$$
$$S^{(0)}\equiv r-a=0$$

and the following transformation is adopted as an appropriate one:

$$r=\bar{r}[1+\in\varphi(\bar{\theta},\bar{\varphi})],\ \theta=\bar{\theta},\ \varphi=\bar{\varphi}.$$

Then, according to Eq. (39), the mixed boundary-condition

$$\left(p_0\frac{\partial\Psi}{\partial n}+q_0\Psi\right)_{r=a(1+\epsilon\phi)}=F(\theta,\varphi)$$

is transformed to the following virtual one:

$$\left(p_0\frac{\partial\bar{\Psi}}{\partial r}+q_0\bar{\Psi}\right)_{r=a}=F+\in p_0(\boldsymbol{N}^{(1)}\bar{\Psi}^{(0)})_{r=a}+\ .\ .\ .$$

where

$$\boldsymbol{N}^{(1)}\equiv\left(\phi\ \frac{\partial}{\partial r}+\frac{\phi_{,\theta}}{r}\frac{\partial}{\partial\theta}+\frac{\phi_{,\varphi}}{r\sin^2\theta}\frac{\partial}{\partial\varphi}\right)$$

9. *The procedure for solving the problem.*

The given problem i.e. Eq.(1) with some boundary-condition on the given boundary C is transformed to the corresponding "virtual" problem i.e. the "virtual" equation

$$\bar{\boldsymbol{L}}\bar{\Psi}=-\bar{h} \tag{40}$$

or, assuming the expression (36),

$$\boldsymbol{L}\bar{\Psi}=-h-\in(\boldsymbol{L}^{(1)}\bar{\Psi}^{(0)}+\boldsymbol{D}^{(1)}h)$$
$$-\in^2(\boldsymbol{L}^{(2)}\bar{\Psi}^{(0)}+\boldsymbol{L}^{(1)}\bar{\Psi}^{(1)}+\boldsymbol{D}^{(2)}h)-\ .\ .\ . \tag{41}$$

with the "virtual" boundary-condition to be obtained according to Eqs. (34), (35), (37), (38) or (39) on the boundary C_0.

This virtual problem is solved, by subjecting Eq.(40) to the ordinary perturbation method, as is shown in the next section, or by treating Eq.(41) by means of Green's formula or otherwise, respectively, according as it is an eigenvalue problem or a boundary-value one (elliptic, parabolic or hyperbolic). The solution thus obtained, being "virtual", must be transformed to the corresponding "real" solution, so to speak, by means of Eq. (7), which is the solution sought for of the given problem. For the virtual solution of the form (36), the corresponding "real" solution Ψ is written, according to Eq. (16), as follows:

$$\Psi=\bar{\Psi}^{(0)}+\in(\bar{\Psi}^{(1)}-\boldsymbol{D}^{(1)}\bar{\Psi}^{(0)})$$
$$+\in^2[\bar{\Psi}^{(2)}-\boldsymbol{D}^{(1)}\bar{\Psi}-(\boldsymbol{D}^{(2)}-\boldsymbol{D}^{(1)}\boldsymbol{D}^{(1)})\bar{\Psi}^{(0)}]+\ .\ .\ . \tag{42}$$

Unlike the functions, the eigenvalues are not varied by the last transformation (7).

§ 3. Eigenvalue problems

The equation

$$\boldsymbol{L}\Psi=-\kappa\Psi \tag{43}$$

which is obtained from Eq.(1) by replacing $h(x)$ by $\kappa\Psi$, and coupled with an appopriately specified boundary-condition on the given boundary C, presents an eigenvalue problem.

Since the main object here is to show the procedure to meet such a case, the problem is assumed to be of a non-degenerate type.

By means of Eq.(5), the given equation (43) with its boundary C is transformed to the corresponding virtual euqation

$$\bar{\boldsymbol{L}}\bar{\Psi}=(\boldsymbol{L}+\in \boldsymbol{L}^{(1)}+\in^2\boldsymbol{L}^{(2)}+\ldots)\bar{\Psi}=-\kappa\bar{\Psi} \quad (44)$$

with the boundary C_0, to which the well-developed ordinary perturbation method[3] is applied, yielding the following eigen-functions $\bar{\Psi}_n$ and eigenvalues κ_n, n denoting the order:

$$\begin{aligned}\bar{\Psi}_n&=\bar{\Psi}^{(0)}{}_n+\in\bar{\Psi}^{(1)}{}_n+\in^2\bar{\Psi}^{(2)}{}_n+\ldots\\ \kappa_n&=\kappa^{(0)}{}_n+\in\kappa^{(1)}{}_n+\in^2\kappa^{(2)}{}_n+\ldots\end{aligned} \qquad (45)$$

where

$$\boldsymbol{L}\bar{\Psi}^{(0)}{}_n=-\kappa^{(0)}{}_n\bar{\Psi}^{(0)}{}_n\,, \quad (\bar{\Psi}^{(0)}{}_n,\bar{\Psi}^{(0)}{}_n)=1$$

$$\bar{\Psi}^{(1)}{}_n=\sum_{m(\neq n)}\frac{L^{(1)}{}_{mn}}{\kappa^{(0)}{}_m-\kappa^{(0)}{}_n}\bar{\Psi}^{(0)}{}_m \quad \text{etc.}$$

$$\kappa^{(1)}{}_n=-L^{(1)}{}_{nn}\,,$$

$$\kappa^{(2)}{}_n=-\left(L^{(2)}{}_{nn}+\sum_{m(\neq n)}\frac{L^{(1)}{}_{nm}L^{(1)}{}_{mn}}{\kappa_m{}^{(0)}-\kappa_n{}^{(0)}}\right), \quad \text{etc.}$$

$$L^{(i)}{}_{mn}\equiv(\bar{\Psi}^{(0)}{}_m\boldsymbol{L}^{(i)}\bar{\Psi}^{(0)}{}_n)\,, \quad i=1,2,\ldots$$

The "virtual" eigenfunctions (45) must be transformed, according to Eq.(42), to the "real" ones

$$\Psi_n=\bar{\Psi}^{(0)}{}_n+\in(\bar{\Psi}^{(1)}{}_n-\boldsymbol{D}^{(1)}\bar{\Psi}^{(0)}{}_n)+\in^2[\bar{\Psi}^{(2)}{}_n-\boldsymbol{D}^{(1)}\bar{\Psi}^{(1)}{}_n-(\boldsymbol{D}^{(2)}-\boldsymbol{D}^{(1)}\boldsymbol{D}^{(1)})\bar{\Psi}^{(0)}{}_n]+\ldots$$

while the "virtual" eigenvalues (45) are the "real" ones, as they are, since they are not varied by the last transformation.

[Example 1] *The eigenfrequencies ω_{ns} of the lateral vibration of a uniform membrane, under a constant tension T and fixed at its boundary $r=a$ $[1+\in\phi(\theta)]$, close to a circle $r=a$ in shape.*

As is easily seen by comparing the equations of the boundaries, given and favorable, an appropriate mapping or transformation is

$$r=\bar{r}[1+\in\phi(\bar{\theta})] \text{ and } \theta=\bar{\theta}$$

($t=\bar{t}$ having no connection here).

The differential equation governing the lateral displacement $\Psi(r,\theta)$ is

$$(\Delta+k^2)\Psi=0$$

where $k\equiv\omega/c$, $c\equiv\sqrt{T/\sigma}$, with ω and σ being the angular frequency and the surface density, respectively.

The above equation, together with its boundary-condition $\Psi=0$ at $r=a(1+\in\phi)$, is transformed to the following:

$$(\Delta+k^2+\in\boldsymbol{L}^{(1)}{}_\triangle+\ldots)\bar{\Psi}=0, \quad \bar{\Psi}=0 \text{ at } r=a,$$

where

$$\boldsymbol{L}^{(1)}{}_\triangle=-\left[2\phi\Delta+\left(2\phi_{,\theta}\frac{\partial}{\partial\theta}+\phi_{,\theta\theta}\right)\frac{1}{r}\frac{\partial}{\partial r}\right]$$

The unperturbed eigenfunctions $\bar{\Psi}^{(0)}{}_{ns}$, such as

$$(\Delta+k^{(0)2}{}_{ns})\bar{\Psi}^{(0)}{}_{ns}=0, \quad \bar{\Psi}^{(0)}{}_{ns}=0 \text{ at } r=a,$$

are written as follows:

$$\bar{\Psi}^{(0)}{}_{ns}=A_{ns}\cos(n\theta-\alpha_{ns})\cdot J_n(k^{(0)}{}_{ns}r), \quad n\geqq0, \ s\geqq1,$$

where A_{ns} and α_{ns} are constants concerning normalization and phase, respectively, and $k^{(0)}{}_{ns}$ are such as $J_n(k^{(0)}{}_{ns}a)=0$.

The boundary-deviation $\phi(\theta)$ is assumed to be expanded in a Fourier series as follows:

$$\phi(\theta)=\sum_{m=0}^{\infty}B_m\cos(m\theta-\beta_m)$$

where B_m and β_m are appropriate amplitude- and phase-constants, respectively.

Then, according to Eq. (45), the eigenfrequencies ω_{ns}, perturbed by the boundary-deviation $\phi(\theta)$, are obtained, to the first order of approximation, as follows:

$$\omega_{ns}=\omega^{(0)}{}_{ns}\left[1-\frac{\epsilon}{2}\sum_{m=0}^{\infty}B_m\frac{2\delta_{m,0}\cos\beta_m+\delta_{m,2n}\cos(2\alpha_{ns}-\beta_m)+\delta_{m+2n,0}\cos(2\alpha_{ns}+\beta_m)}{1+\delta_{n,0}\cos(2\alpha_{ns})}\right]$$

where δ's are usual Kronecker's deltae, therefore e.g. $\delta_{m+2n,0}$ being equal to 1 only when $m+2n=0$ or $m=n=0$ now, and zero otherwise.

This result coincides with Rayleigh's one(4), where his δr is the equivalent of $\epsilon a\phi$ in the present paper.

A glance at the above result obtained for the general from of $\phi(\theta)$ gives immediately the following information about the contributions from the individual terms $B_m\cos(m\theta-\beta_m)$:
(a) The term with $m=0$ expresses the uniform enlargement (or reduction) of a circular membrane with the tension being kept constant. $B_0\cos\beta_0$, being a constant, can be put 1, without losing the generality. Then, the term means that the eigenfrequencies $\omega^{(0)}{}_{ns}$ are decreased (or increased) to $\omega^{(0)}{}_{ns}(1-\epsilon)$, as the radius a is increased (or decreased) to $a(1+\epsilon)$.
(b) For $m\geqq1$, only the terms with $m=$even can perturb only the eigenfrequencies ω_{ns} with $n=m/2$, whereas the terms with $m=$odd not any one, to the first order of approximation.

To the former, an elliptic boundary ($m=2$), etc. belong, whereas an oval boundary ($m=1$), a cinquefoil-shaped (or "umebachi-gata" in Japanese) boundary ($m=5$), etc. belong to the latter.

[Example 2] *The eigenvalue problem concerning the heat conduction of a "corned-beef-can"-shaped uniform matter, close to a rectangular parallelepiped in shape and with its temperature being kept constant or zero on the boundary surface.*

The equation $(\Delta+\kappa)\Psi=0$, which is derived from the original equation of heat conduction $(k^2\Delta-\partial/\partial t)T=0$ (k^2: thermal diffusibility) by putting the temperature $T=\Psi(xyz)\exp(-k^2\kappa t)$, together with the boundary-condition $\Psi=$const. $=0$ on the given boundary surface, presents an eigenvalue problem.

The corned-beef-can-shaped domain and its surrounding boundary $OADBCFHE$, with the corner O at the origin of the orthogonal Cartesian coordinate-system, with the edges OA and OB on the x- and the y-axes, respectively, with a pair of faces $OBEC$ and $ADHF$ making a small inclination ϵ_1 $(0<\epsilon_1\ll1)$ against the yz-plane, and with another pair of faces $OAFC$ and $BDHE$ making a small inclination ϵ_2 $(0<\epsilon_2\ll1)$ against the xz-plane, are mapped or transformed to the rectangular-parallelepiped-shaped domain and the surrounding boundary $OADBC_0F_0H_0E_0$ respectively, by the following transformation:

$$x=\bar{x}+\epsilon_1\bar{z}\left(1-\frac{2\bar{x}}{a}\right)$$

$$y=\bar{y}+\epsilon_2\bar{z}\left(1-\frac{2\bar{y}}{b}\right)$$

$$z=\bar{z}+\epsilon_3\bar{z}\,,\qquad \epsilon_1\sim\epsilon_2\sim\epsilon_3\,,$$

where

$$a\equiv OA=BD=\overline{C_0F_0}=\overline{E_0H_0}$$

$$b\equiv\overline{OB}=\overline{AD}=\overline{C_0E_0}=\overline{F_0H_0}\,.$$

The last equation shows that the height c of the corned-beef-can-shaped matter is related to the height c_0 of the rectangular parallelepiped in the way $c=c_0(1+\epsilon_3)$, and so the former's volume $V\equiv abc[1-\epsilon_1(c/a)-\epsilon_2(c/b)]$ is equal to the latter's volume $V_0\equiv abc_0$, when $\epsilon_3=\epsilon_1(c/a)+\epsilon_2(c/b)$.

The virtual equation with its own boundary-condition is

$$(\Delta+\kappa+\epsilon L^{(1)}{}_{\triangle}+\ldots)\bar{\Psi}=0\,,\quad \bar{\Psi}=0 \text{ on } OADBC_0F_0H_0E_0$$

where

$$\in L^{(1)}{}_{\triangle}=2\left[\in_1\frac{2z}{a}\frac{\partial^2}{\partial x^2}+\in_2\frac{2z}{b}\frac{\partial^2}{\partial y^2}-\in_3\frac{\partial^2}{\partial z^2}-\in_1\left(1-\frac{2x}{a}\right)\frac{\partial^2}{\partial x\partial z}-\in_2\left(1-\frac{2y}{b}\right)\frac{\partial^2}{\partial y\partial z}\right]$$

The unperturbed eigenvalues $\kappa^{(0)}{}_{lmn}$ and the normalized eigenfunctions $\overline{\Psi}^{(0)}{}_{lmn}$ such as $(\Delta+\kappa^{(0)}{}_{lmn})\overline{\Psi}^{(0)}{}_{lmn}=0$ and $\overline{\Psi}^{(0)}{}_{lmn}=0$ on $OADBC_0F_0H_0E_0$, are given as follows:

$$\kappa^{(0)}{}_{lmn}=\left(\frac{l\pi}{a}\right)^2+\left(\frac{m\pi}{b}\right)^2+\left(\frac{n\pi}{c_0}\right)^2,\quad 1\leqq l,m,n$$

$$\overline{\Psi}^{(0)}{}_{lmn}=\sqrt{\frac{8}{abc_0}}\sin\left(\frac{l\pi x}{a}\right)\cdot\sin\left(\frac{m\pi y}{b}\right)\cdot\sin\left(\frac{n\pi z}{c_0}\right)$$

Then, according to Eq.(45), the eigenvalues κ_{lmn} are obtained to the first order of approximation as follows:

$$\kappa_{lmn}=\kappa^{(0)}{}_{lmn}+2\pi^2\left[\in_1\frac{c_0}{a}\left(\frac{l}{a}\right)^2+\in_2\frac{c_0}{b}\left(\frac{m}{b}\right)^2-\in_3\left(\frac{n}{c_0}\right)^2\right]$$

or, in terms of c instead of c_0,

$$\kappa_{lmn}=\pi^2\left[\left(\frac{l}{a}\right)^2+\left(\frac{m}{b}\right)^2+\left(\frac{n}{c}\right)^2+2\left\{\in_1\frac{c}{a}\left(\frac{l}{a}\right)^2+\in_2\frac{c}{b}\left(\frac{m}{b}\right)^2\right\}\right]$$

When $\in_3=\in_1(c/a)+\in_2(c/b)$, κ_{lmn} and $\kappa^{(0)}{}_{lmn}$ are interpreted to concern the corned-beef-can shape and the rectangular parallelepiped shape, respectively, of the same matter of the equal volume. For an arbitrary order lmn of the eigenvalues,

$$(\kappa_{lmn}-\kappa^{(0)}{}_{lmn})_{\text{equal volume}}=2\pi^2\left[\in_1\frac{c}{a}\left\{\left(\frac{l}{a}\right)^2-\left(\frac{n}{c}\right)^2\right\}+\in_2\frac{c}{b}\left\{\left(\frac{m}{b}\right)^2-\left(\frac{n}{c}\right)^2\right\}\right]$$

whose sign varies according to the values of l,m and n.

However, it is determined by the respective smallest eigenvalues κ_{111} and $\kappa^{(0)}{}_{111}$, which shape is more efficient for the matter cooling off, the corned-beef-can shape or the rectangular parallelepiped shape, under the condition of the equal volume and of the same quality. As regards ordinary corned-beef cans,

$$a<c \quad\text{and}\quad b<c, \quad\text{therefore}\quad (\kappa_{111}-\kappa^{(0)}{}_{111})_{\text{equal volume}}>0$$

which means that they cool off more rapidly than when they take the shape of a rectangular parallelepiped of the equal volume.

§ 4. Boundary-Value Problems

The fundamental line along which a given boundary-valve problem should be solved is already given in the last subsection of § 2, and so the detailed explanation is omitted here. Instead, some examples are given to illustrate the present method.

[**Example 1.**] (Parabolic Case) *The heat conduction in an "infinitely large" flat-plate-shaped uniform matter, with its temperature $\Psi(x, t)$ being initially equal to the specified value $f(x)$ as a function of x within it and being kept always at a constant value θ_0 on its two flat surfaces $x=0$ and $x=a(1+\in\phi)$, of which the latter is assumed to move slightly to the direction normal to the surface itself, such as $\phi=\phi(t)$, with $\phi(0)=0$, without breaking the constancy of the thermal diffusibility κ^2 and without introducing any appearance or disappearance of heat except through the conduction.*

By making use of the transformation $x=\bar{x}\{1+\in\phi(\bar{t})\}$ and $t=\bar{t}$, the solution $\Psi(x, t)$ which satisfies the equation $(\kappa^2\partial^2/\partial x^2-\partial/\partial t)\Psi=0$ as well as the boundary-condition

$$(\Psi)_{t=0}=f(x)\ \text{for}\ 0<x<a\ \text{and}\ (\Psi)_{x=0}=(\Psi)_{x=a(1+\epsilon\phi)}=\theta_0\ \text{for}\ t\geqq 0,$$

to the first order of approximation, is obtained as follows:

$$\Psi=\theta_0+\sum_{l=1}^{\infty} A_l \sin(\alpha_l x)\left[1+2\epsilon\kappa^2\alpha_l^2\int_0^t \phi(\tau)d\tau\right]\exp(-\kappa^2\alpha_l^2 t)-\epsilon\sum_{l=1}^{\infty} A_l\alpha_l x\cos(\alpha_l x)\cdot\phi(t)\exp(-\kappa^2\alpha_l^2 t)$$
$$-2\epsilon\sum_{l=1}^{\infty}\sum_{n=1}^{\infty} A_n\frac{ln(-1)^{l+n}}{(l^2-n^2)+4l^2\delta_{l,n}}\sin(\alpha_l x)\int_0^t\frac{d\phi(\tau)}{d\tau}\exp\{\kappa^2(\alpha_l^2-\alpha_n^2)\tau\}d\tau\cdot\exp(-\kappa^2\alpha_l^2 t)$$

where

$$A_l\equiv\frac{2}{a}\int_0^a\{f(\xi)-\theta_0\}\sin(\alpha_l\xi)d\xi\ ,\quad \alpha_l\equiv\frac{l\pi}{a}\ .$$

[Example 2] (Hyperbolic Case) *The lateral vibration of a uniform string, strained between the two ends at* $x=0$ *and at* $x=a\{1+\epsilon\phi(t)\}$, *with* $\phi(0)=0$, *respectively, with the tension being kept constant, as is realized by the use of a smooth pulley, which is made to move longitudinally according to* $x=a(1+\epsilon\phi)$, *also playing the role of a fixed end for the lateral vibration, and through which the string is extended to be attached with a constant load.*

By making use of the transformation $x=\bar{x}\{1+\epsilon\phi(\bar{t})\}$ and $t=\bar{t}$, the lateral displacement $\Psi(x.\ t)$ which satisfies the equation $(\partial^2/\partial x^2-\partial^2/\partial t^2)\Psi=0$ (putting the velocity $c=1$ for the sake of simplicity) as well as the boundary-condition

$$(\Psi)_{t=0}=f(x),\qquad (\partial\Psi/\partial t)_{t=0}=v(x)\qquad \text{for}\quad 0<x<a,$$
$$(\Psi)_{x=0}=(\Psi)_{x=a(1+\epsilon\phi)}=0\qquad\qquad \text{for}\quad t\geqq 0\ ,$$

to the first order of approximation, is obtained as follows:

$$\Psi=\sum_{l=1}^{\infty}\{\sin(\alpha_l x)-\epsilon\phi(t)\alpha_l x\cos(\alpha_l x)\}\{A_l\cos(\alpha_l t)+\frac{B_l}{\alpha_l}\sin(\alpha_l t)\}$$
$$+2\epsilon\sum_{l=1}^{\infty}\sin(\alpha_l x)\int_0^t\sin\{\alpha_l(t-\tau)\}\{\alpha_l A_l\cos(\alpha_l\tau)+B_l\sin(\alpha_l\tau)\}\phi(\tau)d\tau$$
$$-2\epsilon\sum_{l=1}^{\infty}\sum_{n=1}^{\infty}\frac{(-1)^{l+n}\alpha_n}{(\alpha_l^2-\alpha_n^2)+4\alpha_l^2\delta_{l,n}}\sin(\alpha_l x)\left[A_n\sin(\alpha_l t)\cdot\left(\frac{d\phi}{dt}\right)_{t=0}+\int_0^t\sin\{\alpha_l(t-\tau)\}\chi_n(\tau)d\tau\right]$$

where

$$\chi_n(t)\equiv\{A_n\cos(\alpha_n t)+\frac{B_n}{\alpha_n}\sin(\alpha_n t)\}\frac{d^2\phi}{dt^2}-2\{\alpha_n A_n\sin(\alpha_n t)-B_n\cos(\alpha_n t)\}\frac{d\phi}{dt}$$

$$A_n\equiv\frac{2}{a}\int_0^a f(\xi)\sin(\alpha_n\xi)d\xi\ ,\qquad B_n\equiv\frac{2}{a}\int_0^a v(\xi)\sin(\alpha_n\xi)d\xi$$

$$\alpha_n\equiv\frac{n\pi}{a}\ .$$

[Example 3] (Elliptic Case) *The electrostatic potential* $\Psi(r,\theta,\varphi)$ *around a conductor at rest, whose shape* $r=a\{1+\epsilon\phi(\theta,\varphi)\}$ *is close to a sphere* $r=a$ *and whose own potential is held at a constant value* V_0.

By making use of the transformation $r=\bar{r}\{1+\epsilon\phi(\bar{\theta},\bar{\varphi})$, $\theta=\bar{\theta}$, $\varphi=\bar{\varphi}$, and by assuming the expression of ϕ in terms of the spherical harmonics

$$\phi(\theta,\varphi)=\sum_{l=0}^{\infty}\sum_{m=0}^{l}B_{lm}P_l^m(\cos\theta)\cdot\cos(m\varphi-\beta_m)$$

the solution $\Psi(r,\theta,\varphi)$ which satisfies the equation $\Delta\Psi=0$ as well as the boundary-condition $(\Psi)_{r=a(1+\epsilon\phi)}=V_0$ to the first order of approximation, is obtained as follows:

$$\Psi=V_0\frac{a}{r}\left[1+\epsilon\sum_{l=0}^{\infty}\sum_{m=0}^{l}B_{lm}\left(\frac{a}{r}\right)^l P_l^m(\cos\theta)\cos(m\varphi-\beta_m)\right]$$

Especially, when the conductor takes the shape of an ellipsoid (close to a sphere), it is easily verified that the above result coincides with what is derived from the well-known formula

$$\Psi(\mu)=\frac{Q}{2}\int_{\mu}^{\infty}\frac{d\nu}{\sqrt{(a^2+\nu)(b^2+\nu)(c^2+\nu)}}$$

with Q being the electric charge on the ellipsoid-shaped conductor and with the lower limit of integration μ depending upon the observer's point (x,y,z) through the equation

$$\frac{x^2}{a^2+\mu}+\frac{y^2}{b^2+\mu}+\frac{z^2}{c^2+\mu}=1\ ,$$

as is expected.

Acknowledgement

The author wishes to express his sincere thanks to Prof. Isao Oshida for his kind guidance and encouragements throughout this work.

Transonic Flow past a Wavy Wall

By Iwao HOSOKAWA

National Aeronautical Laboratory of Japan, Shinkawa, Mitaka, Tokyo

(Received July 28, 1960)

Transonic flow past an infinitely long sinusoidal wall has not hitherto been thoroughly investigated, although some studies of the high subsonic flow near the critical have been made by Kaplan and others by use of the thin-wing-expansion method and the transonic approximation method. In this paper the author studied transonic flows past a sinusoidal wall including shock waves by use of his new method, and could find the velocity and pressure distributions on the wall with success. The result gives a reasonable model for understanding the transition of the flow pattern from subsonic to supersonic.

§ 1. Introduction

In order to investigate the problem of the existence or non-existence of continuous mixed flows, it seems to be very convenient to study the transonic flow past a wavy wall. In 1940, Görtler[1] found a continuous solution of a high subsonic flow with local supersonic regions past a kind of wavy wall which is correct up to the third approximation and he conjectured it to be convergent. For the case of an exactly sinusoidal wall, the solution of Imai and Oyama[2] by the thin-wing-expansion method seems to be divergent above the critical Mach number. On the other hand, Kaplan[3] showed on the basis of the transonic approximation that a continuous, symmetrical wave solution would diverge above the critical Mach number. According to him, the critical value of the transonic similarity parameter defined after von Kármán is ξ_{crit}, $\kappa=-(0.83244/\pi)^{-2/3}$. Thus the solution of the supercritical flow may be asymmetric and would cease to be continuous.

The present work is concerned with this problem. The author makes use of his new method[4], which will be summarized in the next section. This method can give the reasonable features: shock waves appear whenever mixed flows occur, and the solution tends to the same form as that given by the usual linear theory in the sub- and supersonic extremities. The solution, however, has a weak point in the present problem : shock waves in the real flow are always accompanied by entropy increase, which would destroy periodicity of the flow, while the present hypothetical flow is assumed to be isentropic and periodic. But the present investigation seems to be still significant, because the increase of entropy is comparatively small and the periodicity remains locally.

§ 2. Summary of the Method

The basic equation of the two-dimensional transonic flow can be written as:[4]

$$(1-M_\infty^2)\Phi_{xx}+\Phi_{yy}=(\gamma+1)M_\infty^2\Phi_x\Phi_{xx} \qquad (2.1)$$

where $U_\infty\Phi$ is the perturbation velocity potential, U_∞ and M_∞ are the free stream velocity and Mach number respectively, γ is the ratio of specific heats, and the x-axis is taken in the direction of the free stream.

According to Oswatitsch and Maeder, the approximate potential φ satisfies the linearized equation :

$$(1-M_\infty^2)\varphi_{xx}+\varphi_{yy}=K\varphi_x \qquad (2.2)$$

where K is an appropriately chosen constant. The solution of (2.2) can be found in a simple way with the given boundary conditions, apart from the selection of the value of K.

Here we put

$$\Phi=\varphi+g \qquad (2.3)$$

and establish the equation governing the nonlinear correction term g. Then, with the aid of the order estimation of the equation, g_x can be calculated approximately in the neighbourhood of the boundary and it can be found that g_x and φ_x are of the same order of magnitude. (From this point of view, the linearized theory due to Maeder cannot be of the first order approximation in itself, because of the tacit assumption, $\varphi\gg g$.)

Finally g_x can be integrated as follows:

$$g_x=-\varphi_x+(1-M_\infty^2)/\{(\gamma+1)M_\infty^2\} \pm\sqrt{Y(x)} \qquad (2.4)$$

where

$$Y(x)=\left\{\varphi_x-\frac{1-M_\infty^2}{(\gamma+1)M_\infty^2}\right\}^2 -2\int_{c^*}^{x}\left\{\varphi_{cx}-\frac{K}{(\gamma+1)M_\infty^2}\right\}\varphi_x\,dx \qquad (2.5)$$

and the double sign corresponds to

$$\varphi_x\gtrless(1-M_\infty^2)/\{(\gamma+1)M_\infty^2\} \qquad (2.6)$$

On the proper physical and mathematical grounds, c^* and K are uniquely determined in the following manner :

$$\varphi_x(x=c^*,\ y=0;\ K) =(1-M_\infty^2)/\{\gamma+1)M_\infty^2 \qquad (2.7)$$

$$\varphi_{xx}(x=c^*,\ y=0;\ K) =K/\{(\gamma+1)M_\infty^2\} \qquad (2.8)$$

The former is the condition that $x=c^*$ is the sonic point on the boundary, and the latter means that K should be taken as the value of the acceleration at the sonic point. In treating usual transonic flows, (2.7) and (2.8) constitute the simultaneous equations for finding c^* and K. Next, for purely subsonic or supersonic flows, the value of c^* should be kept fixed at its lower or upper critical value just when the sonic point disappears out of the flow, on account of the continuous transition of the flow field with changing Mach number. And then K should be determined by (2.8) alone.

§ 3. Linearized Transonic Flow Potential

At first we require the solution of (2.2) subject to the boundary conditions:

i) $\varphi_y=f'(x)=i\omega f_0\,e^{i\omega x}$, for $y=0$ (3.1)

ii) grad $\varphi\to0$, for $y\to\infty$ (3.2)

where the wavy boundary is expressed as

$$f(x)=f_0\,e^{i\omega x}\quad (f_0,\ \omega:\ \text{real constants}) \qquad (3.3)$$

Here and hereafter we shall consider only the real parts of the complex expressions.

Now this solution is

$$\varphi=-(i\omega f_0/\mu)\exp\left(-\mu y+i\omega x\right) \qquad (3.4)$$

where

$$\mu=(\beta^4\omega^4+K^2\omega^2)^{1/4}\exp\left(\frac{i}{2}\tan^{-1}\frac{K}{\beta^2\omega}\right) \tag{3.5}$$

$$\beta^2=1-M_\infty^2 \tag{3.6}$$

so that

$$\varphi=-(\omega f_o/|\mu|)\exp[-\mathrm{Re}(\mu)y+i\{\omega x-\mathrm{Im}(\mu)y-\arg(\mu)+\pi/2\}] \tag{3.7}$$

By differentiation we have

$$\varphi_x=(\omega^2 f_o/|\mu|)\exp[-\mathrm{Re}(\mu)y+i\{\omega x-\mathrm{Im}(\mu)y-\arg(\mu)\}] \tag{3.8}$$

$$\varphi_{xx}=(i\omega^3 f_o/|\mu|)\exp[-\mathrm{Re}(\mu)y+i\{\omega x-\mathrm{Im}(\mu)y-\arg(\mu)\}] \tag{3.9}$$

In (3.8), we can see a rough feature of the transonic flow. First, in a supercritical flow in which $K\doteqdot 0$, the perturbed velocity and so the pressure have a phase lag, arg (μ), relative to the wall, which approaches $\pi/2$ as $\beta^2\to-\infty$ so that the solution would agree with that given by the supersonic linear theory. It is interesting to note that arg (μ) becomes $\pi/4$ when $M_\infty^2\to1\pm0$. Secondly, as is seen from (3.7)-(3.9), the perturbed wave is propagated along the straight line:

$$y=\{\omega/\mathrm{Im}(\mu)\}x+\text{const.} \tag{3.10}$$

which tends to the Mach line as $\beta^2\to-\infty$, as should be expected.

§4. Procedure of Refinement

1) *Constants c^* and K*

In the present case, (2.7) and (2.8) become

$$(1-M_\infty^2)/\{(\gamma+1)M^2_\infty\}=\omega^2 f_o/|\mu|\exp[i\{\omega c^*-\arg(\mu)\}] \tag{4.1}$$

$$K/\{(\gamma+1)M^2_\infty\}=i\omega^3 f_o/|\mu|\exp[i\{\omega c^*-\arg(\mu)\}] \tag{4.2}$$

with the aid of (3.8) and (3.9). If we introduce the transonic similarity parameter after Spreiter, $\xi_\infty=(M_\infty^2-1)/[(\gamma+1)M_\infty^2(2f_o)]^{2/3}$, where the wave length is assumed as unity, and another parameter after Maeder, $\alpha=K/2\beta^2$, the equation can be simplified as

$$\pm|\xi_\infty|^{3/2}=\frac{\pi}{(1+\alpha^2/\pi^2)^{1/4}}\times\exp\left[i\left(2\pi c^*-\frac{1}{2}\tan^{-1}\frac{\alpha}{\pi}\right)\right] \tag{4.3}$$

$$\pm2\alpha|\xi_\infty|^{3/2}\ i\,\frac{2\pi^2}{(1+\alpha^2/\pi^2)^{1/4}}\times\exp\left[i\left(2\pi c^*-\frac{1}{2}\tan^{-1}\frac{\alpha}{\pi}\right)\right] \tag{4.4}$$

where the double sign corresponds to $M_\infty\lesseqgtr1$.

Taking the real parts of the above equations, and eliminating $|\xi_\infty|$, we can obtain

$$2\pi c^*=-(1/2)\tan^{-1}(\alpha/\pi) \tag{4.5}$$

and hence the solutions for c^* and α:

$$\cos4\pi c^*=-\xi_\infty/\pi^{2/3} \tag{4.6}$$

$$\alpha=\pm\pi\sqrt{(\pi^{4/3}/\xi_\infty^2)-1} \tag{4.7}$$

where $|\xi_\infty|\leqq\pi^{2/3}$ is assumed.

Next we know from (4.6) that $\mp\pi^{2/3}$ should be the lower and upper critical values of ξ_∞, respectively and then c^*'s are N and $(-1/4)+N$ where N is an integer. Thus in order to know α in the case of $|\xi_\infty|\geqq\pi^{2/3}$, we have only to fix c^* at these values and solve for α by (4.4) in accordance with the prescription given in §2. As a result, it is assured that $\alpha=0$ holds irrespective of the values of ξ_∞ when $|\xi_\infty|\geqq\pi^{2/3}$.

Consequently we obtain the following explicit expressions of the linearized flow velocity.

$$\varphi_x=(\pi^{2/3}/|\beta|)2f_o|\xi_\infty|^{1/2}\exp[i\{2\pi x-(1/2)\tan^{-1}(\pm\sqrt{(\pi^{4/3}/\xi_\infty^2)-1})\}] \tag{4.8}$$

$$=\frac{\pi^{2/3}(2f_o)^{2/3}}{(\gamma+1)^{1/3}M_\infty^{2/3}}\exp\left[i\left\{2\pi x-\frac{1}{2}\tan^{-1}\left(\pm\sqrt{\frac{\pi^{4/3}}{\xi_\infty^2}-1}\right)\right\}\right] \tag{4.9}$$

$$\text{for}\quad|\xi_\infty|\leqq\pi^{2/3}$$

$$=\{\pi(2f_o)/\beta\}\,e^{i(2\pi x)}\qquad\text{for}\quad\xi_\infty\leqq-\pi^{2/3} \tag{4.10}$$

$$=\{\pi(2f_o)/|\beta|\}\,e^{i(2\pi x-\pi/2)}\qquad\text{for}\quad\xi_\infty\geqq\pi^{2/3} \tag{4.11}$$

2) *Sonic Point and Shock Wave Position*

When $|\xi_\infty|\leqq\pi^{2/3}$, we can find another root c^{**} in place of c^* from (4.3) and (4.7) as follows:

$$-\xi_\infty=\pi^{2/3}\cos\{2\pi c^{**}-(1/2)\tan^{-1}(\pm\sqrt{(\pi^{4/3}/\xi_\infty^2)-1})\} \tag{4.12}$$

$x=c^{**}$ is a point located in the decelerated flow region and it is known from (2.4)-(2.6) that there appears some velocity discontinuity at c^{**}. As was known from the previous paper[4),

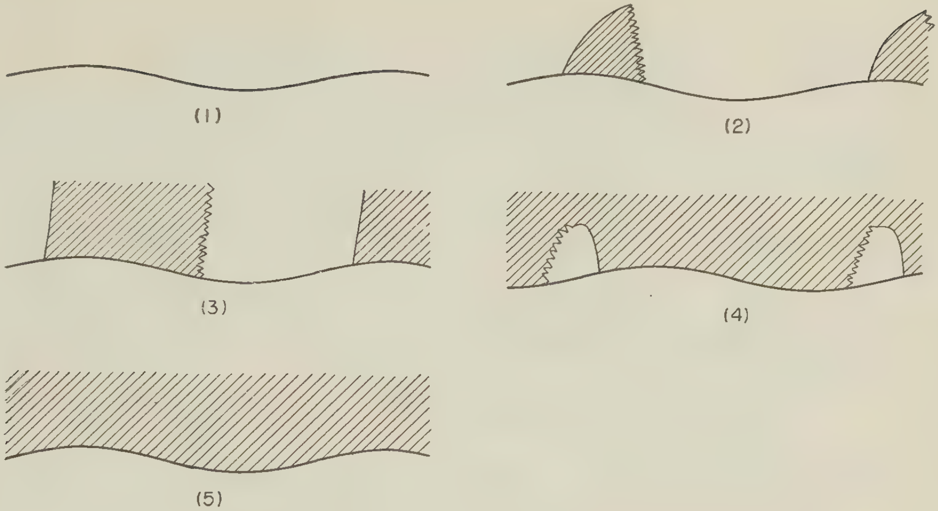

Fig. 1. Pictures of various transonic flows.
(a) subsonic flow.
(b) subsonic supercritical flow.
(c) sonic flow.
(d) supersonic but below upper critical flow.
(e) supersonic flow.
Shaded portions indicate supersonic regions, which are enclosed by sonic lines and shock lines drawn with solid and saw-toothed lines respectively.

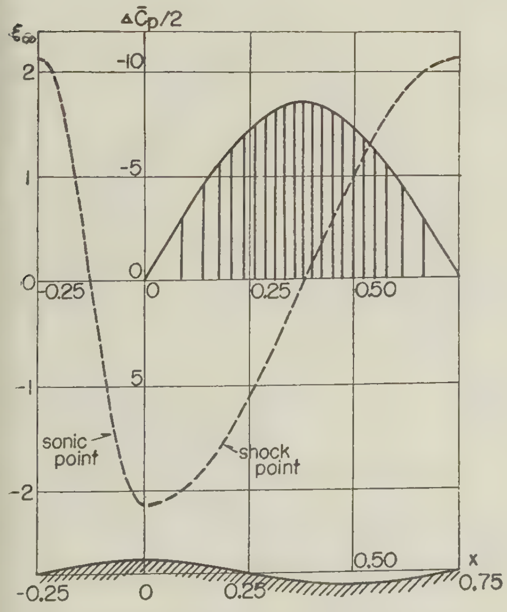

Fig. 2. Movement of sonic point and shock wave position on the wall with varying ξ_∞ and pressure jump at the shock.

it is considered as the position of the shock wave on the wall.

The manners in which the sonic point and the shock point on the wall change with ξ_∞ are shown in Fig. 2. Both of them first appear at the summits of the wavy wall at the instant when M_∞ reaches the lower critical value; then the sonic points move upstream and the shock points downstream with increasing Mach number, until each sonic point joins, at the upper critical Mach number, the receding shock point which has originated at the preceding summit of the wavy wall: thus all the sonic points coincide with the shock points and hence the subsonic regions disappear. This result may be interpreted as shown roughly in Fig. 1.

3) *Results of the Procedure of Refinement*

If we write

$$\varphi_x=(2f_o)/|\beta|\cdot F(x;\ \xi_\infty) \tag{4.13}$$

the following expressions for Φ_x are obtained with the aid of (2.4) and (2.5);

$$\Phi_x=\frac{1-M_\infty{}^2}{(\gamma+1)M_\infty{}^2}\pm\sqrt{2}\sqrt{\frac{(1-M_\infty{}^2)^2}{(\gamma+1)^2M_\infty{}^4}-\frac{(1-M_\infty{}^2)(2f_o)}{(\gamma+1)M_\infty{}^2|\beta|}F(x)+\frac{K(2f_o)}{(\gamma+1)M_\infty{}^2|\beta|}\int_{c^*}^{x}F(x)dx} \tag{4.14}$$

$$=\frac{2f_o}{|\beta|}\left\{(\pm)_1|\xi_\infty|^{3/2}\pm\sqrt{2}\sqrt{|\xi_\infty|^3(\mp)_1|\xi_\infty|^{3/2}F(x)+2|\alpha||\xi_\infty|^{3/2}\int_{c^*}^{x}F(x)dx}\right\} \tag{4.15}$$

for $|\xi_\infty|\leqq\pi^{2/3}$

and

$$\Phi_x=\frac{1-M_\infty^2}{(\gamma+1)M_\infty^2}\pm\sqrt{\frac{(1-M_\infty^2)^2}{(\gamma+1)^2M_\infty^4}+\frac{(2f_o)^2}{|\beta|^2}F(c^*)^2-2\frac{(1-M_\infty^2)}{(\gamma+1)M_\infty^2}\left(\frac{2f_o}{|\beta|}\right)F(x)} \tag{4.16}$$

$$=\frac{2f_o}{|\beta|}\{(\pm)_1|\xi_\infty|^{3/2}\pm\sqrt{|\xi_\infty|^3+F(c^*)^2\,(\mp)_1\,2|\xi_\infty|^{3/2}\,F(x)} \tag{4.17}$$

$$\text{for}\quad |\xi_\infty|\geqq\pi^{2/3}$$

where the double signs with and without the parenthesis $(\ \ )_1$ correspond respectively to $M_\infty\lessgtr 1$ and

$$F(x)\,(\mp)_1|\xi_\infty|^{3/2}\gtrless 0 \tag{4.18}$$

Here if the reduced pressure coefficient,

$$\bar{C}_p=\frac{\{(\gamma+1)M_\infty^2\}^{1/3}}{(2f_o)^{2/3}}C_p=\frac{|\beta|}{(2f_o)|\xi_\infty|^{1/2}}C_p \tag{4.19}$$

is introduced, we can obtain, using the approximate relation $C_p=-2\Phi_x$,

$$\bar{C}_p=-2\left\{(\pm)_1|\xi_\infty|\pm\sqrt{2}\sqrt{|\xi_\infty|^2(\mp)_1|\xi_\infty|^{1/2}F(x)+2|\alpha||\xi_\infty|^{1/2}\int_{c^*}^{x}F(x)\alpha x}\right\} \tag{4.20}$$

$$\text{for}\quad |\xi_\infty|\leqq\pi^{2/3}$$

and

$$C_p=-2\{(\pm)_1|\xi_\infty|\pm\sqrt{|\xi_\infty|^2+F(c^*)^2|\xi_\infty|^{-1}(\mp)_1\,2|\xi_\infty|^{1/2}\,F(x)}\} \tag{4.21}$$

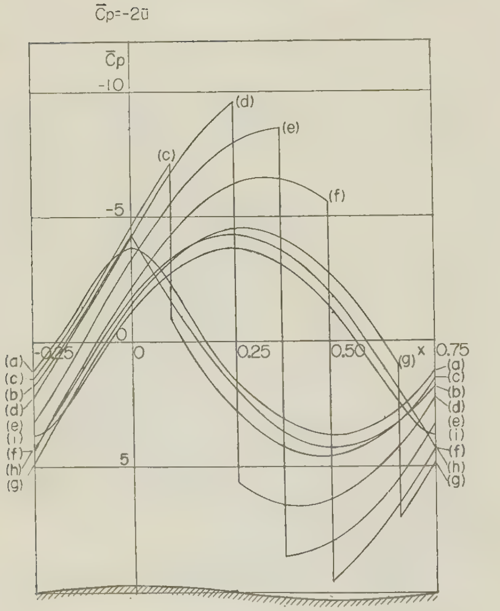

Fig. 3. Pressure distributions on the wall in terms of $\bar{C}_p$.

(a) $\xi_\infty=-2.8$
(b) $=-\pi^{2/3}$
(c) $=-2.0$
(d) $=-1.0$
(e) $=\ 0$
(f) $=\ 1.0$
(g) $=\ 2.0$
(h) $=\ \pi^{2/3}$
(i) $=\ 2.8$

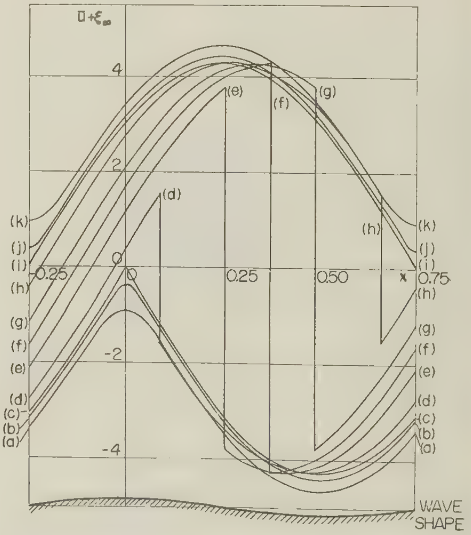

Fig. 4. Velocity distributions on the wall in terms of $\bar{u}+\xi_\infty$.

(a) $\xi_\infty=-2.8$
(b) $=-2.4$
(c) $=-\pi^{2/3}$
(d) $=-2.0$
(e) $=-1.0$
(f) $=\ 0$
(g) $=\ 1.0$
(h) $=\ 2.0$
(i) $=\ \pi^{2/3}$
(j) $=\ 2.4$
(k) $=\ 2.8$

$$=-2|\xi_\infty|^{1/2}\begin{Bmatrix} e^{i(2\pi x)} & (\xi_\infty<o) \\ e^{i(2\pi x-\pi/2)} & (\xi_\infty>o) \end{Bmatrix}+O(|\xi_\infty|^{-2}) \tag{4.22}$$

$$\text{for} \quad |\xi_\infty|\geqq\pi^{2/3}$$

All these results are consistent with the transonic similarity law.

(4.22) may be rewritten in the usual form of the pressure coefficient as follows:

$$C_p=-2\frac{(2f_o)}{|\beta|}\pi\begin{Bmatrix} e^{i(2\pi x)} & (\xi_\infty<o) \\ e^{i(2\pi x-\pi/2)} & (\xi_\infty>o) \end{Bmatrix}+O[(2f_o)^2] \tag{4.23}$$

This agrees with the result given by the usual linear theory.

Next, in order to see directly the velocity distribution in a reduced form that is invariant under the transonic similarity transformation, we introduce the following quantity:

$$\bar{u}+\xi_\infty\equiv\frac{\{(\gamma+1)M_\infty{}^2\}^{1/3}}{(2f_o)^{2/3}}\left\{\Phi_x+\frac{M_\infty{}^2-1}{(\gamma+1)M_\infty{}^2}\right\}=\frac{M^2-1}{\{(\gamma+1)(2f_o)M^2{}_\infty\}^{2/3}} \tag{4.24}$$

Then it indicates the local Mach number distribution in such a manner that

$$\bar{u}+\xi_\infty \gtreqless 0 \qquad \text{when} \qquad M \gtreqless 1 \tag{4.25}$$

Thus we can see our results for the pressure and local Mach number distributions in terms of the respective reduced quantities in Figs. 3 and 4. Now, the half of the pressure jump at the shock is found from (4.20), that is,

$$\Delta\bar{C}_p/2=2\sqrt{2}\sqrt{|\xi_\infty|^2(\mp)_1|\xi_\infty|^{1/2}F(c^{**})+2|\alpha||\xi_\infty|^{1/2}\int_{c^*}^{c^{**}}F(x)dx} \tag{4.26}$$

which is shown in Fig. 2, for a given shock wave position c^{**}.

§ 5. Discussion and Conclusion

A comparison with Kaplan's result for the lower critical flow is shown in Fig. 5. For the wall of the waviness ratio $2f_o=0.01$, the critical Mach number is about 0.91 in his case, according to Shapiro's sample calculation[5], while it is 0.917 in our case. With respect to the peak negative pressure there is no great difference. Thus, our approximation method is more satisfactory in comparison with Kaplan's one which requires more lengthy calculation, in order to inquire into the general feature of transonic flows.

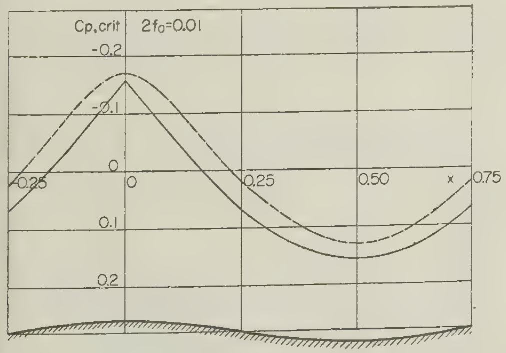

Fig. 5. Comparison of pressure distributions on the wall in the lower critical flow, predicted by Kaplan and by the present method. (The former is based on the figure given in Ref. 5.)
- - - - - - Kaplan, $M_{\infty,\,\mathrm{crit}}=0.91$
———— Present, $M_{\infty,\,\mathrm{crit}}=0.917$

Further, we can find a close analogy between the flows through a one-dimensional Laval nozzle and past a sinusoidal wall. Namely, the flow patterns shown in Figs. 3 and 4 are quite similar to those of the former if the sonic point of the latter is considered as corresponding to the throat, although in our case the sonic point moves upstream along the wall with increasing Mach number. Therefore it is not strange that the curves of $\bar{C}_p(x)$ and $\bar{u}(x)+\xi_\infty$ have sharp angles at the sonic points when the flow is critical (lower or upper). It will be interesting to compare this fact with Wood and Clarke's recent work[6] on the transonic flow in cascades, in which they evaluated, with success, the effect of the nonlinear term of the fundamental

equation (2–1) by replacing the term by the corresponding quantity of the one-dimensional flow.

Thus, it is found that our new approximation method can be applied successfully to the transonic flow past a sinusoidal wall and hence it may be expected that our method would be useful for the consideration of the general feature of the transonic flows.

In conclusion, the author wishes to express his sincere gratitude to Professor R. Kawamura and Mr T. Shigemi for their kind advice and valuable discussions.

Selbstzündung von Kohlenwasserstoff-Luftgemischen in Stosswellen

von Kunio TERAO
Institut für physikalische Chemie der Universität Göttingen

(Received July 4, 1960)

The ignition mechanism of hydrocarbon-air mixtures is discussed. Thus, the ignition probabilities of various hydrocarbon-air mixtures were computed from the fluctuations of their ignition lags in shock waves. From these ignition probabilities, the activation energies of the primary and secondary reactions were calculated.

Next, the activation energies for the C–H and C–C bonds in the reaction with oxygen are estimated, as well as the amount of heat liberated for secondary reactions.

The mean ignition lags of other n-paraffin-air mixtures were, in accord with the experimental conditions, estimated from the above determined values.

Einleitung

Wie in der letzten Arbeit(1) über die Selbstzündung des n–Hexan-Luft-Gemisches in Stoßwellen berichtet wurde, hat die Induktionszeit der Entzündung eines brennbaren Gemisches immer eine Schwankung, von der man aber die Wahrscheinlichkeit der Entzündung des Gemisches in einer Zeiteinheit ausrechnen kann, damit man den Zündmechanismus genauer betrachten kann.

Um den Zündmechanismus der verschiedenen Brennstoffe zu vergleichen, werden in dieser Arbeit Methan–, Äthan–, Äthylen-Luft-Gemische und Äthan-Sauerstoff-Gemisch genau so wie beim n–Hexan-Luft-Gemisch untersucht.

Versuchsergebnisse

Das Experiment wurde genau so wie beim n–Hexan - Luftgemisch durchgeführt, d. h. unter derselben Bedingung wurden zahlreiche Versuche gemacht, so daß man die Schwankung der Induktionszeit der Entzündung messen kann. Von der Schwankung der Entzündungsinduktionszeit wurde die Wahrscheinlichkeit der Entzündung in einer Millisekunde

und in einem Mol Gemisch ausgerechnet. Davon wurden weiter die Aktivierungsenergien der Start- und Sekundärreaktion, Konstante A und B in den Gleichungen 5 und 6 in der letzten Arbeit usw. für Methan-, Äthan-, Äthylen-Luft-Gemische und Äthan-Sauerstoff in verschiedener Temperatur mit verschiedener Konzentration berechnet.

Bild 1, 2, Tabelle I und II zeigen die Ergebnisse. In der Tabelle sind die Verschsergebnisse des n-Hexan-Luftgemisches auch ersichtlich.

1) *Aktivierungsenergie der Startreaktion E_1:*

Nach diesen Ergebnissen kann man erst die Aktivierungsenergie der Startreaktion der Methan-, Äthan-, und n-Hexan-Luftgemische vergleichen. Wie Bild 3 zeigt, ist die Aktivierungsenergie des Methan-Luftgemisches durchschnittlich 27,3 kcal/Mol und viel größer als die der andern, aber der Unterschied der Aktivierungsenergie des Äthan Luftgemisches (19.9 kcal/Mol) und des n-Hexan-Luftgemisches (16.4 kcal/Mol) ist nicht so groß. Es ergibt sich wahrscheinlich aus dem Unterschied der Molekülstruktur. Nämlich Methan hat nur 4 C–H Bindungen. Dagegen hat Äthan 1 C–C und 6 C–H Bindungen und n-Hexan 5 C–C und 14 C–H Bindungen.

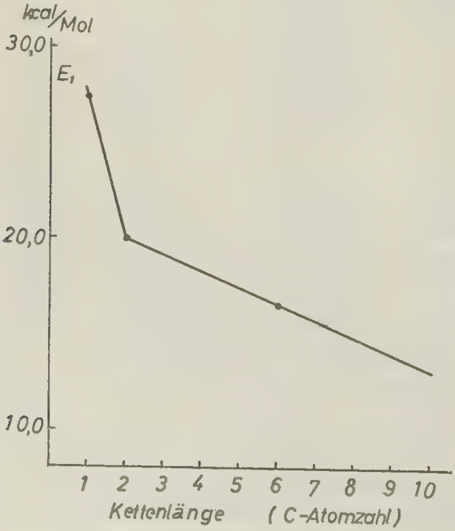

Bild 3.

Bei der Entzündung des Äthan-Luftgemisches soll erst die C–C Bindung auseinandergehen und mit Sauerstoff eine chemische Reaktion machen, weil ihre Bindungskraft kleiner ist als die der C–H Bindung⁽²⁾ und sie sogar den größten Kraftmoment hat. Mit dem n-Hexan-Luftgemisch soll es auch genau so gehen, nämlich die C–C Bindung in der Mitte der C–C Kette muß erst auseinandergehen und mit O_2 eine Reaktion machen. Deshalb muß die Aktivierungsenergie der Startreaktion in den beiden Fällen die Energie sein, mit der eine C–C Bindung auseinandergeht und mit Sauerstoff eine chemische Reaktion macht. Daß die Aktivierungsenergie des Äthan-Luftgemisches etwas größer ist als die des n-Hexan-Luftgemisches, ist deswegen, weil die Kette des n-Hexan viel länger ist und sein Kraftmoment größer sein muß als Äthan.

Beim Methan-Luftgemisch muß erst irgendeine C–H Bindung auseinandergehen, aber die

Bindungskraft der C–H Bindung ist viel größer als die der C–C Bindung. Deshalb ist die Aktivierungsenergie der Startreaktion des Methan-Luftgemisches viel größer als die des Äthan– und *n*–Hexan-Luftgemisches.

Hieraus und aus den Versuchsergebnissen könnte man schließen, daß die Aktivierungsenergie der C–H Bindung für die Reaktion mit O_2 etwa 27,0 kcal/Mol und die der C–C für die Reaktion mit O_2 etwa 20 bis 15 kcal/Mol, aber immer verschieden je nach der Kettenlänge ist, d.h. je länger die Kette ist, um so geringer ist die Aktivierungsenergie der C–C Bindung für die Reaktion mit O_2, wie Bild 3 zeigt.

2) *Reaktionsstufenzahl*:

Wie in der letzten Arbeit beim *n*–Hexan-Luftgemisch erklärt wurde, kann man von dem Zusammenhang zwischen der Konzentration des Brennstoffes und Konstanten A oder B die Reaktionsstufenzahl n_1 und n_2 ausrechnen. Beim Äthan– und Methan-Luftgemisch ist es nicht so deutlich und man kann daraus die Reaktionsstufenzahl nicht gut schätzen, vielleicht deswegen, weil die Reaktionsstufenzahl dabei nicht so groß ist und die Änderung des A oder B mit der Konzentration ziemlich klein ist. Da man aber schon beim *n*–Hexan-Luftgemisch n_1 und n_2 ungefähr schätzen konnte, kann man davon weiter n_1 und n_2 bei andern Brennstoffen schätzen. Da nämlich A proportional $\left(\frac{1}{\lambda}\right)^{n_1+n_2}$ ist, kann man die Reaktionsstufenzahl des verschiedenen Brennstoffes mit derselben Konzentration vergleichen, weil der Unterschied der Molekülsgröße hier fast keine Rolle spielt, und sie damit erhalten. Daraus kann man schließen, daß die Reaktionsstufenzahl des Äthan-Luftgemisches 4 und die des Methan Luftgemisches 3 ist, wenn n_1+n_2 beim *n*–Hexan-Luftgemisch 5 ist, wie schon in der letzten Arbeit geschätzt wurde. Von B kann man n_2 bestimmen. Beim *n*–Hexan-Luftgemisch ist es 4. Daraus wurde n_2 beim Äthan-Luftgemisch 3 und beim Methan-Luftgemisch 2 geschätzt.

3) *Reaktionsvorgänge*:

Da die Aktivierungsenergie der Startreaktion und die Reaktionsstufenzahl schon bekannt sind, könnte man damit die Reaktionsvorgänge einigermaße vermuten.

Beim Methan-Luftgemisch sollte erst eine C–H Bindung mit Stoß eines Sauerstoffmoleküls auseinander gehen und mit O_2 eine Reaktion machen, und dann anschließend andere 2 C–H Bindungen genau so wie die erste aber mit der Wärme von jeder vorgehenden Reaktion nacheinander auseinandergehen und in die Reaktion mit O_2 kommen. Beim Äthan-Luftgemisch kommt erst die C–C Bindung in die Reaktion und anschließend kommen 3 C–H Bindungen nacheinander in die Reaktion mit der Wärme von jeder vorgehenden Reaktion.

Beim *n*–Hexan-Luftgemisch geht vielleicht, wie schon gesagt, erst die C–C Bindung in der Kettenmitte auseinander und das Molekül wird in zwei getrennt.

$$-C-C-C-C-C-C \rightarrow -C-C-C-O \quad -O-C-C-C-$$

Dann wirkt jeder Teil schon wie ein Molekül, d.h. sie haben miteinander keinen besondern Zusammenhang mehr. Eins davon trennt sich weiter und vielleicht geht nochmals eine C–C Bindung auseinander, weil die Bindungskraft der C–C kleiner ist als die der C–H Bindung. Anschließend gehen noch 2 C–H Bindundgen auseinander und kommen in die Reaktion mit O_2. Nämlich an der Primärreaktion nimmt eine C–C Bindung teil und an der Sekundärreaktion nehmen 2 C–C und 2 C–H Bindungen teil. Inzwischen können natürlich mehrere komplizierte Kettenreaktion von sich gehen, aber solange man von solcher konkreten Reaktion absieht und nur die Reaktion mit Sauerstoffmolekülen betrachtet, könnte es mit größer Möglichkeit so wie oben erklärt gehen.

Um diese Sache nochmals klar zu machen, wurde noch ein Experiment mit Äthylen-Luftgemisch gemacht. Wie es in Bild 1 oder Tabelle II gezeigt ist, sind sowohl die Aktivierungsenergien der Primär- und Sekundärreaktion wie A und B fast gleich denen von Methan-Luftgemischen. Das bedeutet nämlich, daß die Entzündungsreaktion des Äthylen-Luftgemisches genau so vor sich geht wie die des Methan-Luftgemisches. Da die C=C Bindung, die Äthylen hat, viel größere Bindungskraft hat als C–H Bindung, geht erst eine C–H Bindung auseinander und dann schließen 2 C–H Bindungen an, genau so wie beim Methan-Luftgemisch.

4) *Die Aktivierungsenergie der Sekundärreaktion E_2 und die zur Sekundärreaktion zugeführte Wärme W:*

Da die Aktivierungsenergien der C–C und C–H Bindung für die Reaktion mit O_2 klar geworden sind und die Reaktionsvorgänge vermutet werden können, kann man daraus die Aktivierungsenergie der Sekundärreaktion ausschätzen.

Beim Methan-Luftgemisch kommt erst 1 C–H Bindung in die Reaktion, die zur Startreaktion gehört, und dann schließen 2 C–H Bindungen in der Sekundärreaktion an. Die Aktivierungsenergie einer C–H Bindung für die Reaktion mit O_2 ist nach dem Experimentsresultat 27,0 kcal/Mol. Deshalb soll die Aktivierungsenergie der Sekundärreaktion $E_2=2\times 27{,}0=54{,}0$ kcal/Mol. Beim Äthan-Luftgemisch kommen 3 C–H Bindungen in die Sekundärreaktion. $E_2=3\times 27{,}0=81{,}0$ kcal/Mol.

Beim *n*-Hexan-Luftgemisch kommen 2 C–C und 2 C–H Bindungen in die Sekundärreaktion. Aber dabei soll die Aktivierungsenergie der C–C Bindung zwischen denen der C–C Bindung in der Mitte der *n*-Hexankette und der Methankette, d.h. 16,4 und 19,9 kcal/Mol, weil die Kettenlänge zur Sekundärreaktion länger ist als Äthan, aber kürzer als *n*-Hexan. Je weiter die Sekundärreaktion vor sich geht, um so kürzer wird die Kettenlänge und um so weniger wird das Kraftmoment, d.h. um so mehr braucht man die Aktivierungsenergie. Hier wurde der Mittelwert 18,0 kcal/Mol genommen.

$$E_2=2\times 18{,}0+2\times 27{,}0=90 \text{ kcal/Mol.}$$

Da E_2-W schon vom Experiment bekannt ist, kann man leicht die zur Sekundärreaktion zugeführte Wärme W ausrechnen. Beim *n*-Hexan-Luftgemisch ist W von 71.0 bis 83,0 kcal/Mol, beim Äthan-Luftgemisch 64,2 bis 65,3 kcal/Mol und beim Methan-Luftgemisch 27,0 bis 35,1 kcal/Mol. Je magerer das Gemisch ist, desto geringer ist die Wärme.

5) *Die ausgeführte Totalwärme bei der Reaktion W_T:*

Die Wärme W, die zur Sekundärreaktion zugeführt wird, ist nur ein Teil der gesammten Wärme W_T, die bei der ganzen Reaktion entsteht. Jetzt denken wir nur an eine C–C bzw. C–H Bindung. Nehmen wir ε als die Aktivierungsenergie für die Reaktion, w_t als die Totalwärme, die gleich der Aktivierungsenergie für die Reversreaktion ist, und Δh als die Reaktionswärme, die man nach der Reaktion merkt und gleich $w_t-\varepsilon$ ist. Für die nachfolgende Reaktion wirkt nicht die Reaktionswärme Δh, sondern die Totalwärme der vorgehenden Reaktion w_t, die der Unterschied zwischen dem angeregten Zustand und dem nach der Reaktion ist. Dabei kann jede nachfolgende Reaktion nicht die ganze Wärme bekommen, sondern einen Teil davon, weil sich die Wärme durch die Stöße mit nichtaktivierten Molekülen vermindern muß.

Die Reaktionswärme Δh kann man nach der Bindungsenergie(2) ausrechnen, wenn man die Reaktionsvorgänge kennt.

Δh bei der Reaktion einer C–H Bindung mit O_2 33,8 kcal/Mol und Δh bei der Reaktion einer C–C Bindung 22,3 kcal/Mol

Die Summe der Aktivierungsenergie und der Reaktionswärme soll die ausgeführte Totalwärme sein.

w_t einer–C–H Bindung bei der Reaktion mit O_2
$=33{,}8+27{,}0\approx 61{,}0$ kcal/Mol

w_t einer C–C Bindung bei der Reaktion mit O_2
$=22{,}3+18{,}0\approx 40$ kcal/Mol

Daraus kann man die ausgeführte Totalwärme von jedem Gemisch errechnen.

Beim Methan-Luftgemisch ist W_T $3\times 61=183$ kcal/Mol, weil dabei 3 C–H Bindungen in Frage kommen. Beim Äthan-Luftgemisch ist es $1\times 40+3\times 61=223$ kcal/Mol und beim *n*-Hexan-Luftgemisch $3\times 40+2\times 61=242$ kcal/Mol.

Die Differenz zwischen der Totalwärme W_T und der zur Sekundärreaktion zugeführten Wärme W ist die Wärme, die in die Umgebung des betreffenden Moleküls übergeht, oder im Molekül bleibt, um es zu wärmen.

Bei der Entzündung muß die Wärme von der Entzündungsreaktion oder der sogenannten Vorreaktion zur Umgebung des betreffenden Moleküls ausgeführt werden, so daß die Reaktion sich zur Verbrennung erweitern kann. Wie bis dahin erklärt wurde, braucht man bis zur Entzündung nicht die vollkommenen Reaktion des Brennstoffsmoleküls, sondern einige Stufen, z.B. bei Methan 3, bei Äthan 4 und bei *n*-Hexan 5. Denn die Wärme von der unvollkommenen Reaktion genügt schon, um einen Teil der Umgebung des Brennstoffsmoleküls zu erwärmen, so daß die Reaktion sich erweitern kann. Diese Wärme soll die Wärme sein, die die Differenz von der Wärme W_T und W ist. Merkwürdig ist es, daß die von der Entzündgsreaktion in die Umgebung ausgeführte Wärme bei jedem Gemisch fast immer gleich etwa 150 kcal/Mol ist. Das bedeutet nämlich, daß man für die Entzündung immer so viel Wärmeausfuhr braucht.

Beim Äthan-Sauerstoffgemisch ist die Aktivierungsenergie der Startreaktion 40 kcal/Mol (Bild 1 und Tabelle II) und die der Sekundärreaktion fast gleich der beim Äthan-Luftgemisch. Vielleicht kommen in die Startreaktion eine C–C und eine C–H Bindung gleichzeitig, weil die Aktivierungsenergie ungefähr gleich der Summe der von C–C und C–H Bindung ist. Deshalb muß die Reaktion der Entzündung der Äthan-Sauerstoffgemisches gesamt 5 Reaktionsstufen haben, nämlich 1 C–C und 4 C–H Bindung kommen in die Reaktion. Das kommt vielleicht daher, daß es so viel Wärme ausführen muß, um die Umgebung zu erwärmen, daß die Reaktion weiter in der Umgebung vor sich gehen kann, weil die spezifische Wärme etwas mehr ist als die der Luft und zwar auch daher, daß es sich mit Sauerstoff leicht Reaktion machen kann, weil es in der Umgebung des Brennstoffsmoleküls viel Sauerstoff gibt.

6) *Wärmeerhaltungskoeffizient*:

Wieviel Prozent von der Totalwärme zur Sekundärreaktion effektiv wirkt, wird von dem Verhältnis der zur sekundären Reaktion zugeführten Wärme W und gegen die Summe der Totalwärme jeder Reaktionsstufe außer der letzten gezeigt. Die Wärme, die in der letzten Reaktionsstufe entsteht, spielt keine Rolle zur Sekundärreaktion. Dieser Wärmeerhaltungskoeffizient ist verschieden je nach der Konzentration, besonders je nach dem Brennstoff. Beim n-Hexan-Luftgemisch ist es 40 bis 46%, beim Äthan-Luftgemisch etwa 40% und beim Methan-Luftgemisch 23 bis 30%. Das ist vielleicht deswegen, weil die Reaktionsvorgänge verschieden sind, nämlich verschiedene chemische Bindungen in die Reaktion kommen. Daraus wurde jeder Wärmeerhaltungskoeffizient für C–C und C–H Bindung bei der Reaction mit O_2 geschätzt. Für C–C Bindung ist es etwa 57% und für C–H 27%, bei der Konzentration etwa 1,3%.

Verallgemeinerung

In der vorigen Arbeit[1] über Selbstzündung des n-Hexan-Luftgemisches wurde erklärt, daß man je nach dem Zustand die Induktionszeit der Entzündung theoretisch ausrechnen kann, wenn die Wahrscheinlichkeit der Entzündung in einer Zeiteinheit und die Zeitlänge, in der keine Entzündung entsteht, bekannt sind. Dazu braucht man aber die Aktivierungsenergien der Start- und Sekundärreaktion E_1 und E_2, die zur Sekundärreaktion zugeführte Wärme W, Konstante A und B. Wenn man die Reaktionsvorgänge der Entzündung kennt, d.h. welche chemische Bindung sich wie oft an der Reaktion beteiligt, kann man schon diese Werte schätzen.

Die Reaktionsvorgänge der n-Paraffine, die man von ihrem Molekülstruktur und von ihrer in die Umgebung des betreffenden Moleküles ausgeführten Wärme schätzen kann, sind Folgende:

Brennstoff	Startreaktion	Sekundärreaktion
CH_4	C–H	2 C–H
C_2H_6	C–C	3 C–H
C_3H_8 und C_4H_{10}	C–C	2 C–C, 2 C–H
C_5H_{12}, C_6H_{14}, C^7H_{16}, C_8A_{18} und $C_{10}H_{22}$	C–C	2 C–C, 2 C–H

Damit kann man jede Reaktionsstufenzahl der Start- und Sekundärreaktion n_1 und n_2

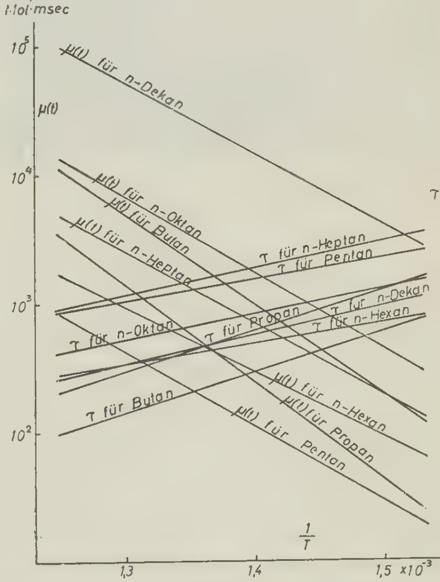

Bild 4.

erhalten, und gleich weiter A und B halbempirisch von den Resultaten des oben berichteten Experiments, E_1 und E_2 kann man auch genau so bekommen. Mit diesen Werten kann man schon die Wahrscheinlichkeiten der Entzündung in einer Millisekunde in einem Mol Gemisch und τ ausrechnen, mit denen man weiter alle Entzündungsinduktionszeiten beliebter n-Paraffin-Luftgemische je nach dem Zustand theoretisch errechnen kann. Bild 4 zeigt die theoretisch berechneten τ und Wahrscheinlichkeiten der Entzündung in einer Millisekunde in einem Mol Gemisch von Propan-, Butan-, Pentan-, n-Heptan, n-Oktan und n-Decan-Luft Im Bild 5 werden die durchschnittlichen Induktionszeiten, die nach dieser Theorie ausgerechnet werden, und die empirisch gemessenen von der Arbeit(3) von A. Martinengo verglichen, in der das Gemisch in einem Stahlzylinder mit einem Kolben schnell adiabatisch gedruckt und gezündet wurde. Die Temperatur verschiebt sich allgemeine nach unten, aber solcher Fehler kommt oft vor, wenn Experiments- und Meßmethode anders ist. Aber sonst stimmen beide Werte ziemlich gut überein, besonders die anschaulichen Aktivierungsenergien E, die von den Neigungen der Kurve $ln\ \tau_i$ in Bezug auf $1/T$ nach Gleichung $\tau_i = \text{Konst.} \times e^{\frac{E}{RT}}$ errechnet werden sollen, stimmen sehr gut überein.

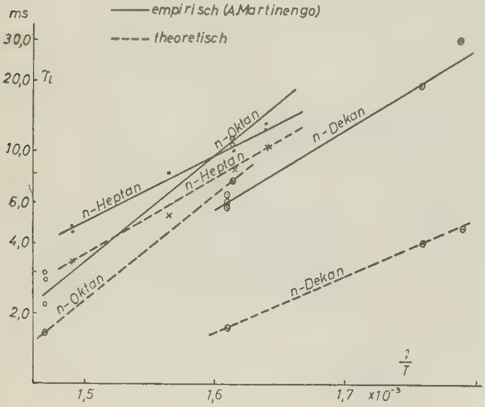

Bild 5.

Zusammenfassung

Mit der letzten und dieser Arbeit ist klar geworden, daß man von der Wahrscheinlichkeit der Entzündung in einer Zeiteinheit, die man aus der Schwankung der Induktionszeit der Entzündung errechnen kann, viel neues wissen und vermuten kann, z.B. welche chemische Bindung an welcher Reaktion teilnimmt, wie groß jede Aktivierungsenergie, die Totalwärme, die Sekundärreaktion zugeführte Wärme, Konstante A und B usw. Nach diesen empirischen und theoretischen Ergebnissen kann man auch die durchschnittlichen Induktionszeiten der Entzündung beliebiger n-Paraffin-Luftgemische schätzen.

Zum Schluß danke ich Herrn Prof. W. Jost und Herrn Dr. Wagner, die mir die Chance gegeben haben, diese Arbeit zu tun, und für die freundliche Leitung.

Glass Cracking Caused by Underwater Spark

By Shin-ichi HYODO
Department of Applied Physics, University of Tokyo, Tokyo
Fumiko OKUDA
Department of Physics, University of Tokyo, Tokyo

(Received July 5, 1960)

Using a Beckman & Whitley high-speed framing camera, the velocity of glass fracture caused by an underwater disruptive electric spark was measured. The observed maximum velocity was about 2.4 km/sec, 60% higher than the usually accepted normal limiting value. A gradual decrease of fracture velocity was also observed. From these observations it has been deduced that the maxium fracture velocity is, contrary to the hitherto assumed theory, dependent on the increasing rate of applied stress.

§ 1. Introduction

Since in 1937 Schardin and Struth[1,2] studied the spread of impact fractures in glass by the use of their multiple-spark camera, not a few investigations have been carried out for the determination of glass-fracture velocity.[3,4,5,6,7,8] They unanimously indicated that for any kind of glass there existed a certain constant maximum velocity corresponding to its chemical composition (about 1500 m/sec for normal glass), which was not affected either by the over-all stress at the moment of fracture or by the temperature of glass specimen. According to Dimmick[5], the effect of the latter on a soda-lime glass can be expressed as the temperature coefficient on the order of -0.15 m/sec/°K. This maximum velocity is approximately equal to one half of the velocity of transverse waves and to one third of that of longitudinal waves in the material studied. Theoretical considerations supporting this limiting value from the standpoint of its correlations with elastic waves were also developed by Poncelet[9], Yoffe[10], Mott[11], and Robert and Wells[12].

In some of his earlier works, however, Hirata[13] presented a photograph like the one in Fig. 1, which shows the initial state of glass fracture produced by underwater spark discharge. It should be noticed that this shadowgraph of growing cracks was taken in the light emitted from the underwater spark itself with some suitable arrangement of a reflecting spherical mirror placed under the glass plate. Therefore, even if the light duration of the spark be 1 μsec (this is rather an over-estimation for ordinary spark shadowgraphs), the velocity of glass fracture in this case would surpass the above-mentioned limiting value.

The main purpose of our work was to check this point by means of successive high-speed photography.

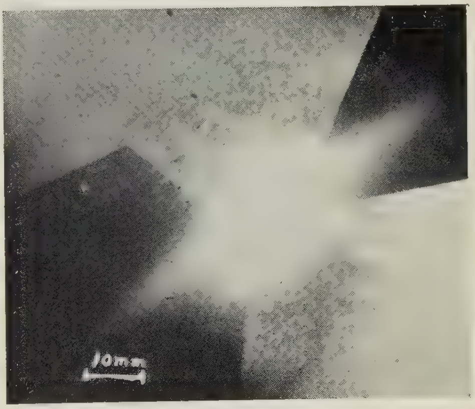

Fig. 1. A silhouette photograph of growing glass cracks initiated by an underwater electric spark.

§ 2. Experimental Procedure

The specimen was prepared by cutting an ordinary sheet glass. Between this specimen having a square form of about 7×7 cm^2 and 1.4 mm thickness and the glass plate having the same form but a larger thickness were sandwiched two pieces of aluminium foil cut in a spear-like shape as a couple of electrodes as shown in Fig. 2. The tips of the foils were placed facing each other with a gap of about 1 mm between them. After such procedure was carried out wholly in the water with special care to extrude any trace of air bubbles, the specimen assembly was left in a water tank equipped with a glass window in its bottom.

The schematic diagram of the whole experimental arrangement is shown in Fig. 3. In order to catch the sequence of the events, a high-speed framing camera (Beckmen & Whitley Model 189) was used. As this instrument is not equipped with any adequate shutter, a Xenon flash lamp of sufficiently short duration was adopted as the illumination source so as to prevent the film from double exposure. When the rotating mirror in the camera attained a definite speed, a sharp pulse was brought out from the camera by manual switching just before the mirror came to the position of the first frame. This pulse served both for firing the flash lamp immediately and for triggering the main underwater spark after the delay of 2 μsec or so.

When the third electrode of the three-point gap was triggered, a high voltage of 50 KV, at which the Leyden jar had been kept, was

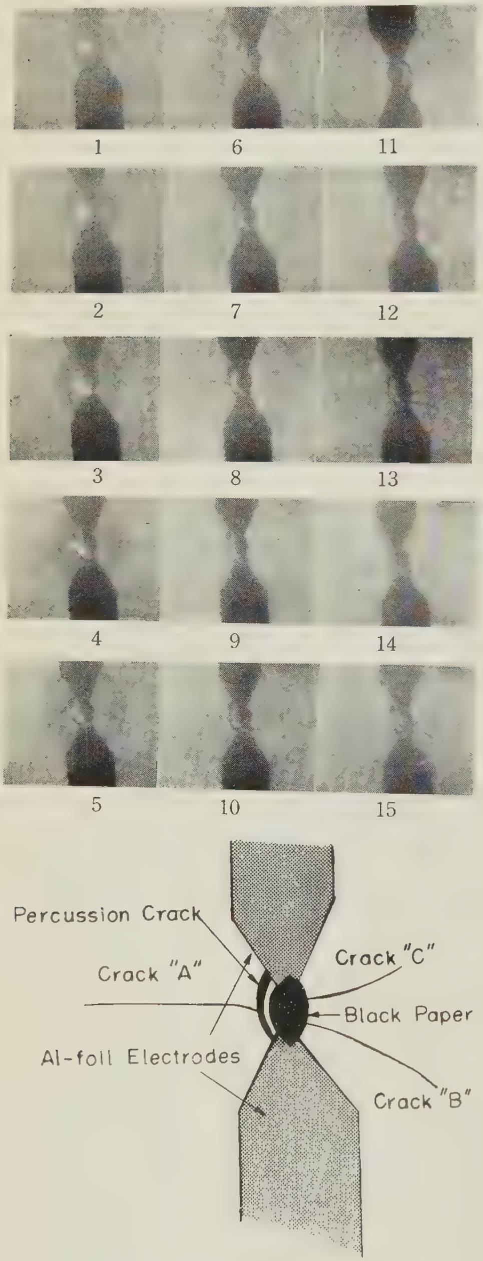

Fig. 4. A sequence of 15 pictures taken at a rate of 1.8×10^6/sec, using the Beckman & Whitley high-speed framing camera. The sequence shows the initial stage of glass fracture produced by underwater spark discharge.

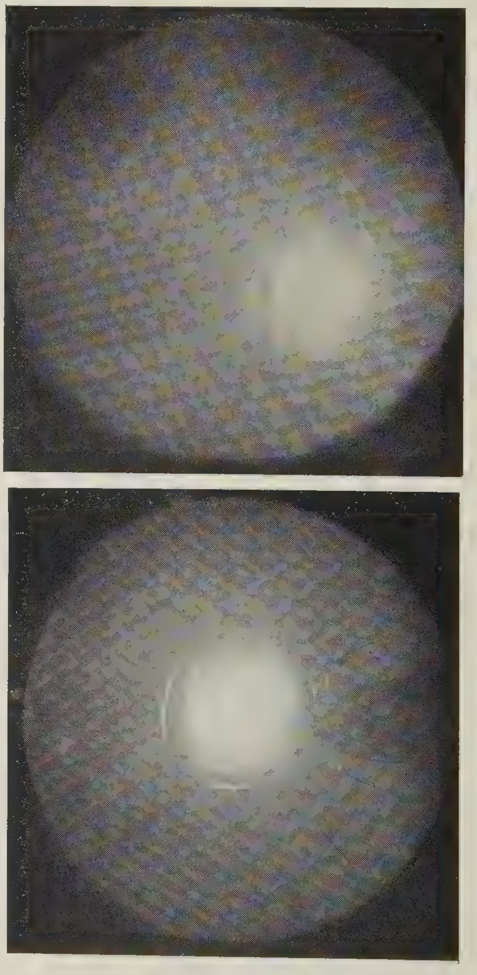

Fig 8. Two successive views, taken with a high-speed cine-micrograph, of a fast-cracking of a thin glass sheet. Exposure time for each was 6×10^{-7} sec; interval between frames was 2.4×10^{-6} sec.

suddenly applied to the underwater electrodes. Then a gaseous conduction channel formed across the gap. The rate of current rise was so great that the growth of the gaseous conduction channel was strictly restrained by the inertia of the water, and this resulted in high pressure upon the gas of the channel and cosequently also upon the water around. It was the pressure wave thus generated in the water that caused the glass specimen to fracture. It may be said that the loading time in this method is extremely short as compared with other mechanical impacts.

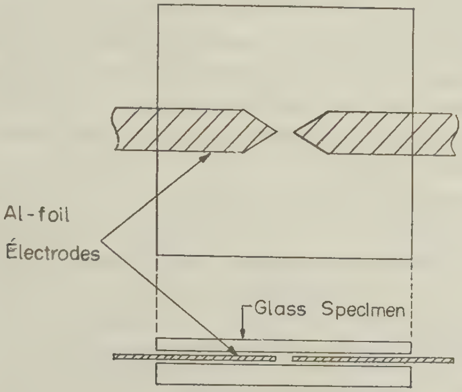

Fig. 2. Arrangement of Al-foil electrodes sandwiched between glass plates.

After illuminating the phenomenon in silhouette, light from the source was deflected to the horizontal direction by the plane mirror placed above the water tank and finally fell into the objective lens of the high-speed camera through a large condenser lens. As the pictures were liable to be spoiled by the light directly coming from the luminous underwater spark, a tiny piece of black paper was placed over the position of the electrode gap.

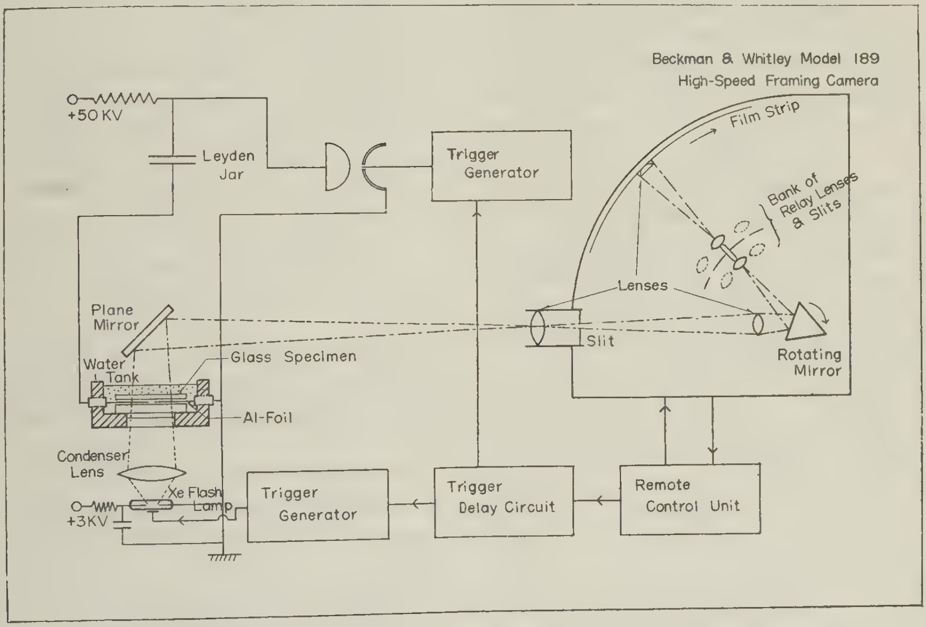

Fig. 3. A schematic diagram of the whole experimental arrangement.

§ 3. Results and Discussions

In Fig. 4 is illustrated a typical sequence of pictures of glass fracture produced by underwater spark. They were taken at a rate of 1.8×10^6 frames per sec. It can be seen that at first a percussion crack of ellipitic form appears and then from its margin a few cracks commence to grow in the directions radially outward from the center of percussion. In addition, the pressure wave in the water is also clearly photographed propagating in a circular form ahead of the cracks. The propagation-time curves of these cracks and a pressure wave are indicated in Fig. 5.

Partly because of the scattering of light at a number of glass-water boundaries through which the illuminating light from the Xenon lamp passes and partly because of slight defects in the condenser lens which is located not so far out of the focus of the objective lens, the resolution of fine details in the shadowgraphs cannot be very satisfactory. For the determination of the propagation distance, therefore, measurement was repeated seven to ten times for each shot on the enlarged positive photographs either by direct scaling or by a travelling microscope. The mean square root deviations of such observed values are 0.40 mm, and are indicated by the bars annexed to each of the points in Fig. 5. It may be natural to assume here that the very early stage of the appearance of a crack is not detectable in these photographs if the length of the crack does not exceed the order of 0.4 mm. A smoothed out curve is drawn covering the system of plotted points in Fig. 5, and at the successive points along this curve the respective gradients to the curve are obtained graphically. The relation between the crack velocity thus obtained and the time elapsed after the beginning of the fracture is shown in Fig. 6, while Fig. 7 shows the velocity versus the extending length of the crack.

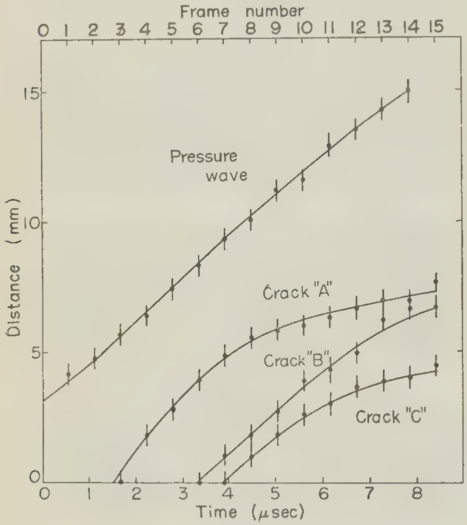

Fig. 5. Measurement of three cracks and a pressure wave shown in Fig. 4.

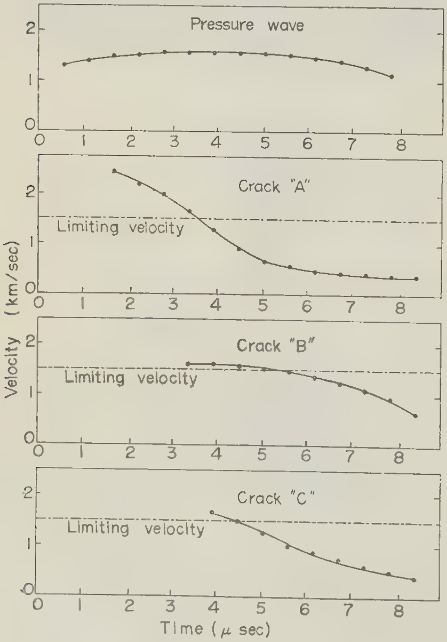

Fig. 6. Velocity versus time.

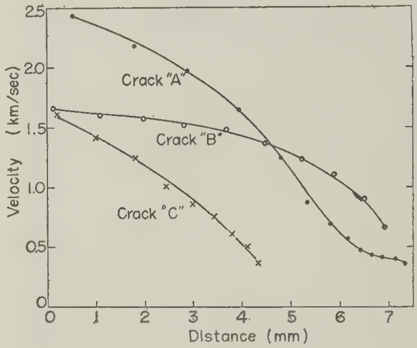

Fig. 7. Velocity versus length of cracks.

According to Figs. 6 and 7, the fracture velocity of the crack "A" at its initial stage attains a value as large as 2.4 km/sec, which is about 60% larger than the generally accepted maximum velocity. Although the precision of velocity determination by means of differentiation of the length-time curve is not sufficiently high, yet it is unbelievable that the maximum velocity in this case is higher not than the normal limit, even if a conceivable range of errors is taken into account.

As is already known, there are some cracks running apparently faster than the limiting velocity. For example, if a fine scratched line exists in the internal part, or on the surface, of a glass plate and the direction of maximum loading tension coincides approximately with this line, a crack with secondary fractures will follow this line with enormous velocity. Secondary fractures can also be initiated sucessively at numerous points with some distances apart in front of the normal cracks, as is reported by Pugh *et al.*[14)15)] when violent shock waves much faster than the fracture velocity are applied. This view, however, does not apply to the present case, for although the cracks we observed are those that have developed secondarily from the margin of the ellipitic percussion crack, the velocity we measured is that of the extension of those secondary cracks themselves, not the superposed one.

It might be supposed that the observed supervelocity is due to an extraordinarily large impact energy. But this cannot be the case, because the impact energy is by no means conspicuous; this would have been less than 10^8 erg, even if the whole energy reserved in the Leyden jar had been dissipated for producing fractures, whereas, in the experiment of Schardin and Struth who shot rifle bullets against glass targets, the consumed energy should have been greater than that in our experiment in the order of magnitude. Thus we are lead to the idea that the normal maximum fracture velocity can be surpassed if the loading rate of an impact attains some extremely high value. In other words, we are suggesting that the most important factor that influences the maximum fracture velocity may be $\dot{S}$ or $\ddot{S}$, where S denotes the overall stress at the moment of fracture and the dot means the time derivative.

Recently Schardin[16)] stated that the fracture velocity V_f should be determined by an equation of the following form:

$$V_f = F(T, \rho, E, \mu, X)$$

where T indicates the surface energy in the material, ρ the density, E Young's modulus, μ Poisson's ratio, X the residual plastic energy. His equation will hold, so long as $\dot{S}$ or $\ddot{S}$ is not so large.

Further he gave interesting remarks as follows. "It is an astonishing fact that during the twenty years that high-speed photography has been used to study fracture phenomena no continuous velocity decrease of a crack once running at maximum speed could be observed. Very often a crack stops rapidly, and no transition phase can be detected within the space and time resolution of the applied equipment (order of magnitude; 1 mm and 1 μsec, respectively). This is true for high-speed as well as for low-speed loading."

As a fundamental reason for the non-existence of a gradual decrease of fracture velocity, he presumed that a certain value of exterior stress is indispensable for the proceeding of a fracture and it stops abruptly when the exterior stress comes below this value owing to the consumption of kinetic energy through the fracture. His presumption, however, seems to be somewhat hasty when viewed in the light of the results of our study.

The only condition under which a velocity decrease is observed by high-speed photography is when hackle marks appear, he states[17)]. In our case no hackle marks could be observed so far as the resolution by the unaided eye is concerned.

In the crack "B" of Fig. 5 the marked points are seen much scattered around the mean smoothed curve. This is due to the fact that we drew the curve so that its time derivative might be a monotonically decreasing function. However, it may be more natural to consider that the variation of the fracture velocity is not always monotonic on the way of crack propagation, for Schardin already found evidences of cracks stopping and starting again.

In Fig. 8 two photographs are given which were taken with a high-speed cine-micrograph[18)19)]. They also show the fracture of a thin plate (0.25 mm in thickness) of the microscope cover glass caused by the underwater spark. While in the first frame no radial cracks can be found, several cracks have developed in the second frame. As the framing rate in this case was 4.2×10^5 per sec and the magnification was $4.2\times$, the estimated velocity of the longest crack is higher than 2.2 km/sec, which agrees well with the value in Fig. 6.

In conclusion of these discussions, we should like to comment upon Hirata's remarks on the single-exposure photograph such as in Fig. 1. Though the duration of light output from the spark was much longer than his estimation probably because of the vaporization of the foil electrodes, it took time of the same order before radial cracks started from the margin of initially formed percussion cracks, so the two effects compensated each other and his estimation of fracture velocity did not differ so widely from the results of our investigations.

§ 4. Conclusion

While there has been a generally accepted view that the maximum fracture velocity of glass is quite independent of the method of application of impact, we have found, by measurement, a higher fracture velocity when the fracture was initiated by the underwater electric spark. Such supervelocity could be observed only transiently and was confined to the initial region around the origin of the cracks. The fracture velocity went down soon to the normal value, and after that gradually decreased. This phenomenon was found for the cracks which began to appear at a comparatively early stage of fracture. For the cracks developing later no such remarkable supervelocity was observed, though the gradual decrease of fracture velocity could be traced, contrary to the usual assumption made according to the results hitherto obtained from the usual high-speed photography.

We wish to express our best thanks to Prof. Moriso Hirata for his stimulating guidance and suggestions. Cordial thanks are also due to Mr. Taijirō Uchida of Nihon University who operated the Beckman & Whitley high-speed framing camera.

Fatigue Properties of Zinc Single Crystals and Polycrystals

Mikio Yamamoto and Jirô Watanabé

The Research Institute for Iron Steel and Other Metals, Tôhoku University
Sendai

(Received September 9, 1960)

Zinc single crystals with the [0001], $[10\bar{1}0]$, and $[11\bar{2}0]$ orientations and zinc polycrystals having the grain size of 130∼400 grains/cm², have been subjected to the cantilever rotating fatigue tests at room temperature. 99.99% pure zinc was used for the preparation of the specimens; single crystals were made by the Bridgman method, and polycrystals were produced by sucking up the melt into galss tubes, in argon atmosphere or vacuum. The specimens were polished carefully with emery papers 0∼0.5, then polished chemically with ethyl alcohol plus nitric acid plus hydroperoxide (1:1:1), and finally annealed at 350°C for 2 hours in the state sealed in a vacuum.

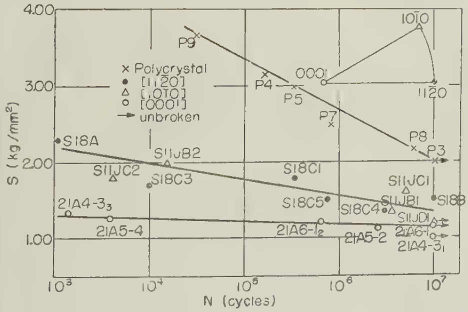

Fig. 1. Fatigue properties of zinc single crystals and polycrystals.

The maximum alternating bending strees, S, *versus* the logarithm of the number of cycles to fractur, N, curves are shown in Fig. 1, which indicates that the curves are linear and that both the slope of the curve and the fatigue strength are the greatest for polycrystals and become less in the order of $[11\bar{2}0]\cong[10\bar{1}0]$ and [0001] single crystals. The S–N curve for [0001] crystals lies nearly parallel to the abscissa, showing that the fatigue failure occurs in a very narrow stress range above which the crystals cleavage-fracture along the (0001) plane immediately after the load was applied. Similar S–N curves were observed in the low temperature fatigue tests on zinc and iron polycrystals which showed brittle fracture.[1] These facts may indicate that brittle or less plastic crystals show no or less fatigue. The S–N curves are nearly the same for $[11\bar{2}0]$ and $[10\bar{1}0]$ crystals, in which the plastic deformation proceeds by multiple slips of $\{11\bar{2}2\}[\bar{1}\bar{1}23]$ system as well as by twinning of the $\{10\bar{1}2\}[10\bar{1}\bar{1}]$ system and finally the failure occurs by stepped-like cleavage along the $\{10\bar{1}0\}$ planes of the matrix and along the {0001} planes of the twin.

The endurance limit, defined conviniently as the fracture stress at 10^7 cycles, is 2.0 kg/mm² for polycrystals, 1.30 kg/mm² for $[11\bar{2}0]$ and $[10\bar{1}0]$ crystals, and 1.10 kg/mm² for [0001] crystals. The comparison of these data with those of the statical strength, determined from tests made on single crystals of the same orientations as the fatigued ones, indicates that, in [0001] crystals, the normal stress operating on the (0001) cleavage plane at the endurance limit is about a half of the normal fracture stress observed in the statical test, but the resolved shear stress operating along the (0001) $[11\bar{2}0]$ direction at the endurance limit coincides very well with the critical resolved shear stress of the $(0001)[11\bar{2}0]$ slip in the static deformation. The latter relation also holds for the $\{11\bar{2}2\}[\bar{1}\bar{1}23]$ slip system and for the $\{10\bar{1}2\}[10\bar{1}\bar{1}]$ twinning in $[11\bar{2}0]$ and $[10\bar{1}0]$ crystals. These findings mean that the fatigue stress below which the specimen crystal never break equals to the minimum stress at which slip or twinning starts, in consistent with the observation by Hempel et al.[2] that the endurance limit of iron single crystals coincides with their yield strength.

It is to be added that the fatigue properties of polycrystals are independent on the grain size in accordance with the observation by Fegredo and Greenough.[3]

NMR of Co^{59} in Ferromagnetic Hexagonal Cobalt Metal

By Yoshitaka KÔI and Akira TSUJIMURA
Faculty of Engineering, Tokushima University, Tokushima, Japan
and Toshimoto KUSHIDA
Department of Physics, Faculty of Science, Hiroshima University, Hiroshima, Japan

(Received July 13, 1960)

The NMR in ferromagnet was first observed in *cubic* cobalt metal by Gossard and Portis[1]. The resonance frequency of Co^{59} is 213 Mc/sec at room temperature, and the frequency extrapolated to 0°K is 217.2 Mc/sec,[2,3] implying an effective field of 217.5×10^3 oersteds at the site of the nucleus. The field arises from the hyperfine interaction between the nucleus and both the core and the conduction electrons, as has been discussed by Marshall[4]. Therefore, the resonance frequency gives useful information about the electronic configuration. From this point of view, the resonance in *hexagonal* cobalt is very interesting. Portis and Gossard[3] searched for the resonance, but did not succeed probably because of the insufficient sensitivity of their spectrometer. The present authors have succeeded in observing the resonance, and it is the purpose of this note to report the results of the experiment.

The sample was about 0.5 gm. of finely divided and well annealed Co metal. A superregenerative spectrometer was used for detecting the resonance. It was frequency-modulated, and the resonance signal was displayed on an oscilloscope. As is well known, superregenerative scheme is adapted for detecting weak resonaeces because of its high sensitivity, but its serious disadvantage is that the apparent shape of the resonance signal varies appreciably with the condition of the quenching. Therefore, accurate determinations of the line width, the intensity, and the frequency were impossible.

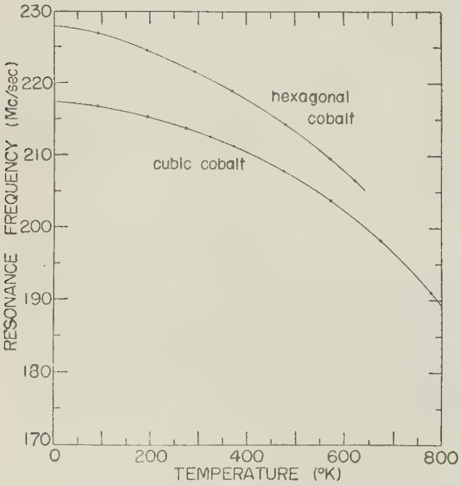

Fig. 1. The resonance frequency of Co^{59} as a function of temperature. The error in the determination of the frequency is ±0.5 Mc/sec for hexagonal cobalt.

The line width is estimated to be about 0.4 Mc/sec by comparing the signal with that in cubic cobalt[3]. The intensity is much weaker than that in cubic phase. It is obvious that a large anisotropy energy in hexagonal cobalt is responsible for this reduction in intensity. In fact, the intensity increases with increasing temperature and reaches the maximum at about 230°C where the anisotropy constant K_{u1} changes its sign[5]. The maximum intensity is about ten times as strong as that at room temperature.

The frequency-*versus*-temperature curve is shown in Fig. 1 together with the curve for cubic cobalt.[2,3,6] It is seen that the frequency decreases with increasing temperature more rapidly in hexagonal cobalt than in cubic one. The frequency extrapolated to 0°K is 228.0±0.5 Mc/sec, which corresponds to an effective field of $(228.4\pm0.5)\times10^3$ oersteds. This value is slightly larger than that determined by the specific-heat measurement at low temperature[7,8] and also than the value in cubic cobalt. The difference of about 11×10^3 oersteds between the values in hexagonal and cubic cobalt would be due to the contribution from the dipolar field of 3d electrons, though it is only one seventh of Marshall's estimation.

Co^{59} resonances in Co alloys are now being investigated.

Dielectric Constants and Loss Tangents of $(\text{Glycine})_3\text{H}_2\text{SO}_4$(TGS) at 3.3 KMc/s

By Eiji NAKAMURA and Jiro FURUICHI
Department of Physics, Faculty of Science, Hokkaido University, Sapporo Japan

(Received August 11, 1960)

Dielectric constants, ε', and loss tangents, $\tan\delta$, of TGS were measured at the 3.3 KMc/s from room temperature to about 80°C. The experimental method was almost the same as that of previous one[1]. But instead of the cylindrical cavity in the previous paper, a rectangular parallelepiped cavity resonating in TE_{105} mode was used. The electric field of this mode was given by

$$\left.\begin{aligned} &\boldsymbol{E}_x=\boldsymbol{E}_z=0\,, \\ &\boldsymbol{E}_y=a\sin\frac{\pi}{A}x\sin\frac{5\pi}{C}z \qquad (a\text{: constant})\,, \end{aligned}\right\} \quad (1)$$

where A and C are dimensions of the cavity along the x and z directions. If a cylindrincal dielectric specimen is placed at one of the positions at which the electric field is maximum, and if its sides are parallel to the electric field and both ends are in perfect contact with the cavity wall, the dielectric constant and the loss tangent of the specimen can be obtained by following expressions;

$$\left.\begin{aligned} &\varepsilon'=\frac{v_c}{2v_s}\cdot\frac{f_1-f_2}{f_2}+1\,, \\ &\tan\delta=\frac{1}{4\varepsilon'}\frac{v_c}{v_s}\left(\frac{1}{Q_2}-\frac{1}{Q_1}\right), \end{aligned}\right\} \quad (2)$$

as far as f_1-f_2 is small, where v_c, v_s, f and Q stand for the volume of the cavity, the volume of the specimen, resonant frequency and Q value of resonance, respectively, and also suffix 1 and 2 mean the empty cavity and cavity containing the specimen, respectively. Since the specimen is cylindrical, v_c/v_s equals the ratio of cross-sectional area of the cavity and the specimen perpendicular to the y direction. A resonant cavity of $7\times0.4\times30\,\text{cm}^3$ was used in our measurements. Loaded Q value of the empty cavity was about 1,400. The measured values of ε' and $\tan\delta$ did not depend on the specimen volumes.

Table I.

Specimen	Cross-sectional Area (cm²)
1*	0.86×10^{-4}
2	$4.8\ \times10^{-3}$
3	$7.8\ \times10^{-3}$
4	1.11×10^{-2}
5	2.30×10^{-2}

* Cross-sectional area of the specimen 1 is estimated from f_1-f_2.

Table I gives the dimensions of the used TGS specimens. All the specimens have square cross-sections, and monoclinic b-axis is orientated to the field direction. In Fig. 1 the temperature variations of both the dielectric constant and loss tangent along the b-axis are shown. The data at 1 Mc/s were obtained by using an inductive-ratio-arm bridge. The relaxation frequency of TGS at the Curie point has been reported to be 500 Mc/s[2]. However, the dielectric constants at 3.3 KMc/s were found not to be appreciably smaller in the measured temperature region except near the Curie temperature compared with the values at lower frequencies, and also the observed loss tangents were not very large in these regions. Hence, we may say that the dielectric dispersion is not effective even at 3.3 KMc/s in these temperature regions. We may expect, therefore, that relaxation frequency has a minimum at the Curie point, as was shown in Rochelle salt[3]. In order to verify this expectation, it would be necessary to extend the measurement to higher frequencies.

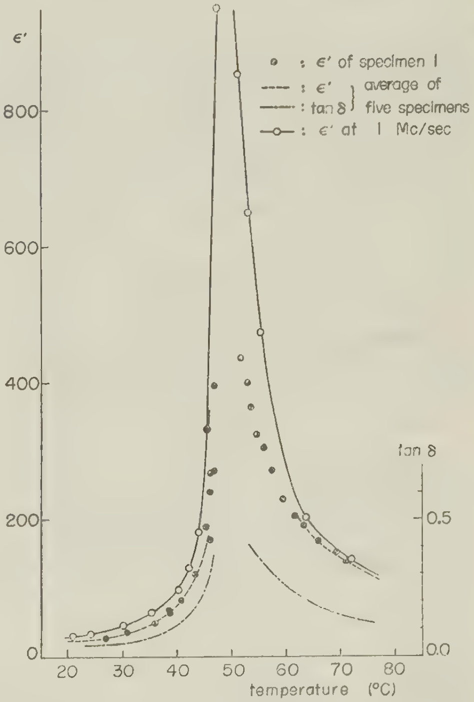

Fig. 1. ε' and $\tan\delta$ of TGS along the b-axis.

Some Properties of Titanium Sesquioxides Containing Vanadium Ions

By Tatsuyuki KAWAKUBO, Taketoshi YANAGI
and Shoichiro NOMURA

Physics Department, Tokyo Institute of Technology O-okayama, Meguro-ku, Tokyo

(Received August 22, 1960)

Experimental data have been presented that show marked changes in the electrical[1], magnetic[2] and thermal[3] properties of Ti_2O_3 in the temperature range of 160°~200°C. It has also been examined by X-ray diffraction studies[2] that the lattice parameters of Ti_2O_3, which has the corundum type structure with the trigonal symmetry, change abruptly in the same temperature region. The sudden change in magnetic susceptibility has suggested that an antiferromagnetic ordering would be present below the transition temperature, but any positive evidence for antiferromagnetism has not been obtained by a recent neutron diffraction study[4]. The present report is concerned with studies on Ti_2O_3-V_2O_3 solid solutions containing up to ten molar percents of V_2O_3.

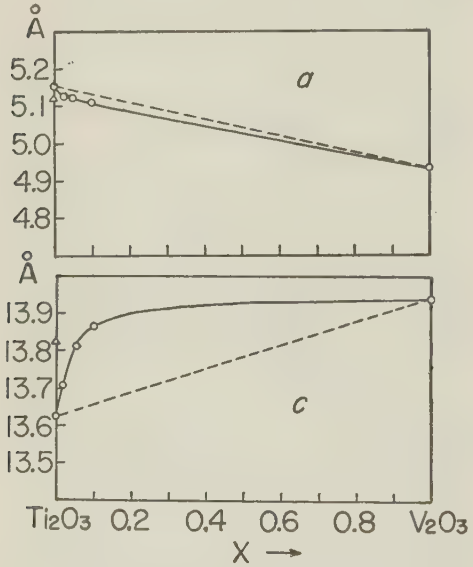

Fig. 1. Lattice parameters a and c of $(Ti_{1-x}V_x)_2O_3$ at room temperature. The values for Ti_2O_3 at 280°C[2] are given by the marks Δ and the values for V_2O_3 are due to ASTM Card.

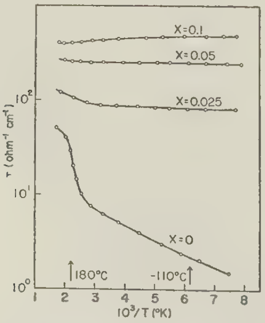

Fig. 2. Electrical conductivity of $(Ti_{1-x}V_x)_2O_3$ as a function of reciprocal temperature.

The specimens used were prepared by sintering the mixture of Ti, TiO_2 and V_2O_5 powders of desired ratio in a carbon resister vacuum furnace under the pressure of 10^{-4} mmHg, at 1450°C, for about 5 hours. The hexagonal lattice parameters a and c for $(Ti_{1-x}V_x)_2O_3$ at room temperature are shown in Fig. 1. An outstanding fact found in our work is that the lattice parameters observed in the solid solution series show a great deviation from that of Vegard's law and their values lie nearly to those of pure Ti_2O_3 obtained above the transition temperature. A marked difference was also observed between the electrical conductivities of pure Ti_2O_3 and its solid solutions. The result is shown in Fig. 2. The electrical conductivity of pure Ti_2O_3 shows a characteristics of semiconductor and has a stepwise increase near 180°C. This anomalous feature, when some amount of Ti^{3+} ions in Ti_2O_3 are replaced by V^{3+} ions, becomes extremely indistinct and the semiconducting character of the electrical conduction changes to the metallic one. For $Ti_{1.8}V_{0.2}O_3$, the electrical conductivity apparently decreases with increasing temperature.

It may be said from these expeaimental facts that the transition observed in pure Ti_2O_3 is sensitively affected by the existence of a small content of V^{3+} ions. Assuming one electron per cation to be available in stoichiometric Ti_2O_3, we may say that a small deviation of the number of electrons in cation from one causes a large effect on the properties of Ti_2O_3. Further, the facts observed in our study seem to favor a model proposed by Goodenough[5], which gives an idea of the electron pair bond formation between cations in Ti_2O_3 at low temperatures.

The authers wish to express their sincere thanks to Professor Shozo Sawada for his helpful discussions and continual encouragement.

Photoconductivity of Cu-activated Cadmium Sulphide-Selenide

By Sumitada ASANO

Department of Physics, Faculty of Science, Okayama University

(Received September 24, 1960)

Spectral response of photoconductivity of CdS has been extensively investigated. On the other hand, we know that the emission band and absorption edge of ZnS phosphor shift towards longer wave-lengths by adding increasing quantity of CdS, ZnSe or CdSe1). In this paper we report the spectral response of photoconductivity of Cu-activated Cd(S:Se) at room temperature. The starting materials, pure CdS and CdSe powder, were prepared by careful procedures mentioned in the previous paper2). The mixture of CdS and CdSe powder was dried at 110°C after adding 5×10^{-2} mole % of $CuCl_2$ as activator and 2 mole % of KCl as co-activator. Then it was put on a silica boat and fired in a silica tube for 15 minutes at 1000°C in nitrogen atomosphere.

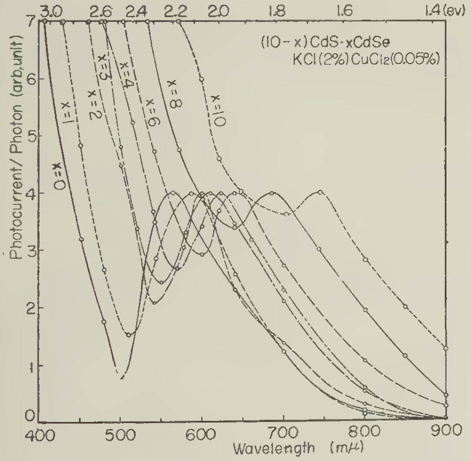

Fig. 1. Spectral response of photoconductivity. The peak of each sample is arranged to have the same height.

The sample was ground and settled on a conducting glass plate by sedimentation in ethyl-alcohol without any binder, and pressed to a flat metal sheet mounted in an evacuated glass vessel so that the sample was sandwitched between the conducting glass plate and the metal sheet. The sample then became a uniform layer about 0.3 mm in thickness. A uniform light beam from a tungsten lamp was led onto the conducting glass plate through a glass monochromator. The spectral energy distribution of the beam incident on the sample through the conducting glass had been measured previously by a vacuum thermocouple. A DC voltage of several volts was applied across the sample from a battery source. The results are shown in Fig. 1.

As is shown in the figure, the peak due to copper shifts regularly towards longer wave-lengths, as in the case of the emission band in Cu-activated Zn(S:Se) phosphors. The trough observed between the fundamental and copper absorption bands becomes shallower with increasing proportion of CdSe. Besides, the spectral reflectance of each sample was measured in comparison with standard MgO powder by using the same apparatus as in the reference cited3). Then the value of forbidden gap of each sample was determined from the position of absorption edge in the reflectance spectra. The average rate of reduction in the forbidden gap is about 0.69×10^{-2} eV/mole % of CdSe, whereas that in the energy gap for copper absorption obtained from Fig. 1 is about 0.52×10^{-2} eV/mole % of CdSe. These facts show that the forbidden gap is decreased more rapidly than the energy gap for copper absorption and that the ground state of copper, in the samples containing large proportion of CdSe, tends to be immerged in the valence band4).

The response time in the decay of photocurrent after sufficient irradiation at the wave-length of copper peak was measured for various irradiances using an electromagnetic oscillograph. The response time t_0 of the sample approximately obeys the relation

$$t_0=kL^{-n}\,,$$

where L is the photon density incident upon the sample, k the constant characteristic to the sample and $n\simeq0.5$. k decreases rapidly with increasing proportion of CdSe. This will be attributed mainly5) to the fact that the thermal depth of shallow traps concerned in current decay decreases and trapped electrons may be easily released into the conduction band with increasing proportion of CdSe. This fact is observed also in thermoluminescence experiments on (Zn:Cd)S and Zn(S:Se) phosphors6).

Details will be published later.

On the Ferrimagnetic Resonance of Europium Iron Garnet

By W. P. Wolf
Clarendon Laboratory, Oxford, England

(Received June 22, 1960)

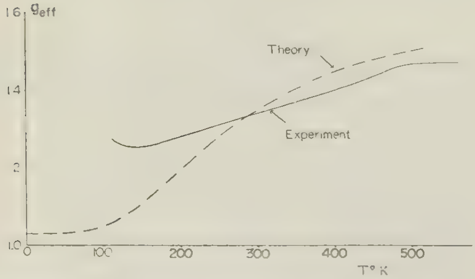
Recent microwave experiments on polycrystalline europium iron garnet (EuIG) have shown⁽¹⁾ that this substance has a rather low *g*-value, (1.34 at 300°K), which varies with temperature. The purpose of this note is to account semi-quantitatively for the observed magnitude of *g* and its temperature variation.

In any strongly coupled ferrimagnetic system the effective *g*-value which determines the resonance condition, is given by⁽²⁾

$$g_{eff}=\frac{2mc}{e}\frac{\boldsymbol{M}}{\boldsymbol{A}}\quad,$$

where $\boldsymbol{M}$ is the total magnetic moment, in units of Bohr magnetons per molecule, and $\boldsymbol{A}$ is the total angular momentum, in units of $h/2\pi$ per molecule. The magnitude of $\boldsymbol{M}$ in EuIG and its variation with temperature has been measured by Pauthenet⁽³⁾, and it has recently been explained theoretically.⁽⁴⁾ The theory showed that $\boldsymbol{M}$ can be accounted for in terms of the algebraic sum of the magnetic moment of the Fe^{3+} sublattices behaving very much as in yttrium iron garnet (YIG), and an antiparallel magnetic moment due to the Eu^{3+} ions. The latter arises from an exchange interaction with the Fe^{3+} ions as in other substances, but with the difference that it is almost entirely of an *induced* nature, due to off diagonal matrix elements from the spectroscopic ground state $J=0$ to the first excited state $J=1$. This mechanism gives rise to an induced magnetic moment because $\boldsymbol{L}+2\boldsymbol{S}$ is not a constant of the motion, but it does not produce any angular moment, which is proportional to $\boldsymbol{L}+\boldsymbol{S}$. Therefore we would expect $\boldsymbol{A}$ in EuIG to be very similar to its magnitude in YIG, in which it has value

$$A_{\mathrm{YIG}}=\frac{2mc}{e}\cdot\frac{M_{\mathrm{YIG}}}{g_{\mathrm{YIG}}}\quad,$$



Variation of the resonance *g*-value with temperature. Solid line, experimental results⁽¹⁾; broken line, theoretical results calculated from $2M_{\mathrm{EuIG}}/M_{\mathrm{YIG}}$, taken from curves 1 and 2 of reference (4).

where g_{YIG} is very close to 2.⁽⁵⁾ Thus the *g*-value in EuIG should be close to $2M_{\mathrm{EuIG}}/M_{\mathrm{YIG}}$.⁽⁶⁾ Using curves 1 and 2 in Figure 1 of reference 4, this gives the broken line shown in the Figure. The agreement with the experimental results is quite reasonable, in view of the simplifying assumptions, and the fact that the theory contains no adjustable constants other than the coefficient a which normalizes curve 2 at $T=0°K$.

At the lowest temperatures there is a systematic divergence which is not explained. It may be connected with the observed broadening and doubling of the lines, which were ascribed to anisotropy effects in the polycrystalline material.⁽¹⁾ If this is so the theory should apply better to single crystal data.⁽⁷⁾ Another possible explanation for the discrepancy might be the effect of rare earth or other impurities, either in the resonance samples or in Pauthenet's magnetic moment samples.

The present theory is very crude. Improvements could be made a) by allowing for the small amount of angular momentum due to the $J=1$ state in Eu^{3+}; b) the change in the Fe^{3+} sublattice magnetization, and hence $\boldsymbol{A}$, due to the back-action of the Eu^{3+} ions on the Fe^{3+} sublattices; c) inadebuacies of the molecular field theory, especially at the highest and lowest temperatures. All these effects are potentially quite important (~10%), but the considerable complications do not seem worthwhile at present in view of the reasonable agreement of the simple theory.

The author would like to thank Professor J. H. Van Vleck for stimulating discussions.

6) This form is superficially similar to the recent explanation of *g*-values in other rare earth garnets (C. Kittel, Phys. Rev. **115** (1959), 2587, but its origin is quite different. In other rare earths the angular momentum is quenched by rapid relaxation, while in Eu^{3+} it is suppressed by the spin-orbit coupling.

Reflection and Absorption Spectra of LiF in the Extreme Ultraviolet Region

By Riso KATO, Kaizo NAKAMURA,
Atsuo MATSUI and Yoichi UCHIDA

Depertment of Physics, Faculty of Science,
Kyoto University.

(Received September 10, 1960)

Fundamental optical absorptions of alkali halides in the extreme ultraviolet region have been investigated by several authors$^{1)-3)}$. The absorption spectra were measured on evaporated thin films because of their large absorption coefficients in the region. For LiF, however, the absorption method cannot be used to investigate the fundamental optical absorption for the lack of appropriate substrates, and the reflection method is expected to be the most useful for this purpose.

Thus, in the present experiment the reflection spectrum of LiF was measured. A single crystal of LiF had been kindly offered by Prof. Pringsheim, and its newly cleaved surface was used. The cryostat for reflection measurements is shown schematically in Fig. 1. It is a modified one of Walker's type$^{4)}$. The vacuum monochromator$^{5)}$ used was the Seya-Namioka type. Since it has no window in the optical path, measurements could be carried out down to 800 Å with the band width of about 2 Å.

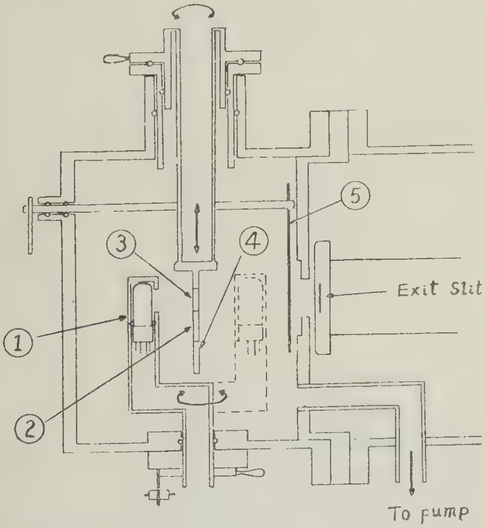

Fig. 1. Shematic diagram of the cryostat for reflection measurements.
(1): photomultiplier rotatable around the sample holder.
(2): sample holder movable along the vertical axis.
(3): window for sample.
(4): window for reference.
(5): turret with several filters.

The obtained reflection spectrum is shown by curve (1) in Fig. 2. Curve (2) shows the absorption spectrum of the same crystal with the correction of reflection effect. The reflection measurements were carried out with the incident angle of 15° at room temperature. The values of reflectivity may contain the experimental errors of about 10% which might arise from mechanical operation of the cryostat and from incompleteness in the correction of stray light. But the tendency of the curve is not affected by the errors, because the reflection measurements were made by recording each about 100 Å segment of the spectrum.

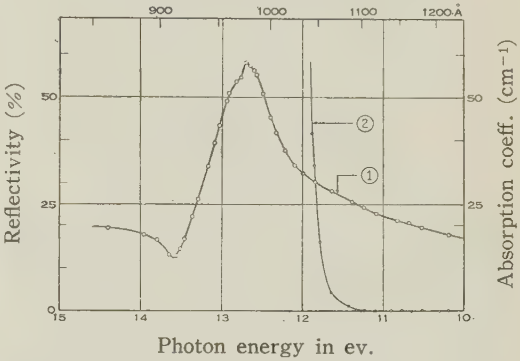

Fig. 2. Reflection and absorption spectra of LiF single crystal measured at room temperature.
Curve (1): reflection spectrum.
Curve (2): absorption spectrum.

As seen in curve (1), a peak was found at 12.7 ev and a "shoulder" was observed at about 13.8 ev. In accordance with the fact$^{2)}$ and the theoretical consideration that reflection peaks nearly coincide with absorption peaks, the newly found 12.7 ev peak and 13.8 ev "shoulder" in the reflection spectrum of LiF at room temperature are assigned to the exciton peak and the onset of the band-to-band transition respectively. Furthermore, as seen in curve (1), the shape of the reflection spectrum near the peak suggests that the exciton band in LiF has a mutiplet structure which will be confirmed with success in measurements at low temperatures.

The Effect of Plastic Deformation on the Cluster Formation in an Al-Cu 4% Alloy

By Keisuke MATSUURA and Shigeyasu KODA

The Sesearch Institute for Iron,
Steel and Other Metals,
Tohoku University, Sendai

(Received September 22, 1960)

According to recent investigations1),2) the high rate of cluster formation in Al-Cu alloys quenched from a temperature of a uniform solid solution range is ascribed to the quenched-in vacancies. In the present work, the effect of plastic deformation on such a clustering of solute atoms is examined with a 4% Cu alloy by measuring the electric resistivity, and the roles of dislocations and vacancies in the clustering process are also discussed. The polycrystalline specimens, 0.7 mm in diameter, were water-quenched or air-cooled after being solution-treated between 520 and 530°C, and were dipped without delay in liquid nitrogen. After being streched to various extents (0~17.8%) in liquid nitrogen, they were transferred to a bath of constant temperature to make ageing. The determination of the electric resistance at any stage of ageing process was carried out in a liquid nitrogen bath in order to suppress any further progress of ageing during resistance measurement. Some of the results are shown in Fig. 1, where ΔR is the increase of resistivity during ageing and R_0 the initial resistivity just after water-quenching or air-cooling. The following tendencies are recognized.

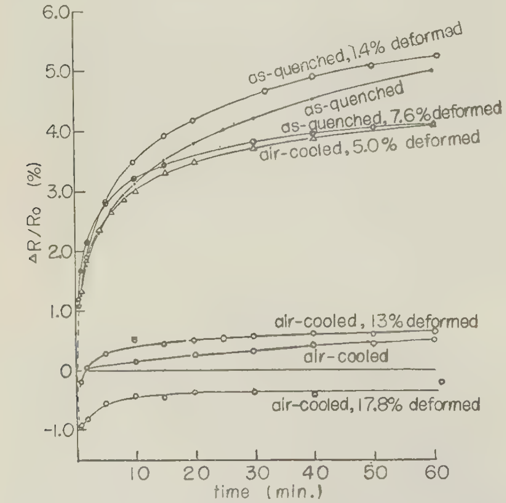

Fig. 1. Change of electric resistivity on ageing at 0°C.

(1) Both for water-quenched and air-cooled specimens, resistivity increases during ageing process after plastic deformation if the latter is small as in the case of several percent or less elongation. Such an increase is ascribed to cluster formation. However, in air-cooled specimens a decrease of resistivity is observed at the beginning of ageing after large deformation such as elongation exceeding about 13%. This decrease may be due to the annihilation of defects produced by plastic deformation.

(2) Except such an initial decrease of resistivity the plastic deformation after water-quenching or air-cooling increases the increasing rate of resistivity in the early stages of ageing. In air-cooled specimens the effect is more evident.

(3) On the other hand, the rate of increase in resistivity of deformed specimens decreases with ageing time more rapidly than that of the undeformed water-quenched one. This rapid decrease becomes more pronounced with increasing amount of elongation.

(4) The initial rate of resistivity increase in an air-cooled, 4-5% elongated specimen is about the same as that of a water-quenched. The results obtained for both specimens in the range of ageing temperature between 18 and −30°C were compared. From a curve of $\{d(\Delta R)/R_0 dt\}_{t=0}$ plotted against $1/T$ the activation energy of about the same value 0.47~0.52 eV was obtained for both cases. These results suggest that the initial rate of cluster formation is enhanced by the excess vacancies produced by plastic deformation. On the other hand, the fact that the rate decreases rapidly with ageing time for deformed specimens may be explained by the fact that dislocations are the effective sinks of excess vacancies3): that is, the increase in dislocation density leads to the rapid annihilation of excess vacancies and, therefore, to the rapid decrease of the rate of clustering. However, there may be another possibility that the clusters formed at distorted regions are stable and their development is hindered, as pointed out by Graf and Guinier4). It has been reported that the cluster formation is hindered by prestrain after quenching5),6). On the other hand, it is known that small clusters form immediately after or during plastic deformation at

room temperatures[7),8)]. All these facts which seem inconsistent at first sight fully confirm to the results obtained in the present investigation.

Distribution Coefficient of Zinc in Gallium Arsenide

By Akikazu SHIBATA

Sony Coporation, Shinagawa, Tokyo

(Received August 24, 1960)

The distribution coefficients of many substances in Ge and Si are reported though, not so many are reported in compound semiconductors. During the course of study of intermetallic semiconductor compounds in our laboratory, the distribution coefficient of Zn in GaAs was obtained through the impurity distribution study in GaAs ingots. The well-known formula giving the impurity distribution of a solidified ingot in the case of normal freezing was the basis of the determination of the distribution coefficient in this work; that is[1)],

$$C^S(g)=KC_0^L(1-g)^{K-1}\ ,$$

therefore,

$$\log C^S(g)=(K-1)\log+\log KC_0^L\ ,$$

where g, the fraction of the melt which has been solidified; C^S, the impurity concentration of the solid as a function of the fraction; C_0^L, the original impurity concentration involved in the melt; and K, the distribution coefficient. Thus, by plotting $\log C^S(g)$ vs $\log(1-g)$, a straight line can be obtained, and the tangent of the line, δ, gives the distribution coefficient as $K=(1+\delta)$.

Among the possible dopants in Group III–V intermetallic compounds, Zn and Cd are the most favorable dopants for p-type materials and Se and Te for n-type. In this work, the distribution coefficient of Zn in GaAs, which has not yet been reported so far as the author awares, was determined.

A vacuum sealed quartz tube, $ID=16$ mm, containing about 15 g of Zn doped GaAs was held in a horizontal furnace and kept at about 1280°C for several hours. The uniform distribution of the impurity concentration in the melt was not examined, however, the uniformity was assumed. The melt was then pulled out from the furnace to be solidified with a speed of 25 mm/hr. The obtained ingot was a large grain polycrystal and had a length of about 65 mm. The direction of the crystal growth was not examined.

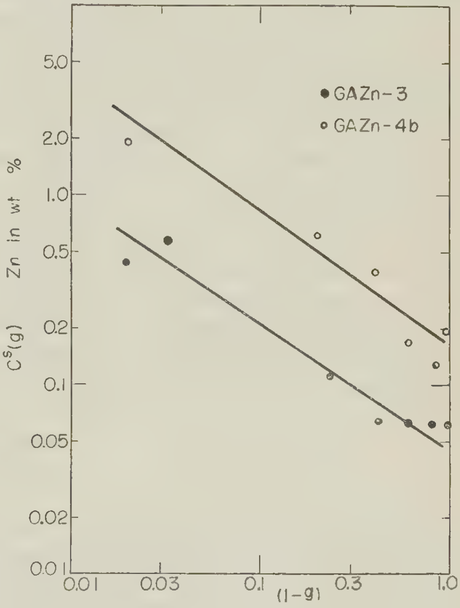

Fig. 1. Zn distribution as a function of position.

The initial concentrations of Zn in the two samples used, GAZn-3 and GAZn-4b, were 0.45 and 0.9 wt% respectively. Six to seven specimens were cut from each ingot and the Zn concentration was determined chemically using Polarography Method.

From the results, $\log C^S(g)$ vs $\log(1-g)$ were plotted which are shown in the Fig. 1. Two best fit straight lines were drawn and the tangents of the lines were determined graphically. The resultant tangents were -0.68 and -0.70 for GAZn-3 and GAZn-4b respectively. The distribution coefficients were then determined as 0.32 and 0.30 respectively. Consequently, the distribution coefficient of Zn in GaAs was concluded as 0.31.

Interaction Types and Selection Rules in Baryon Processes

By Seitaro NAKAMURA

Department of Physics, Faculty of Science, University of Tokyo, Tokyo, Japan

(Received September 13, 1960)

In the previous letter[1)], we have introduced an interaction Hamiltonian of the strong interaction for baryons by assuming new symmetry—"κ-charge independence"—which is an extension of the idea of symmetrical meson theory. κ-charge of baryons is defined from the 2×2 Pauli matrices: $Q_\kappa=(1+\kappa_3)/2$, just as electric charge of nucleons is defined from the ordinary τ matrices, $Q_e=(1+\tau_3)/2$. We assign $\kappa_3=1/2$ for the Ξ-particles and nucleons, $\kappa_3=-1/2$ for the Σ and Λ-particles, just as we assign $\tau_3=1/2$ for proton and $\tau_3=-1/2$ for neutron. Instead of using the ordinary isospin space, we adopt a three dimensional charge space, called N-space, where electric charge is defined by the relationship $Q_e=N_3$. This is not identical with the M-space representation proposed by d'Espagnat, Prentki and Salam[2)], and by Takeda[3)], because strangeness is not used in our representation. In order to give a Hamiltonian symmetric in κ-space and also in N-space, (both of which are three dimensional and orthogonal to each other,) we assume the existence of sixteen kinds of mesons which mediate the strong interactions among baryons. They are in the states with $Q_\kappa=\kappa_3=1, 0, -1$ ($|\kappa|=1$) and $Q_\kappa=\kappa_3=0$ ($|\kappa|=0$), to each of which there correspond four values $Q_e=N_3=1, 0, -1$ (triplet) and 0 (singlet). It is shown that kaons correspond to mesons with $Q_\kappa=\pm1$, strangeness-two mesons to those with $Q_\kappa=0$ ($|\kappa|=1$) and pions to those with $Q_\kappa=0$ ($|\kappa|=0$). We assume the existence of two kinds of kaons, the one coupling the Ξ-particle with the Σ and Λ-particles and which we denote L-kaons, and the other coupling nucleons with the Σ and Λ-particles and which we denote K-kaons.

Now we shall determine the interaction types by introducing two assumptions which follow: i) Parity is conserved in the strong interactions. ii) Invariance under time-reversal of the Wigner type is required. As a result, the interaction Hamiltonian for $H_{\Sigma\Sigma\pi}$ (given in (14) in the previous letter[1)]) will be cancelled out by adding the hermitian conjugate part.

$$H_{\Sigma\Sigma\pi}=0\,,\qquad H_{\Sigma\Lambda\pi}=0\,,\qquad g'\text{: pure imag.}\qquad \Omega_{\Sigma\Sigma\pi}=\gamma_5, \gamma_5\gamma_\mu\,;\qquad \Omega_{\Sigma\Lambda\pi}=\gamma_5, \gamma_\mu, \gamma_5\gamma_\mu\,.$$

$$H_{\Sigma\Sigma\pi}\equiv g'\overline{\boldsymbol{\Sigma}}\times\Omega_{\Sigma\Sigma\pi}\boldsymbol{\Sigma}\cdot\pi+\text{h.c.}\,;\qquad H_{\Sigma\Lambda\Pi}\equiv g'(\overline{\boldsymbol{\Sigma}}\Omega_{\Sigma\Lambda\Pi}\Lambda\cdot\pi+\overline{\Lambda}\Omega_{\Sigma\Lambda\Pi}\boldsymbol{\Sigma}\cdot\pi)+\text{h.c.}\,.$$

Thus we have not global symmetry[4)] in the pion-baryon interaction. Analyses[5)-6)] on the branching ratios for the inelastic scattering of K^--meson by proton seem to support the present result.

With regard to the other interactions, we are open to many possibilities, depending on the relative parities of baryons and the intrinsic parities of mesons. For instance, we may consider the following two possibilities for the strong interaction between Σ and Λ through D-mesons.

A) $H_{\Sigma\Sigma D}=0\,,\qquad H_{\Sigma\Lambda D}\neq0\,,\qquad g\text{: pure imag.}\qquad \Omega_{\Sigma\Sigma D}=\gamma_5, \gamma_5\gamma_\mu\,;\qquad \Omega_{\Sigma\Lambda D}=\gamma_5, \gamma_\mu, \gamma_5\gamma_\mu\,.$

B) $H_{\Sigma\Sigma D}=0\,,\qquad H_{\Sigma\Lambda D}=0\,,\qquad g\text{: pure imag.}\qquad \Omega_{\Sigma\Sigma D}=\gamma_5, \gamma_5\gamma_\mu\,;\qquad \Omega_{\Sigma\Lambda D}=1\,.$

$$H_{\Sigma\Sigma D}\equiv g\overline{\boldsymbol{\Sigma}}\times\Omega_{\Sigma\Sigma D}\boldsymbol{\Sigma}\cdot\boldsymbol{D}+\text{h.c.}\,;\qquad H_{\Sigma\Lambda D}\equiv g(\overline{\boldsymbol{\Sigma}}\Omega_{\Sigma\Lambda D}\Lambda\cdot\boldsymbol{D}+\overline{\Lambda}\Omega_{\Sigma\Lambda D}\boldsymbol{\Sigma}\cdot\boldsymbol{D})+\text{h.c.}\,.$$

For the case A), we must find the selection rule to prove the metastability of $D^\pm$-meson, lest the Ξ-particle should be unstable against the decay process $\Xi\rightarrow\pi+N$. For the case B), we have no trouble about the metastability of $D^\pm$-mesons as the strangeness-two mesons recently reported.

From the final expressions for the interaction Hamiltonians (9)-(12) in the previous letter[1)], with the present assumptions i), ii) and B), we can infer the selection rules to determine the baryon-processes.

For the strong interactions:

(I) $\Delta n_1=0\,,$ (II) $\Delta n_2=0\,,$ (III) $\Delta n_3=0\,,$

where

$$n_1=n_N+n_\Sigma+n_\Lambda+n_\Xi\,,$$

$$n_2=n_N+n_K+n_\Xi+n_L\,,$$

$$n_3=n_N+n_K+2n_D-n_\Xi-n_L\,.$$

Here n_N, n_Σ, n_Λ and n_Ξ are the particle numbers for the respective particles; for mesons we assign:

$n_K=+1\quad(K_+{}^+, K_+{}^0)\,,\qquad n_L=+1\quad(L_+{}^-, L_+{}^0)\,,$

$=-1\quad(K_-{}^-, K_-{}^0)\,,\qquad =-1\quad(L_-{}^+, L_-{}^0)\,,$

$n_D=+1\quad(D^+)\,,\qquad n_D=0\quad(D^0)\,,\qquad n_D=-1\quad(D^-)\,.$

The selection rule (I) implies conservation of the baryon number. The selection rule (II) denotes conservation of κ-charge. The selection rule (III) corresponds to conservation of strangeness strictly when we are not involved with strangeness-two particles. It is remarkable, however, to have reached the law of strangeness in this case, because we did not start by assuming strangeness as a quantum number of particles. On the other hand, the present theory introduces a new selection rule of conservation of κ-charge in (II). For instance, the process $\Xi^- + P \to \Lambda + \Lambda$ is forbidden by (II), but it is allowed by the strangeness rule alone. As a result, we are led to assume the necessary existence of Ξ-hyperfragments, which from the strangeness rule alone should decay instantaneously.

The Magnetic Properties of NiBr$_2$

By Ichiro TSUBOKAWA

The Research Institute for Iron, Steel and Other Metals, Tohohu University, Sendai, Japan

(Received September 8, 1960)

It has been shown by several authors[1),2)] that the hexagonal di-chloride of iron, cobalt and nickel show interesting magnetic properties, meta-magnetism. Also the antiferromagnetic spin ordering of these compounds was ascertained by means of neutron diffraction experiments[3)]. During the course of the investigation of bromides of the iron group elements, the present author will report the magnetic properties of NiBr$_2$.

A specimen of NiBr$_2$ was prepared by the same method described in the previous paper[4)]; powder nickel (99.9%) was heated to about 720°C in bromine vapor (99.9%). The compound thus obtained had an appearence of a thin hexagonal-like plate and tinged red color. It was confirmed by Debye-Scherrer X-ray photographs that the crystal structure of the compound was the CdCl$_2$ type.

The magnetic susceptibility of the compound obtained was measured at intervals from the liquid helium point to room temperature by using a magnetic balance. The result is shown in Fig. 1. The temperature variation of the susceptibility shows antiferromagnetic behavior having a maximum susceptibility at a temperature close to 60°K. This temperature is considered to be the antiferromagnetic Néel point. The inverse susceptibility above the Néel point is also plotted in Fig. 1. An asymptotic Curie temperature θ_p was estimated as -20°K from $1/\chi - T$ relation. Now, Kanamori[5)] suggested that the superexchange interaction in the c-plane of the hexagonal structure containing Ni^{2+} ions is ferromagnetic. Hence the superexchange interaction along the c-axis is antiferromagnetic, and is weak compared to the former, because the metal ions are separated by two layers of anions. On the other hand, for NiCl$_2$, $T_N = 52$°K $\theta_p = 68.2$°K$>$0°K. Consequently, the antiferromagnetic exchange interaction along the c-axis of NiBr$_2$ is stronger than that of NiCl$_2$.

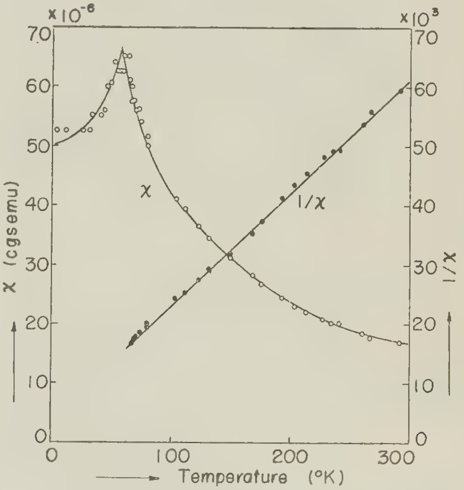

Fig. 1. Susceptibility and inverse susceptibility vs. temperature curves.

From the relation $1/\chi - T$, we estimated the Curie constant C_M and the effective Bohr magneton number p_{eff} as 1.12 and $3.0\mu_B$ respectively. The spin quantum number S is also obtained as 2.1/2 assuming that the Landé factor is two. This value corresponds to S of the Ni^{2+} ion.

Infrared Absorption of Electrons Through Piezoelectric Scattering

By Toshio TANAKA
Department of Applied Physics,
Faculty of Engineering,
Tokyo University, Tokyo

(Received September 1, 1960)

The absorption of a photon by free carriers cannot occur unless the free carriers gain the momentum by collisions with some lattice imperfection. The infrared absorption due to the interactions of electrons with lattice vibtrations of acoustic mode was treated first by Fan, Spizer and Collins[1] basing on the deformation potential model and thereafter has been analyzed in more detail by many authors[2],[3], indicating that the absorption coefficient varies with the photon frequency as

$$\alpha\propto\omega^{-n}\,,$$

where

$$n=3/2 \text{ for } \hbar\omega\gg kT\,,\qquad n=2 \text{ for } \hbar\omega\ll kT\,.$$

Recently the results measured by Thomas[4] in ZnO crystals represent that the absorption coefficient shows a stronger frequency dependence.

Here, we shall consider the absorption of an infrared photon by conduction electron in crystals with wurtzite structure through piezoelectric scattering.

In ionic crystals with wurtzite structure, which show piezoelectric effects, the acoustic lattice vibrations can produce an electric polarization which scatters electrons. The polorization is

$$\boldsymbol{P}=\boldsymbol{P}_{\text{piezo}}+\alpha\boldsymbol{E}=\boldsymbol{P}_{\text{piezo}}-4\pi\alpha\frac{(\boldsymbol{P}\cdot\boldsymbol{q})}{q^2}\boldsymbol{q}\,, \tag{1}$$

where $\boldsymbol{q}$ is the wave vector, the first and second terms represent respectively the piezoelectric polarization and the polarization induced by the macroscopic electric field, which is obtained from Maxwell equation or microscopic consideration of the lattice. Accordingly, Eq. (1) becomes

$$\boldsymbol{P}\cdot\boldsymbol{q}=(\boldsymbol{P}_{\text{piezo}}\cdot\boldsymbol{q})/1+4\pi\alpha=(1/\varepsilon_s)(\boldsymbol{P}_{\text{piezo}}\cdot\boldsymbol{q})\,.$$

Here $\boldsymbol{P}_{\text{piezo}}$ can be expressed as follows;

$$\boldsymbol{P}_{\text{piezo}}=(P_1,\ P_2,\ P_3)\,,$$

$$P_1=-i\sum_{q,\alpha}\left(\frac{\hbar}{2\rho\omega(\boldsymbol{q},\ \alpha)\Omega}\right)^{1/2}e_{15}(\varepsilon_1q_3+\varepsilon_3q_1)(be^{i\boldsymbol{qr}}-b^*e^{-i\boldsymbol{qr}})\,,$$

$$P_2=-i\sum_{q,\alpha}\left(\frac{\hbar}{2\rho\omega(\boldsymbol{q},\ \alpha)\Omega}\right)^{1/2}e_{15}(\varepsilon_2q_3+\varepsilon_3q_2)(be^{i\boldsymbol{qr}}-b^*e^{-i\boldsymbol{qr}})\,,$$

$$P_3=-i\sum_{q,\alpha}\left(\frac{\hbar}{2\rho\omega(\boldsymbol{q},\ \alpha)\Omega}\right)^{1/2}\{e_{31}(\varepsilon_1q_1+\varepsilon_2)+e_{33}\varepsilon_3q_3\}(be^{i\boldsymbol{qr}}-b^*e^{-i\boldsymbol{qr}})\,,$$

where ρ the density, Ω the volume of the crystal, e_{15}, e_{31}, e_{33} the piezoelectric constants, $\omega(\boldsymbol{q},\alpha)$ and $\boldsymbol{\varepsilon}(\boldsymbol{q},\alpha)$ are the frequency and the unit polarization vector belonging to mode $(\boldsymbol{q},\alpha)$ of acoustic lattice vibrations, and b and b^* denote the annihilation and production operators of a phonon, respectively.

The interaction energy between an electron and the lattice vibrations

$$\mathscr{H}(\boldsymbol{r}_{el})=-\frac{4\pi}{\varepsilon_s}e\sum_{q,\alpha}\left(\frac{\hbar}{2\rho\omega(\boldsymbol{q},\ \alpha)\Omega}\right)^{1/2}a(\boldsymbol{q},\ \alpha)\{b\exp(i\boldsymbol{qr}_{el})+b^*\exp(-i\boldsymbol{qr}_{el})\}\,,$$

where

$$a(\boldsymbol{q},\ \alpha)=\frac{1}{q^2}\{e_{15}(\varepsilon_1q_1q_3+\varepsilon_2q_2q_3+\varepsilon_3q_1{}^2+\varepsilon_3q_2{}^2)+e_{31}(\varepsilon_1q_1q_3+\varepsilon_2q_2q_3)+e_{33}\varepsilon_3q_3{}^2\}\,,$$

from which the first- order phonon scattering matrix elements $(\overset{a}{V_s{}^e})$ are derived;

$$(\overset{a}{V_s{}^e})=\frac{8\pi^2e^2\hbar}{\varepsilon_s{}^2\Omega\rho}\cdot\frac{\{a(\boldsymbol{q},\ \alpha)\}^2}{\omega(q,\ \alpha)}\begin{cases} n(\boldsymbol{q},\ \alpha) & \text{for phonon absorption}\\ n(\boldsymbol{q},\ \alpha)+1 & \text{for phonon emission}\,.\end{cases}$$

Using these scattering matrix elements, we can calculate easily the absorption cross section in second-order Born approximation

$$\sigma(\omega)=\frac{2\pi}{\hbar}\left[\frac{2\pi e^2\hbar^4}{3\sqrt{\varepsilon_0}\,cm^{*1/2}}\cdot\frac{1}{(kT)(\hbar\omega)^3}\right]\sum_{x}Av_0\sum_{f}|(V_s)|^2q^2\sum_{p=0}^{1}(-)^P\delta\Big\{(E(\boldsymbol{k}_f)-E(\boldsymbol{k}_0))/kT$$
$$\mp\frac{\hbar\omega(q,\ \alpha)}{kT}-(-)^P\frac{\hbar\omega}{kT}\Big\}\,,$$

where Av_0 means the thermal average on initial states $\boldsymbol{k}_0$ of electrons, $\sum_f$ means the sum on final states $\boldsymbol{k}_f$, and the summation on α indicates that the longitudinal and transverse lattice vibrations should be taken into account. The term of $P=1$ in the last summation has been introduced by taking account of stimulated emission. Here, for simplicity, we have considered that the conduction band is spherical. Inserting Eq. (4) into Eq. (5),

$$\sigma(\omega)=\frac{2\sqrt{2}\,\pi^{3/2}}{3\varepsilon_s{}^2\sqrt{\varepsilon_0}\,\rho}\cdot\frac{e^4e_{15}{}^2}{c\cdot m^{*1/2}}(kT)^{-3/2}z^{-2}e^z K_1(z)(1-e^{-2z})\left\{\frac{4}{105}\,\frac{1}{u_l{}^2}\left(32+32\frac{e_{31}}{e_{15}}+24\frac{e_{33}}{e_{15}}+12\frac{e_{31}e_{33}}{e_{15}{}^2}+8\frac{e_{31}{}^2}{e_{15}{}^2}+15\frac{e_{33}{}^2}{e_{15}{}^2}\right)\right.$$
$$\left.+\frac{8}{105}\,\frac{1}{u_t{}^2}\left(19-2\frac{e_{31}}{e_{15}}+2\frac{e_{33}}{e_{15}}-6\frac{e_{31}e_{33}}{e_{15}{}^2}+3\frac{e_{31}{}^2}{e_{15}{}^2}+3\frac{e_{33}{}^2}{e_{15}{}^2}\right)\right\},$$

where $z=\frac{\hbar\omega}{2kT}$, u_l and u_t are the sound velocities belonging to each mode and $K_1(z)$ is the modified Bessel function of order 1, which, has the following asymptotic forms

$$K_1(z)\sim\left(\frac{\pi}{2z}\right)^{1/2}e^{-z}\left(1+\frac{3}{8z}-\frac{15}{128z^2}+\cdots\right)\quad\text{for}\quad z\gg1\,,$$
$$\sim\frac{1}{z}\qquad\text{for}\quad z\ll1\,.$$

Therefore,

$$\sigma(\omega)\propto T\cdot\omega^{-5/2}\quad\text{for}\quad z\gg1\,,$$
$$\propto T^{1/2}\omega^{-2}\quad\text{for}\quad z\ll1\,,$$

For CdS crystals, $\sigma=1.4\times10^{-17}\,\text{cm}^2$ at $T=300°\text{K}$ and $\lambda=10\mu$. This manitude is comparable with one derived by the deformation-potential model. Unfortunately, we have no knowledge about physical constants for other crystals with wurtzite structure. Although we expect that the effect is more dominant in ZnO crystal the effects of electron scattering due to the optical-lattice vibrations may predominate[5] there. The author would express his sincere thanks to Prof. Y. Suge for his encouragement.

Optical Properties of Irradiated LiF Crystals in the Extreme Ultraviolet Region

By Riso Kato, Shin-ichi Nakashima*,
Kaizo Nakamura and Yoichi Uchida

Department of Physics, Faculty of Science, Kyoto University

(Received June 16, 1960)

Optical absorptions of LiF single crystals irradiated with β- or γ-rays were measured in the extreme ultraviolet and some relations to the results[1] hitherto obtained were found.

A vacuum spectrophotometer of Seya-Namioka type with a concave grating of 1 m radius and 1200 line/mm constructed in our laboratory[2] were used. The light source was a cold cathode hydrogen discharge tube operated on D.C. 1 ampere at about 1 mm Hg. With these apparatus the useful spectral range reached down to about 900 Å and measurements could be carried out within the band width of about 2 Å. Present studies were done on LiF crystals obtained from Prof. Pringsheim and from the Harshaw Chem. Co. They were found the purest among those available.

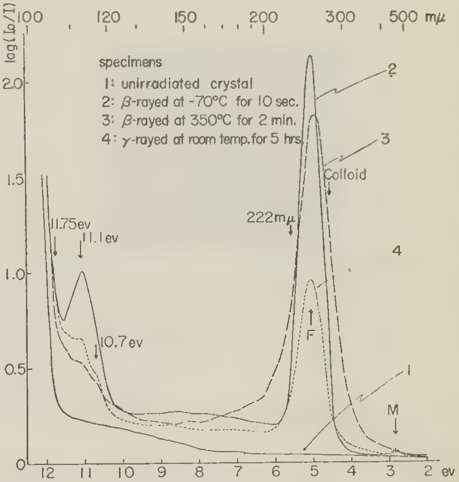

Fig. 1. Absorption spectra of LiF crystals irradiated with 0.9 MeV β-rays from a Van de Graaff machine or with γ-rays from Co^{60} (measured at room temperature).

As seen in Fig. 1, specimen 2 was found to have an absorption band at 11.1 eV well separated from the fundamental band. The band seems to be proportional in height to F band. In specimens 3 and 4, however, a composite shoulder was observed and seems to consist of at least two bands at 11.75 and 11.1 eV. The much longer wavelength components were seen faintly at about 10.7 and 9.5 eV. They became also appreciable in specimen 2 when it was irradiated with F light. Their intensities depend sensitively on histories of sample treatment and differ from crystal to crystal (Fig. 2). The width of each band at 5 eV in Fig. 1 suggests that specimens 3 and 4 contain 222 mμ and collid bands[1] overlapping on F bands. It was found that when specimen 2 was bleached with F light the band at 11.1 eV decreased and the absorption at 11.75 eV increased as 222 mμ band appeared (Fig. 2 (a)). Thus the existence of 222 mμ band is closely related to 11.75 eV band. The behavior of 11.1 eV band reminds us of β band[3], but its separation from the 1st exciton band exceeds 1 eV and the appearance of 11.75 eV and 222 mμ bands accompanying the irradiation with F light made the analysis difficult. Further experiments are required to confirm the nature of 11.1 eV band. With the assumption that the concen-

---

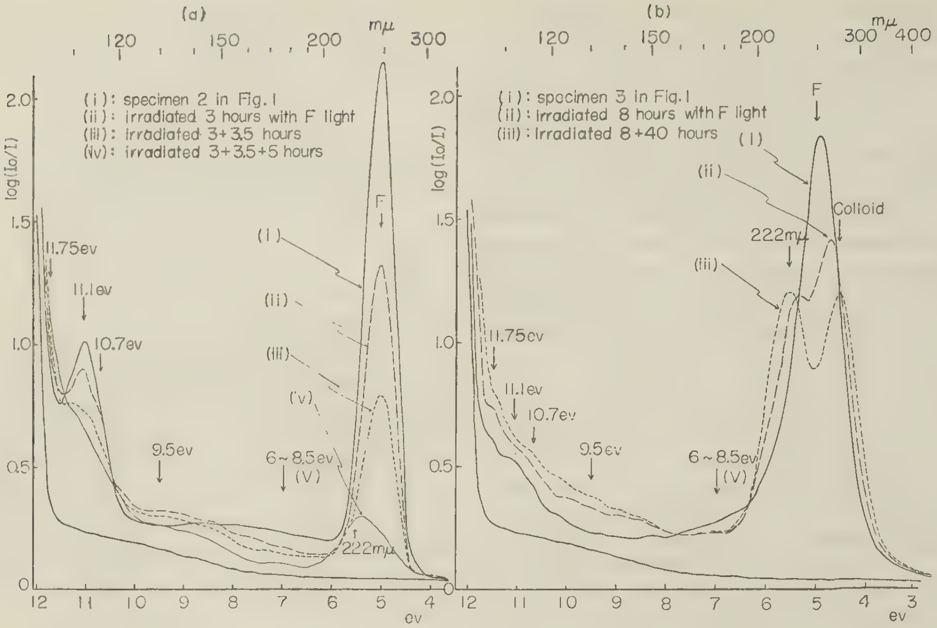

Fig. 2. Absorption spectra of irradiated LiF after bleaching with F light (measured at room temperature).

tration of 11.1 eV center is equal to F center, the oscillator strength of the band is estimated to be about 0.25.

As seen in Fig. 2(a), a broad absorption from 6 to 8.5 eV (curve (i)) disappeared with F light irradiation and is considered tentatively as a V band. As for the nature of 222 mμ band, our knowledge has been meager. Now in this experiment it appeared strongly in specimen 3 (Fig. 2(b)). Having been quenched to room temperature immediately after β-ray irradiation at 350°C, specimen 3 is likely to contain many defects. Then it is reasonable to consider that electrons released from F centers by the F light irradiation are trapped in some kind of the defects to form 222 mμ centers. In fact, in specimen 2 irradiated with β-rays at −70°C, the rate of change from F to 222 mμ band is much smaller than in specimen 3 as seen in Fig. 2. Finer experiments and quantitative discussions will be reported in the near future.

Study of Solid-Solution Single Crystals Containing BaTiO$_3$

By Tunetaro Sakudo
Electrotechnical Laboratory, Nagatacho, Tokyo

(Received September 3, 1960)

Recently many investigations have been made about the single crystals of solid-solutions of the perovskite-type ferroelectrics. The present note reports several results obtained in the cases of $BaTiO_3$-$SrTiO_3$ and $BaTiO_3$-$PbTiO_3$ solid-solution single crystals.

Crystals have been grown by modified Remeika's method using KF as flux. Solid-solution ceramics of the pertinent composition were chosen as solute materials. Maximum soaking temperatures were varied according to the compositions of solute. The soaking temperature was raised in the case of (Ba-Sr) TiO_3 and was lowered in (Ba-Pb) TiO_3, than in the case of $BaTiO_3$.

In the course of growing crystals it was observed that the butterfly-wing habit of pure $BaTiO_3$ disappeared gradually and the crystal size became smaller with increasing mole-ratio of Sr and Pb to Ba, as reported earlier by Kisaka et al.[1] Rather large square-plate crystals with {100} faces, as shown in

Fig. 1, were used in dielectric measurements. This crystal habit was denoted by DeVries[2] as untwinned [110] dendrite in the case of $BaTiO_3$.

Fig. 2 shows the plot of dielectric constant as function of temperature for (Ba-Pb) TiO_3 crystals. It is noticed from the figure that compositions of the grown crystals differ from those of the starting materials, as the Curie points of the crystals are different from those of the ceramics of the pertinent compositions.[3] Such phenomena were observed also in the case of (Ba-Sr) TiO_3. Compositions of the crystals were ascertained by the fluorescent X-ray analysis and the lattice-constant measurement. The relations between the compositions of solutes and grown crystals are shown in Fig. 3. These results are in disagreement with those of Kisaka et al. in (Ba-Sr) TiO_3.[1]

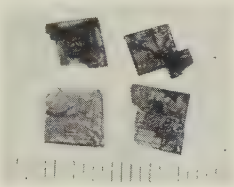

Fig. 1. Crystals grown from $(Ba_{0.9}Pb_{0.1})TiO_3$.

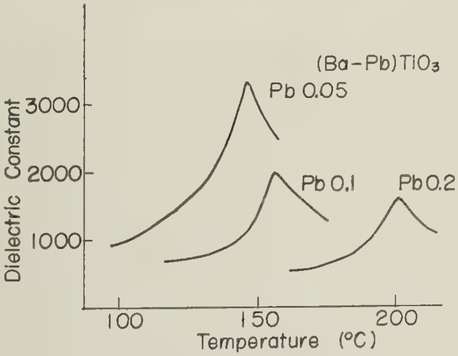

Fig. 2. Dielectric constant *vs* temperature for $(Ba\text{-}Pb)TiO_3$.

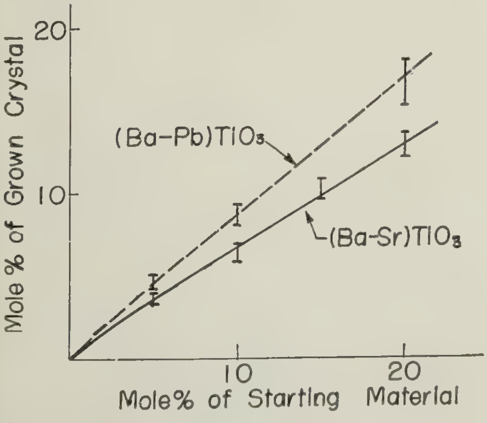

Fig. 3. Relation between the compositions of solutes and grown crystals.

In the series of (Ba-Pb) TiO_3, the spontaneous polarization and the coercive field were measured by observing the dielectric hysteresis loop. The birefringence was obtained by measuring the separation of birefringence bands in Na monochromatic light. The results are listed in Table I. In the measured region, the spontaneous polarization and the coercive field are seen to increase almost linearly with Pb content.

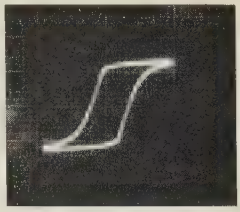

Fig. 4. Hysteresis loop of the crystal grown from $(Ba_{0.8}Pb_{0.2})TiO_3$.

Table I. Characteristics of (Ba-Pb) TiO_3 crystals.

Mole % of $PbTiO_3$ in Solute	0	0.05	0.1	0.2
Mole % of $PbTiO_3$ in Crystal	0	0.04	0.078	0.18
Curie temperature (°C)	125	144	165	202
Spontaneous polarization $\left(\frac{\mu\,\text{coul}}{\text{cm}^2}\right)$	23	27	28.5	36
Coercive field $\left(\frac{\text{kV}}{\text{cm}}\right)$	0.9	1.7	4.8	11
Birefringence $\frac{\Delta n}{n}$	0.053	/	0.050	0.048

Khodakof et al.[4] have reported that the thermal treatment remarkably changed the dielectric properties of the crystals of (Ba-Sr) TiO_3, but such phenomena were not observed in our experiment.

This work was supported by the Scientific Research Expenditure of the Ministry of Education.

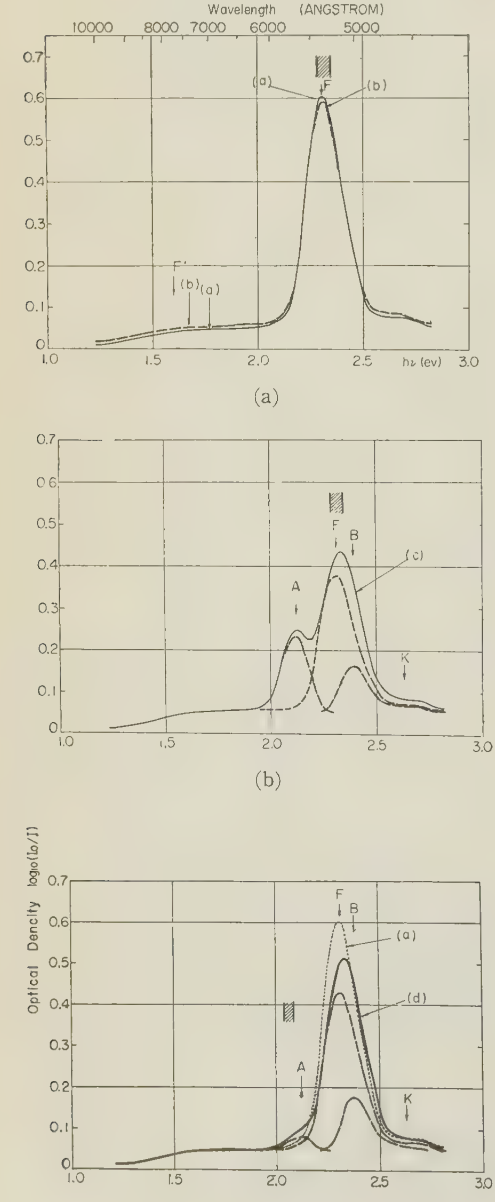
On the Reversible Optical Conversion Between A- and B-centers in Colored KCl Crystals

By Hiroshi Ohkura and Takeshi Uchida

Department of Applied Physics, Osaka City University, Osaka, Japan

(Received September 3, 1960)

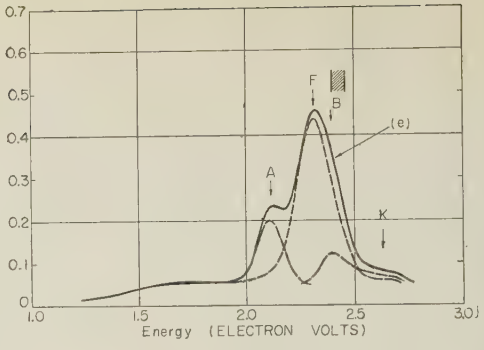
We have observed a new reversible process in the optical conversion between A-and B-centers. Optical absorption measurements were carried out at about −180°C. KCl crystals made by repetitions of Kyropoulos' method were colored additively in the atmosphere of a previously distilled sodium metal vapor.



(a)

(b)

(c)



(d)

Fig. 1. A sequence of absorption measurements on additively colored KCl of 1.80 mm thickness subject to subsequent irradiation with F–, A–, and B-light. The absorption measurements were made at about −180°C. Curve (a), unbleached; Curve (b), after ten minutes F-light bleaching at −180°C; Curve (c), after ten minutes F-light bleaching at −20°C; Curve (d), after forty minutes A-light bleaching at −180°C; Curve (e), after one hour B-light bleaching at −180°C. The shaded area represents the wavelength region covered by the irradiating light during bleaching.

The results will be discussed (subsequently) with the reference to a typical example for a specimen of 1.80 mm in thickness shown in Fig. 1. Curve (a), Fig. 1, shows the optical absorption spectrum of the additively colored crystal of KCl exhibiting only F-centers. Curve (b), shown as the dashed curve, is the saturated absorption curve after ten minutes F-light (5300 A) bleaching at −180°C. Before carrying out next procedures, the F' band in curve (b) was reverted to the F band by warming the crystal to room temperature. Curve (c), obtained after ten minutes F-light bleaching at −20°C, shows the F band bleach together with the simultaneous increase of the A and B bands. These bands are illustrated as the dashed curves on the same graph, which are obtained by substracting appropriately the F band absorption (the dashed curve) from the curve (c). In addition to these bands, there is a slight increase of absorption at the high frequency side of the B band, a part of which is overlapped on it.

The crystal is now subjected to A-light (6000 A) bleaching at −180°C. Curve (d), obtained after forty minutes A-light bleaching, is compared with the curve (a), shown as the dotted curve on the same graph. It shows the bleaching of A-centers together with the simultaneous increase of B-centers, without the appreciable change of both

F- and F'- bands. These bands are illustrated by the dashed curves on the same graph. The crystal is then subjected to B-light (5100 A) bleaching at −180°C, the result is shown in curve (e), in which each band is illustrated by the dashed curve. We now find that the A band recovers at the expense of the B band during B-light irradiation.

The occurrence of this conversion between A and B band depends on the temperature. For instance, no change was observed when above mentioned optical excitations were carried out at −200°C.

We wish to thank Professor H. Kawamura and Mr. M. Tomura for their advice and encouragement in the course of this work.

Anomalous Paramagnetic Resonance in $Ni(NH_3)_6Cl_2$

By Muneyuki DATE

Department of Physics, Faculty of Science,
Osaka University, Osaka

(Received August 6, 1960)

An anomalous paramagnetic resonance was observed in the single crystal of $Ni(NH_3)_6Cl_2$ below the liquid nitrogen temperature. This ammine complex of nickel has a cubic crystalline structure in which each nickel ion is surrounded by six NH_3 groups forming a regular octahedron$^{1)}$. Isotropic paramagnetic resonance absorption was observed above the liquid nitrogen temperature with $g=2.16$. The observed line width was 150 oersted, which is independent of the orientation of the crystal within experimental errors. Accordingly, it may be concluded that the crystalline electric field acting on each nickel ion is perfectly cubic and that therefore there is no splitting in the lowest spin triplet.

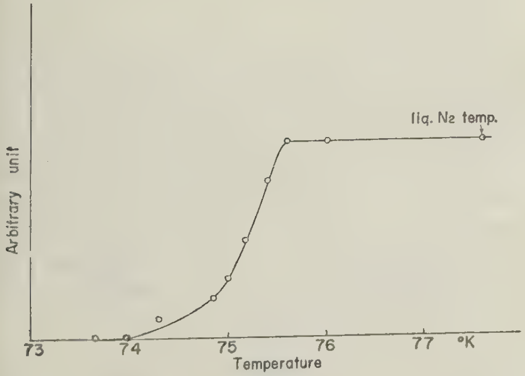

Fig. 1. Temperature dependence of absorption intensities at 36.17 kMc/sec. magnetic field is along the {100} direction.

Below 76°K, however, the resonance line vanishes suddenly, the variation of the relative intensity being shown in Fig. 1. This vanishing is independent of the orientation of the crystal and no line broadening of the paramagnetic resonance, which is usually observed above the antiferromagnetic transition temperature, is observed near the transition temperature in the present case.

The observed transition may be due to the quenching of the free rotations of the NH_3 groups below 76°K. Hindered rotation of ammonia or ammonium radicals in solid is frequently observed in various compounds. In our case, the quenching of the rotational motion of the NH_3 groups will produce a crystalline electric field of a lower symmetry acting upon each nickel ion and this field will induce an initial splitting of the ground state spin triplet. Then the resonance point will shift largely from that which corresponds to $g=2.16$, and thus one will observe the vanishing of the normal resonance below the transition point. Although there is a possibility of observing the spin resonance of the distorted crystal below the transition temperature if the distortion of the unit octahedron were regular in space, and the magnitude of distortion were not extremely large, there was no resonance absorption below 74°K at 36 kMc/sec up to 10 kilo oersted.

The vanishing of the paramagnetic resonance does not seem to occur from magnetic origin. By susceptibility measurements Kido and Watanabe$^{2)}$ have shown that there is no remarkable change near the liquid nitrogen temperature. Recently, however, Watanabe$^{3)}$ observed the temperature dependence of the g-value by careful susceptibility measurements and showed that $g=2.18\pm0.03$ at room temperature and $g=2.21\pm0.03$ near the liquid hydrogen temperature. These data are consistent with ours, so far as we assume the variation of the g-value to be due to a slight deformation of the unit octahedron below 76°K. Proton resonance experiment performed by Kim and Sugawara$^{4)}$ showed that the line disappeared below 1.6°K, which may be due to the antiferromagnetic transition and may have no relation to our observation.

Absorption Spectra of Potassium Bromide-Thallium Phosphors

By Tokumichi TAMAI

Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka

(Received September 10, 1960)

The absorption spectra of potassium bromide-thallium phosphors have been studied at both liquid nitrogen and room temperatures. Single crystals were prepared by dissolving a small quantity of thallous bromide in a melt of potassium bromide and growing up by the well-known Kyropoulos method in this laboratory. Concentrations of thallous ions are 0.001, 0.01, and 0.1 mol% in the melt. An automatic recording spectrophotometer was used to measure the absorption spectra of these crystals. Although a considerable amount of information can be found in the literatures concerning the properties of the potassium bromide-thallium phosphors,[1-7] yet absorption band in the region of 210 mμ have not been clearly resolved. Muuss[7] has reported the bands at 4.76, 5.57, 5.81, and 6.12 eV at room temperature, and the last three bands have been only partly resolved. In the present experiment three bands at 4.79, 5.60, and 5.92 eV have been clearly resolved at liquid nitrogen temperature, but the band at 6.12 eV was not observed at both liquid nitrogen and room temperatures. Fig. 1 shows typical absorption curves.

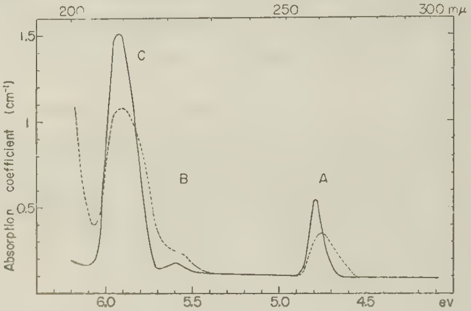

Fig. 1. Typical absorption spectra of the potassium bromide-thallium phosphor, solid line was taken at liquid nitrogen temperature and dotted line taken at room temperature.

Table I. The absorption peaks and the half-widths of various bands at both liquid nitrogen and room temperatures, and the values of the oscillator strengths of A, B and C bands, taking the value of the oscillator strength of C band as unity.

		A	B	C
Absorption peaks	Room Temperature	4.76 (eV)	5.56 (eV)	5.90 (eV)
	Liquid Nitrogen Temperature	4.79 (eV)	5.60 (eV)	5.92 (eV)
Half-width	Room Temperature	0.17 (eV)	not clear	0.265 (eV)
	Liquid Nitrogen Temperature	0.096 (eV)	0.088 (eV)	0.19 (eV)
Oscillator strength of the absorption transitions at liquid nitrogen temperature, taking that of C band as unity		0.155	~0.014	1

The absorption bands at 4.79 and 5.92 eV correspond to A and C bands as denoted by Seitz[8] respectively. The band at 5.60 eV should be assiged to B band because height of the absorption band varies linearly with the concentration of thallous ion and the ratio of the oscillator strength of this B band to that of A or C band is nearly equal to the corresponding ratio in the case of the bands in potassium iodide-thallium phospors.[9,10] The absorption peaks and the half widths are summarized in Table I.

The half-widths of A and C bands are narrower than the values reported by Lorentz,[2] and that of A is equal to Muuss' value.[7] As seen in Fig. 1, the half-width of C band is wider than those of A and B bands, and the shape of C band is clearly asymmetric. Thus it is likely to consisted of at least two bands, and it will be suggested that $^1P_1$ level is probably perturbed by the crystalline field which is not a cubic symmetry, and separated by three levels.[10] Further discussion with detailed measurements will be reported later on.

The author would like to express his gratitude to Prof. Y. Uchida for his guidance and discussions on the work.

N Bands in Alkali Halide Crystals

By Sadao HATTORI

Department of Natural Science, Nagoya Branch,
Aichi Gakugei University, Nagoya

(Received September 10, 1960)

The N bands of some alkali halide crystals were investigated. The samples, cleaved out of the single crystals grown from the melts of KCl, NaCl, KBr, KI and LiF were colored at room temperature with the irradiation of X rays from a tungsten target through a beryllium window, operated at about 50 kv and 15 ma. The colored samples were bleached with their respective F light at room temperature to develop the N_1 and N_2 bands, except for LiF for which the whole light from a low pressure Hg lamp was used and furthermore at about 100° to 150°C to develop the N bands in reasonable times.

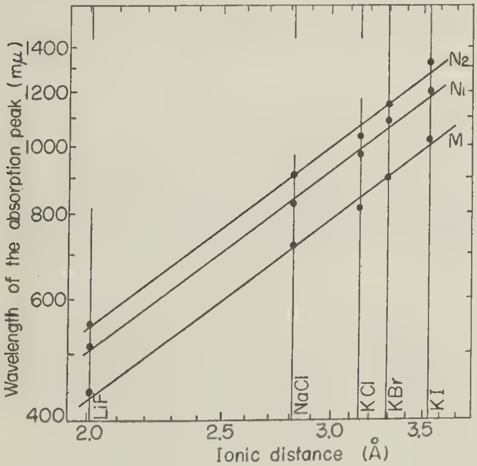

Fig. 1. The relation between the wavelengths of absorption peaks of N_1, N_2 and M bands and the ionic distances of various salts, measured at −170°C.

The N_1 and N_2 bands thus obtained, as well as the M bands of these salts were shown in Fig. 1 satisfying well Ivey's relation.[1] The N bands, except for the N_2 bands of KBr and KI, were obtained earlier[2] and the results obtained here were in good agreement with them. The N_2 bands of KBr and KI were so slight that it was uncertain that they were in fact the N_2 bands, but these bands, as shown in the figure satisfied comparatively well Ivey's relation together with the N_2 bands of the other salts investigated here.

The N_1 and N_2 bands were investigated in more details with NaCl, for which the two bands were well separated even at room temperature, with the following results:

1) The N_2 band was destroyed while the N_1 band was enhanced with the irradiation of the M band light at room temperature. This is shown in Fig. 2. (Similar results were also obtained with KCl.) However, the rate of the destruction of the former band was much larger than that of the enhancement of the latter band.

2) When the crystal was irradiated with the M band light after the X ray coloring, only the N_1

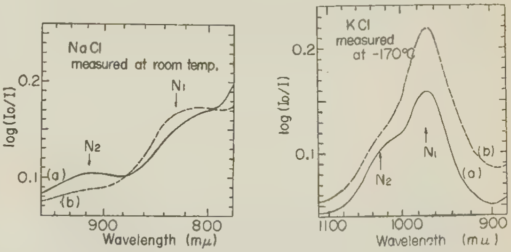

Fig. 2. The N_1 and N_2 bands of the X ray colored NaCl and KCl crystals irradiated, (a) with the F band light and (b) with the M band light at room temperature, after the irradiation with the F band light.

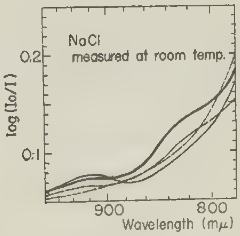

····· X rayed 41 KV. 12 ma. 15 hours (0.47)*
—— 10 min. at 98°C (0.42)*
━━ 100 min. at 98°C (0.39)*
— — — 15 hours at 98°C (0.25)*

* The number means the optical density of the M-band for each curve.

Fig. 3. The thermal behaviors of the N_1 and N_2 bands of the X ray colored NaCl crystals, when the crystal was kept at 98°C in the dark.

band was enhanced.

3) Only the N_2 band was enhanced appreciably in the X ray colored crystal which was kept at about 30°C during 20 hours in the dark. At higher temperatures, e.g. at 98°C, both bands were enhanced but the rate of growth in this thermochemical reaction was much larger for the N_2 band than for the N_1 band. After reaching their maxima, they decayed gradually (Fig. 3).

These results seem to indicate that the N_1 and N_2 bands are rather due to different centers. Further details of the nature of these two bands are now under investigation.

The author wishes to express his thanks to Professor Y. Uchida of Kyoto University for his kind interests and encouragement.

A Correction to my Paper "The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, I."

By Tsugio MORI
Ôtsu Senior High School, Ôtsu,
Shiga-ken, Japan

(Received September 13, 1960)

In the two papers published under the title "The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, I[1] and II[2]", the author maintained that we should replace the expression

$$\frac{1}{n}\sum_{i<j}^{n}\sum \mathbf{X}^{j-i-1} \qquad \mathrm{I(20)}$$

by

$$\{1+g(n)\}(\mathbf{1}-\mathbf{X})^{-1}\,. \qquad \mathrm{I(23)}$$

This replacement was needed in order to compare the calculated values of $\langle\mu^2\rangle$ and $\langle R^2\rangle$ with their experimental values, although we did not know whether $\lim(\mathbf{X}^n/n)$ was $\mathbf{0}$ or infinity. But, after the publication of the texts I and II, the author found a way of the verification of the formula

$$\lim_{n\to\infty}\frac{1}{n}\mathbf{X}^n=\mathbf{0}\,. \qquad \mathrm{I(22)}$$

Therefore, the statements in p.1485 of this volume, running from Eq. (22) to Eq. (24), must be corrected as the following.

" However, the verification of the formula

$$\lim_{n\to\infty}\frac{1}{n}\mathbf{X}^n=\mathbf{0} \qquad (22)$$

is not simple, for $\mathbf{X}$ is not orthogonal. Some authors have neglected the verification of (22), and put (22) as the assumption. On the other hand, there was another group of authors who have stated that they were interested only in the case of (22). The difference between their standpoints was small, and many authors have reduced (20) to

$$\frac{1}{n}\sum_{i<j}^{n}\sum \mathbf{X}^{j-i-1} \longrightarrow (\mathbf{1}-\mathbf{X})^{-1}\,.$$

However, it is remarked that the above reduction brings $\lim(\sum\sum \mathbf{X}^{j-i-1}/n)$ into a quantity which is independent of n. In other words, the formula (19) reduces into

$$\langle\mu^2\rangle=(\mathrm{const.})\, n\mu_0^2\,,$$

which corresponds to the random coil, or the unperturbed (Gaussian) coil in general. If we wish to treat an interrupted configuration which is neither the Gaussian coil nor the crystalline configuration, a jump of thought is needed. In this paper, we use the replacement

$$\frac{1}{n}\sum_{i<j}^{n}\sum \mathbf{X}^{j-i-1} \longrightarrow \{1+g(n)\}(\mathbf{1}-\mathbf{X})^{-1}\,, \qquad (23)$$

where $g(n)$ is a function of n. The replacement (23) may be unaccountable so far as we stick to (22). However, it must be rather significant that we can make a progress from the Gaussian coil by the use of (23). If $\lim g(n)$ is a constant which is independent of n, we have the Gaussian coil. In this way, we can write

$$\lim_{n\to\infty} g(n)\begin{cases} =\infty \text{ (for most chain configurations)} \\ = \text{a const. (for the Gaussian coil)} \end{cases}\text{''}. \qquad (24)$$

The verification of

$$\lim_{n\to\infty}\frac{1}{n}\mathbf{X}^n=\mathbf{0} \qquad \mathrm{I(22)}$$

may be treated in the next paper under the title "The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, III."

Analysis of the NMR Spectra of Acrylic Acid and Ethyl Acrylate

By Yoji ARATA,
University of Electro-Communications, Chofu, Tokyo
Hiroshi SHIMIZU,
Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo
and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo

(Received September 28, 1960)

The NMR spectra of acrylic acid and ethyl acrylate were measured at 56.4 Mc and analyzed by the method proposed by McConnell, McLean and Reilly[1] with the aid of parametron digital computer PC-1 at the University of Tokyo. The spectrum of acrylic acid is very complicated as shown in Fig. 1. The values of chemical shifts and spin-spin coupling constants are shown in Table I as well as those for ethylenic protons obtained in the literature[2]. The values in Table I were obtained by means of the least squares method, which made the analysis of the spectrum very easy; the details of the analysis will be published elsewhere[3]. As we examine the results of Table I, we notice that the spin-spin coupling constant between gem protons of acrylic acid is considerably larger than those of ester and of normal ethylene groups. This may be interpreted in terms of decreasing HCH angle[4] of this acid.

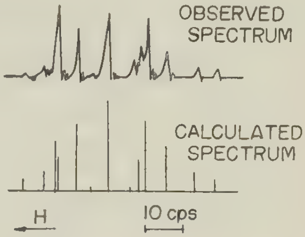

Fig. 1. The observed and calculated spectra of acrylic acid.

Table I. Values of chemical shifts and spin-spin coupling constants of acrylic acid and ethyl acrylate.

	Chemical shifts (cps)	Spin-spin coupling constants (cps)		
		J_{trans}	J_{cis}	J_{gem}
Acrylic acid (R: COOH)	$\nu_\gamma-\nu_\beta=30.8$ $\nu_\alpha-\nu_\beta=12.5$	13.4	8.3	5.7
Ethyl acrylate (R: $COOC_2H_5$)	$\nu_\beta-\nu_\alpha=43.7$ $\nu_\gamma-\nu_\alpha=36.3$	16.4	7.8	−0.2
Normal ethylenic group[2]		17∼18	8∼11	1∼2

It is pleasure for us to thank Mr. Ichiro Yamaguchi and Mr. Naohiro Hayakawa of the Japan Atomic Energy Research Institute who gave us the opportunity to make measurements by the NMR spectrometer, Varian V-4300C, in their laboratory.

On the Resistance Anomaly of Dilute Zinc Alloys at Low Temperatures

By Yoshio MUTO
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received September 20, 1960)

In the previous note[1], we reported that the dilute alloys of zinc with manganese show a minimum in the electrical resistance-temperature curves and the decrease of the electrical resistance in the magnetic field. It was planned to obtain further information by extending the study on the electrical properties of the dilute alloys. As zinc used previously was not good in purity, high purity zinc (99.999%) was adopted as the solvent metal and melted with small amounts of manganese, chromium and tin, respectively. The method of preparation of the specimens was the same as described in the previous note. Then the specimens were placed in a furnace heated at 350°C and rapidly quenched into water. Judging from the equilibrium diagrams, all specimens are considered to be within the solubility range. In these specimens, no important impurity could be detected.

Fig. 1 shows that the electrical resistance of Zn–Mn alloys increases with decreasing temperature. We believe that Zn–Mn alloys show a resistance minimum above 4.2°K. It is also noted that for the case of the most concentrated Zn–Mn (0.12 at. %) alloy prepared the rate of increase of the electrical resistance decreases with decreasing temperature. Thus, it may be expected that a resistance maximum will appear at an extremely low temperature. In Fig. 2, it is seen that the electrical resistance of dilute Zn–Cr alloys also increases with decreasing temperature. Zn–Cr alloys have also a resistance minimum above 4.2°K. Fig. 3 shows the electrical resistance of a Zn–Sn alloy revealing no anomalous behaviour. The absolute value of electrical resistance of this specimen is much smaller than that of Zn–Mn and Zn–Cr alloys.

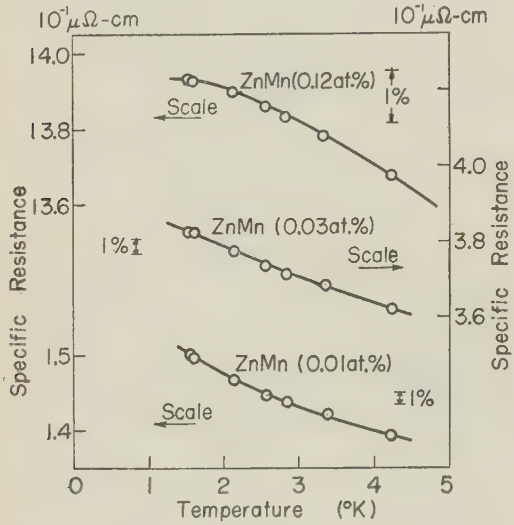

Fig. 1. Specific resistance versus temperature of zinc alloyed with manganese.

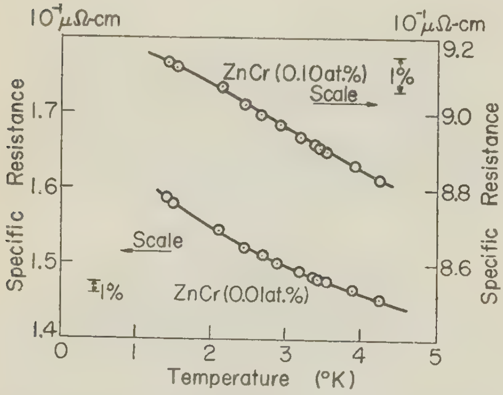

Fig. 2. Specific resistance versus temperature of zinc alloyed with chromium.

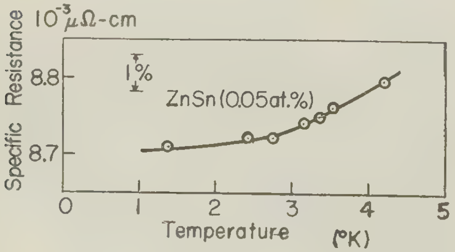

Fig. 3. Specific resistance versus temperature of zinc alloyed with tin.

Judging from the above experimental results, the electrical resistance of zinc alloy containing a non-transition metal shows no anomaly, while the zinc alloys containing transition metals have a resistance minimum. Recently, Hedgcock, Muir and Wallingford[2] obtained the similar results on magnesium alloys. On the other hand, Pearson, Rimek and Templeton[3),4] observed that the electrical resistances of both poly- and single crystal of Cu–Fe alloy show a minimum, and the electrical resistance of polycrystalline Cu–Sn alloy shows a minimum while that of single crystal shows no anomalous behaviour. In view of these results, it seems that the electronic properties of the dilute alloys containing transition metals show the anomalous behaviour probably due to the exchange interaction between the conduction electrons and the magnetic ions, while the electronic properties of the dilute alloys containing non-transition metals are to be explained by spin-independent scattering mechanisms.

The author wishes to express his sincere thanks to Prof. T. Fukuroi, Assist. Prof. Y. Shibuya and Assist. Prof. S. Tanuma for their kindness and stimulating discussions concerning the present work.

Infrared Absorption of Free Carriers in Ionic Crystals

By Toshio TANAKA

Department of Applied Physics, University of Tokyo, Tokyo, Japan

(Received Sep. 6, 1960)

In the previous short note[1)] we estimated the infrared photon absorption cross section through piezoelectric scattering of free carriers, whereby we pointed out that the appreciable effect on the infrared absorption of the interactions between electrons and the lattice vibrations of the longitudinal optical mode in crystals such as ZnO, CdS etc. might be expected. Here we shall estimate the magnitude and the photon frequency dependence of the infrared absorption of free carriers in ionic crystals.

The electronic polarization produced by the optical lattice vibrations has a strong interaction with electrons. The interaction Hamiltonian[2)] is

$$H_{\mathrm{int}}=\sum_q\{V_q b_q e^{iq\mathrm{II}}+V_q{}^* b_q{}^* e^{-iq\mathrm{II}}\}$$

where

$$V_q=4\pi i\sqrt{e^2\hbar/2\gamma\omega_l V}\cdot 1/q,\quad \gamma\equiv\omega_l{}^2/4\pi(1/\varepsilon_\infty-1/\varepsilon_s)\,.$$

Here ω_l is the frequency of the longitudinal optical mode of the lattice vibration, ε_∞ and ε_s are the high-frequency-and the static-dielectric constants respectively, and b_q and $b_q{}^*$ are phonon destruction and creation operators. Due to the interactions electrons can gain the momentum from the phonons and, therefore, can absorb photons. The absorption cross section is calculated in Born approximation[3)];

$$\sigma(\omega)=\frac{2\pi}{\hbar}\left[\frac{4\pi^2}{3}\cdot\frac{e^4\hbar^5\omega_l}{\sqrt{\varepsilon_\infty}\cdot C\cdot V\cdot m^{*2}}\left(\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_s}\right)(\hbar\omega)^{-3}\right]Av_0\sum_f\left(n_q\sum_{p=0}^{1}(-1)^p\delta(E(\boldsymbol{k}_f)-E(\boldsymbol{k}_0)-\hbar\omega_l-(-1)^p\hbar\omega\right)$$

$$+(n_q+1)\sum_{p=0}^{1}(-1)^p\delta(E(\boldsymbol{k}_f)-E(\boldsymbol{k}_0)+\hbar\omega_l-(-1)^p\hbar\omega))$$

$$=\frac{8\sqrt{2}\sqrt{\pi}}{3}\cdot\frac{e^4\hbar\omega_l(kT)^{1/2}}{\sqrt{\varepsilon_\infty}\cdot C\cdot m^{*1/2}}\left(\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_s}\right)(\hbar\omega)^{-3}$$

$$\times\left\{\begin{array}{ll}\left[nz_1e^{z_1}K_1(z_1)+(n+1)z_2e^{z_2}K_1(z_2)-(n+1)\dfrac{e^{-2z_1}}{2}(1+z_1+z_1e^{z_1}K_1(z_1))-nz_2e^{-z_2}K_1(z_2)\right] & \text{for } \omega\geq\omega_l\\ \left[nz_1e^{z_1}K_1(z_1)+\dfrac{(n+1)}{2}(1+z_3+z_3e^{z_3}K_1(z_3))-nz_3e^{z_3}K_1(z_3)-\dfrac{e^{-2z_1}}{2}(n+1)(1+z_1+z_1e^{z_1}K_1(z_1))\right] & \text{for } \omega\leq\omega_l\end{array}\right\}$$

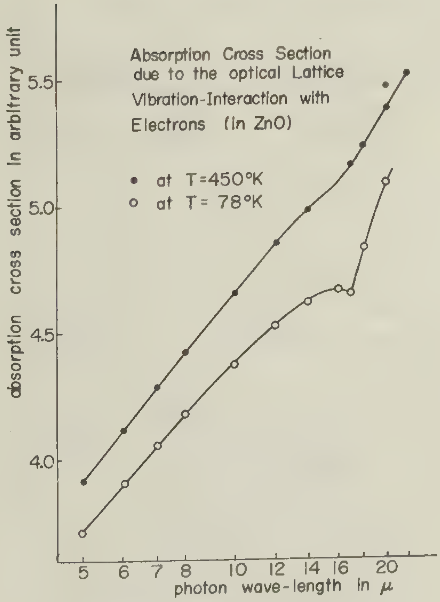

Fig. 1.

In the above equation the terms of $p=1$ have been introduced by taking account of the stimulated emission of photon. $K_1(z)$ is the modified Bessel function of order 1; and $z_1\equiv\hbar(\omega+\omega_l)/2kT$, $z_2\equiv\hbar(\omega-\omega_l)/2kT$ and $z_3\equiv\hbar(\omega_l-\omega)/2kT$; and n is the mean phonon number.

Let us attempt to apply the equation to the case of ZnO crystal. Using the following values, $m^*=0.06\,\mathrm{m}$, $\varepsilon_\infty=4$, $\varepsilon_s=8.15$ and $\hbar\omega_l=0.0733\,\mathrm{ev}$, we find that $\sigma\doteqdot1.7\times10^{-15}\,\mathrm{cm}^2$ at $\lambda=10\,\mu$ and $T=300$°K. This magnitude is comparable with the experimental value $\sigma=1.2\times10^{-15}\,\mathrm{cm}^2$[4)]. The dependence of the absorption cross section on the photon wavelength is shown in Fig. 1 for $\tau\omega>1$.

The λ^3-dependence in short wavelength region measured[4)] in ZnO crystals seems not to be explained.

The author wishes to express his sincere thanks to Prof. Y. Suge for his encouragement.

Strong Interaction of Baryons

Hy Seitaro NAKAMURA
Department of Physics, University of Tokyo,
Tokyo, Japan

(Received September, 8, 1960)

On the three dimensional charge space, we can write a Hamiltonian of the weak interaction as an invariant[1)–3)], while the formulation on the usual isospin space enforces us to give a spinor Hamiltonian for that. For the strong interaction, however, the three dimensional representation leads us to violation of strangeness. As a trial case, let us forget strangeness[4)–5)] and find a new quantum number which takes place of strangeness.

We shall introduce a two component spinor Ψ_μ, and define 2×2 matrices, κ_L, in this κ space.

$$\left.\begin{aligned}\Psi_\mu=\begin{pmatrix} p_\mu \\ q_\mu \end{pmatrix},\quad & p_1=(\Xi^-+p)/\sqrt{2}\,, && p_2=(\Xi^--p)/\sqrt{2}\,i, \\ & p_3=(\Xi^0-n)/\sqrt{2}\,, && p_0=(\Xi^0+n)/\sqrt{2} \\ & q_1=(\Sigma^-+\Sigma^+)/\sqrt{2}\,, && q_2=(\Sigma^--\Sigma^+)/\sqrt{2}\,i, \\ & q_3=\Sigma^0, && q_0=\Lambda \end{aligned}\right\} \tag{1}$$

$$\kappa_1=\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},\ \kappa_2=\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix},\ \kappa_3=\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},\ \kappa_0=\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \tag{2}$$

We consider a new charge $Q_\kappa=(1+\kappa_3)/2$, which is 1 for p and 0 for q. According to the principle[6)] of interchange-ability of particles which is an extension of symmetric meson theory, we assume a strong interaction between p and q through four groups of mesons, $\mathfrak{K}_+$, $\mathfrak{K}_0$, $\mathfrak{K}_-$ and $\mathfrak{K}_0'$.

$$p_+\to q_0+\mathfrak{K}_+\ , \qquad q_0\to p_++\mathfrak{K}_-\ , \tag{3}$$

$$p_+\to p_++\mathfrak{K}_0(\mathfrak{K}_0')\ , \qquad q_0\to q_0+\mathfrak{K}_0(\mathfrak{K}_0')\ . \tag{4}$$

Each group is assumed to be composed of four members in the states of $Q_e=N_3=1,\ 0,\ -1$ (triplet) and 0 (singlet) in the three dimensional charge space, which we shall call N-space.

$$\left.\begin{aligned}\mathfrak{K}_+ &=\left(K^+,\ \frac{L_+{}^0-K_+{}^0}{\sqrt{2}},\ L^-,\ \frac{L_+{}^0+K_+{}^0}{\sqrt{2}}\right) \\ \mathfrak{K}_- &=\left(L^+,\ \frac{L_{-0}-K_-{}^0}{\sqrt{2}},\ K^-,\ \frac{K_-{}^0+L_-{}^0}{\sqrt{2}}\right)\end{aligned}\right\} \tag{5}$$

$$\left.\begin{aligned}\mathfrak{K}_0 &=(D^+,\ D^0,\ D^-,\ D^{0\prime}) \\ \mathfrak{K}_0' &=(\pi^+,\ \pi^0,\ \pi^-,\ \pi^{0\prime})\end{aligned}\right\} \tag{6}$$

Here the upper suffices are electric charge, and the lower suffices κ-charge. Thus we can write down an interaction Hamiltonian of the strong interaction among baryons through mesons, $\mathfrak{K}_+$, $\mathfrak{K}_-$, (κ-charge exchange terms) and $\mathfrak{K}_0$, $\mathfrak{K}_0'$ (κ-charge neutral terms). We assume that H is of κ-charge independence which follows;

$$\begin{aligned}H=\ & a\overline{\Psi}_{[i}\kappa_L\Phi_{Lj}\psi_{k]}+b\overline{\Psi}_0\kappa_L\Phi_{Lj}\Psi_j+c\overline{\Psi}_j\kappa_L\Phi_{L0}\Psi_j \\ & +d\overline{\Psi}_j\kappa_L\Phi_{Lj}\Psi_0+e\overline{\Psi}_0\kappa_L\Phi_{L0}\Psi_0+a'\overline{\Psi}_{[i}\kappa_0\Phi_{0j}'\Psi_{k]} \\ & +b'\overline{\Psi}_0\kappa_0\Phi_{0j}'\Psi_j+c'\overline{\Psi}_j\kappa_0\Phi_{00}\Psi_j+d'\overline{\Psi}_j\kappa_0\Phi_{0j}\Psi_0 \\ & +e'\overline{\Psi}_0\kappa_0\Phi_{00}\Psi_0+\text{h.c.} \\ & \qquad i,\ j,\ k=1,\ 2,\ 3, \qquad L=1,\ 2,\ 3.\end{aligned} \tag{7}$$

$$\begin{aligned}\Phi_{+,\mu} &=\left(\frac{L^-+K^+}{\sqrt{2}},\ \frac{L^--K^+}{\sqrt{2}\,i},\ \frac{L_+{}^0-K_+{}^0}{\sqrt{2}},\ \frac{L_+{}^0+K_+{}^0}{\sqrt{2}}\right), \\ \Phi_{0,\mu} &=\left(\frac{D^-+D^+}{\sqrt{2}},\ \frac{D^--D^+}{\sqrt{2}},\ D^0,\ D^{0\prime}\right), \\ \Phi_{-,\mu} &=\left(\frac{K^-+L^+}{\sqrt{2}},\ \frac{K^--L^+}{\sqrt{2}\,i},\ \frac{L_-{}^0-K_-{}^0}{\sqrt{2}},\ \frac{L_-{}^0+K_-{}^0}{\sqrt{2}}\right), \\ \Phi_{0,\mu}' &=\left(\frac{\pi^-+\pi^+}{\sqrt{2}},\ \frac{\pi^--\pi^+}{\sqrt{2}\,i},\ \pi^0,\ \pi^{0\prime}\right). \\ & \qquad \mu=1,\ 2,\ 3,\ 0.\end{aligned}$$

Here a, b, c, d, e and a', b', c', d', e' are coupling constants. If we assume further

$$ai=b=c=d=e\equiv g\ , \quad -a'i=b'=c'=d'=e'\equiv g'\ , \tag{8}$$

we get using the matrix representation[7)]

$$\begin{aligned}H_{\mathfrak{K}_+}=g\Big[& (\overline{p}\,\overline{n})\begin{pmatrix} \Sigma^0 & \sqrt{2}\,\Sigma^+ \\ \sqrt{2}\,\Sigma^- & -\Sigma^0 \end{pmatrix}\begin{pmatrix} K^+ \\ K^0 \end{pmatrix} \\ & +(\overline{\Xi}{}^0\overline{\Xi}{}^-)\begin{pmatrix} \Sigma^0 & \sqrt{2}\,\Sigma^+ \\ \sqrt{2}\,\Sigma^- & -\Sigma^0 \end{pmatrix}\begin{pmatrix} L^0 \\ L^- \end{pmatrix} \\ & +(\overline{p}\,\overline{n})\begin{pmatrix} \Lambda & 0 \\ 0 & \Lambda \end{pmatrix}\begin{pmatrix} K^+ \\ K^0 \end{pmatrix} \\ & +(\overline{\Xi}{}^0\overline{\Xi}{}^-)\begin{pmatrix} \Lambda & 0 \\ 0 & \Lambda \end{pmatrix}\begin{pmatrix} L^0 \\ L^- \end{pmatrix}\Big]+\text{h.c.}\ ,\end{aligned} \tag{9}$$

$$\begin{aligned}H_{\mathfrak{K}_-}=g\Big[& (\overline{K}{}^+\overline{K}{}^0)\begin{pmatrix} \Sigma_0 & \sqrt{2}\,\Sigma^+ \\ \sqrt{2}\,\Sigma^- & -\Sigma^0 \end{pmatrix}\begin{pmatrix} p \\ n \end{pmatrix} \\ & +(\overline{L}{}^0\overline{L}{}^-)\begin{pmatrix} \Sigma^0 & \sqrt{2}\,\Sigma^+ \\ \sqrt{2}\,\Sigma^- & -\Sigma^0 \end{pmatrix}\begin{pmatrix} \Xi^0 \\ \Xi^- \end{pmatrix} \\ & +(\overline{K}{}^+\overline{K}{}^0)\begin{pmatrix} \Lambda & 0 \\ 0 & \Lambda \end{pmatrix}\begin{pmatrix} p \\ n \end{pmatrix} \\ & +(\overline{L}{}^0\overline{L}{}^-)\begin{pmatrix} \Lambda & 0 \\ 0 & \Lambda \end{pmatrix}\begin{pmatrix} \Xi^0 \\ \Xi^- \end{pmatrix}\Big]+\text{h.c.}\ ,\end{aligned} \tag{10}$$

$$\begin{aligned}H_{\mathfrak{K}_0}=g/\sqrt{2}\Big[& (\overline{p}\,\overline{n})\begin{pmatrix} \sqrt{2}\,D^+ & 0 \\ 0 & \sqrt{2}\,D^+ \end{pmatrix}\begin{pmatrix} \Xi^0 \\ \Xi^- \end{pmatrix} \\ & +(\overline{\Xi}{}^0\overline{\Xi}{}^-)\begin{pmatrix} \sqrt{2}\,D^- & 0 \\ 0 & \sqrt{2}\,D^- \end{pmatrix}\begin{pmatrix} p \\ n \end{pmatrix} \\ & +(\overline{p}\,\overline{n})\begin{pmatrix} D^0 & 0 \\ 0 & -D^0 \end{pmatrix}\begin{pmatrix} p \\ n \end{pmatrix} \\ & +(\overline{\Xi}{}^0\overline{\Xi}{}^-)\begin{pmatrix} D^0 & 0 \\ 0 & -D^0 \end{pmatrix}\begin{pmatrix} \Xi^0 \\ \Xi^- \end{pmatrix} \\ & -\left(\overline{\boldsymbol{\Sigma}}\times\boldsymbol{\Sigma}\cdot\boldsymbol{D}+\overline{\boldsymbol{\Sigma}}\cdot\boldsymbol{D}\Lambda+\overline{\Lambda}\boldsymbol{D}\cdot\boldsymbol{\Sigma}\right)\Big] \\ & +g/\sqrt{2}\,[(P\overline{P}+\overline{\Xi}{}^-\Xi^-+\overline{n}n+\overline{\Xi}{}^0\Xi^0) \\ & -(\overline{\Sigma}{}^+\Sigma^++\overline{\Sigma}{}^-\Sigma^-+\overline{\Sigma}{}^0\Sigma+\overline{\Lambda}\Lambda)]D^{0\prime}+\text{h.c.}\ ,\end{aligned} \tag{11}$$

$$
\begin{aligned}
H_{\mathfrak{K}_0}{}' = g'/\sqrt{2}\Big[(\bar{p}\bar{n})&\begin{pmatrix} \pi^0 & \sqrt{2}\pi^+ \\ \sqrt{2}\pi^- & -\pi^0 \end{pmatrix}\begin{pmatrix} p \\ n \end{pmatrix} \\
&+(\bar{\Xi}^0\bar{\Xi}^-)\begin{pmatrix} \pi^0 & \sqrt{2}\pi^+ \\ \sqrt{2}\pi^- & -\pi^0 \end{pmatrix}\begin{pmatrix} \Xi^0 \\ \Xi^- \end{pmatrix} \\
&+(\bar{\boldsymbol{\Sigma}}\times\boldsymbol{\Sigma}\cdot\boldsymbol{\pi}+\bar{\boldsymbol{\Sigma}}\cdot\boldsymbol{\pi}\cdot\Lambda+\bar{\Lambda}\cdot\boldsymbol{\pi}\boldsymbol{\Sigma})\Big] \\
&+g'/\sqrt{2}\,[(\bar{P}P+\bar{\Xi}^-\Xi^-+\bar{n}n+\bar{\Xi}^0\Xi^0) \\

\end{aligned}
\tag{12}
$$

It is seen in (9)-(12) that charge independence[7] in the ordinary isospin representation is valid in the strong interactions (3)-(4), except in the processes involving D^0-mesons. From (9)-(10) we see that the K-kaons couple only nucleons with the Σ and Λ-particles, while the L-kaons couple only the Ξ-particles with the Σ and Λ-particles. In (11) $D^{\pm}$-mesons are of strangeness-two mesons for the nucleon-Ξ coupling, but are of strangeness-zero mesons for the $\Xi-\Lambda(\Sigma)$ coupling. In (12), the pion-baryon interactions are given just as we expect.

Excitation Functions for Alpha-particle Reactions on Fe^{56} and Fe^{57}

By Shigeo TANAKA, Michiaki FURUKAWA, Shiro IWATA*, Masuo, YAGI**
Hiroshi AMANO*** and Takashi MIKUMO
Institute for Nuclear Study, University of Tokyo
Tanashi-Machi, Tokyo

(Received July 1, 1960)

Excitation functions for the (α, pn), $(\alpha, p2n)$, $(\alpha, 3n)$ and $(\alpha, \alpha pn)$ reactions on Fe^{56} and the $(\alpha, \alpha p)$ reaction on Fe^{57} were measured by the activation method using a stacked-foil technique, the alpha-particle energies ranging from 17 to 40 MeV. The measured excitation functions for the alpha-particle reactions on Fe^{56} (present work) were compared with those for the proton reactions on Co^{59} (Sharp et al.); the compound nucleus Ni^{60} being the same for two cases. The comparison gives a test of the validity of compound nucleus theory. The ratios of corresponding cross sections seem to agree well with the theory (except in the case of resulting Co^{57}). However, it may be seen that the two curves corresponding to the same residual nucleus in each case do not entirly coincide in energy.

§1. Introduction

Ghoshal tested the applicability of Bohr's[1] compound nucleus hypothesis of nuclear reaction to the medium-energy region[2]. According to Bohr's hypothesis, we may write $\sigma(a,b)/\sigma(a,b')=\sigma(a',b)/\sigma(a',b')$ provided that the excitation energy of the compound nucleus is the same. In Ghoshal's experiment, the compound nucleus, Zn^{64}, was formed both by proton bombardment of Cu^{63} and by alpha-particle bombardment of Ni^{60}. The relation

$$\sigma(p,\ n):\sigma(p,\ 2n):\sigma(p,\ pn)$$
$$=\sigma(\alpha,\ n):\sigma(\alpha,\ 2n):\sigma(\alpha,\ pn)$$

was observed to hold when 7 MeV was added to the proton energy to match the excitation energy of the compound nucleus. The validity of Bohr's hypothesis was also confirmed to the reactions in heavy elements by John.[3] He compared the excitation functions for $Pb^{206}(\alpha, xn)$ with those for $Bi^{209}(p, xn)$, where $x=2$, 3 or 4. The cross sections of the alpha-particle and proton reactions were in good agreement with each other provided that the proton energy was shifted by adding 11.9 MeV.

It has been pointed out, however, by Eastman, Isenor, Bainbridge and Duckworth[4] and also by John[3] that the energy shift required to fit the experiment to the compound nucleus theory is not exactly equal to the value derived from mass measurement. This discrepancy might throw some doubt on the validity of the compound nucleus theory.

The present experiment has been undertaken in order to give a further test of the above considerations. The excitation functions measured here for the (α, pn), $(\alpha, p2n)$, $(\alpha, 3n)$ and $(\alpha, \alpha pn)$ reactions on Fe^{56} are compared with those for the corresponding proton reactions on Co^{59} measured by Sharp, Diamond and Wilkinson.[5]

This experiment is also a part of the present authors' systematic study in which the cross sections of the alpha-particle reactions on medium-weight nuclei at intermediate energies are investigated. The $(\alpha, \alpha p)$ reaction on Fe^{57} is also reported here.

§2. Experimental

The bombardments were performed with the external alpha-particle beam from the 160 cm INSJ variable energy cyclotron by means of a "stacked-foil" technique. The beam was collected in a Faraday cup and the total charge of the beam was measured by a current integrator. A more detailed description of the bombarding system is given in the previous reports.[6-7] In different experiments, the initial alpha-particle energies were 40.2, 32.1 and 32.0 MeV, and certain energy region was overlapped in different runs. The energy dependence of cross sections was measured by using the stacked-foil technique in which target foils were interspaced with aluminum absorbers. The value of the energy loss of alpha-particles in aluminum absorber was taken from the works of Bichsel, Mosley and Aron,[8] Burkig and MacKenzie,[9] and Sternheimer,[10] whereas that in iron target was calculated from the stopping power formula of Bethe et al. using the estimated mean excitation potential ($I=13\ Z$ and $Z=26$).

*** Japan Atomic Energy Research Institute, Tokai-Mura, Ibaragi.

The targets consisted of natural-iron foils (7.7±0.1 mg/cm^2) whose purity was approximately 99.8%.

After the bombardment, the target foil was dissolved in acid and nickel, manganese, cobalt and iron were chemically separated by means of an anion exchange resin.

The disintegration rates of the samples were determined with a calibrated GM counter, a $4\pi\beta$-counter and an (1−3/4 in. dia.×2 in. high, 1−1/2 in. dia.×1 in. high and well type) NaI scintillation counter. The counting procedure is given in detail in the Appendix.

§ 3. Results and Discussion

The absolute cross sections are plotted as a function of alpha-particle energy in Fig. 1, which also includes the energy spread in target foil and the estimated error of the magnitude of cross section for some experimental points. The Fe$^{56}(\alpha, p2n)$Co^{57} and the Fe$^{56}(\alpha, 3n)$Ni^{57} cross section were not calculated below 29 MeV because of the interference of the Fe$^{54}(\alpha, p)$Co^{57} and the Fe$^{54}(\alpha, n)$Ni^{57} reaction, respectively.

The interference above 29 MeV is estimated from the data of Fe^{54} [11] and included as a source of error in the vertical line in Fig. 1.

The comparison between the alpha-particle

Solid line represents the excitation function for each corresponding proton reaction on Co^{59} (Sharp et al.)

reactions on Fe^{56} and the proton reactions on Co^{59} is illustrated in Fig. 2. The compound nucleus produced in both cases is Ni^{60}. According to the compound nucleus theory, the relative yields of these reactions should be the same regardless of target provided that the excitation energy of the compound nucleus is the same. The excitation energy of the compound nucleus is $B_\alpha + 56/60\,E_\alpha$ for the alpha-particle reactions; or, $B_p + 59/60\,E_p$ for the proton reactions. Where B_α and B_p represent the binding energies of an alpha-particle to Ni^{60} and of a proton to Ni^{60}, respectively; E_α and E_p are the kinetic energies of an alpha-particle and of a proton in the laboratory system. The quantities B_α and B_p are deduced from the mass values which have recently been measured with high precision by Quisenberry, Scolman and Nier[12]; $B_\alpha = 6.31$ MeV and $B_p = 9.54$ MeV.

It will be seen in Fig. 2 that the two curves corresponding to the same residual nucleus in each case do not entirely coincide in energy. The difference is about 2 MeV and is in the opposite direction to what appears in both Ghoshal's and John's experiments. The uncertainty in energy may come from the uncertainties in the bombarding energies. The alpha-particle energy is estimated to be accurate to ± 0.5 MeV at 20 MeV; taking into account the uncertainties of incident energy, target thickness and estimated value of energy loss. The present authors have experienced good agreement in series of bombardments. The precision of the alpha-particle energy at 20 MeV is estimated to be ± 0.3 MeV. The proton bombardment was performed by Sharp, Diamond and Wilkinson[5] with the internal scattered beam of the Harvard University 95 in. synchrocyclotron. The available initial proton energies were 73.5 and 100.3 MeV, and it was estimated that the energy at the front of the target stack was accurate to ± 0.6 MeV. The bombardments were also made by them with the 32 MeV proton linac at Berkeley to get good resolution in the low-energy portions of Ni^{57} and Co^{58} excitation functions, and the energy of the incident protons was known to ± 0.2MeV. Hence the uncertainty in energy may amount 1 MeV at $E_{\mathrm{exc}} = 25$ MeV in their experiment and ours. On the other hand, it might be thought that the errors in absolute cross sections also reduce the discrepancy in energy. These two uncertainties are not altogether impossible to eliminate the discrepancy in energy at all. However, it is more likely to see that there is a discrepancy in energy in this comparison. More accurate experiments are required to see exactly whether the discrepancy is significant.

When the proton curve in Fig. 2 is made to shift by subtracting about 2 MeV, the two curves corresponding to the same residual nucleus in each case seem to match quite well (except in the case of producing Co^{57}) both in the shape of excitation function and in the magnitude of cross section. The difference between the value of the cross section for the Fe^{56} $(\alpha, p2n)Co^{57}$ reaction and that for the $Co^{59}(p, p2n)Co^{57}$ reaction should be again checked experimentally.

The excitation function for the $Fe^{57}(\alpha, \alpha p)Mn^{56}$ reaction is shown in Fig. 3.

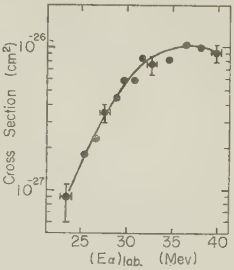

Fig. 3. Excitation function for the reaction $Fe^{57}(\alpha, \alpha p)Mn^{56}$.

Authors' thanks are due to Prof. I. Nonaka and the other members of staff of Low Energy Division in this Institute for their constant interest and encouragement. The help of Messrs. T. Karasawa, A. Suzuki, H. Ogawa, H. Adachi, Y. Miyazawa, and T. Yamada in operating the cyclotron is gratefully acknowledged. The continued assistance of Mr. T. Ando throughout the work is also acknowledged.

Appendix

Counting procedures

Ni^{57}—After Ni^{57} was allowed to decay to Co^{57}, *Ni^{57}* was measured as Co^{57}.

Co^{58}—The 810 KeV γ-ray photopeak was measured with an 1–3/4 in. dia. ×2 in high NaI scintillation counter. The contribution

of Co^{56} was subtracted by comparing the sample with a Co^{56} standard source. The disintegration rate of Co^{58} was obtained by applying the photopeak efficiency to the counting rate. The photopeak efficiency in the present equipment was obtained by calibrating with the various standard sources of known disintegration rates. The disintegration rate was also checked by a $4\pi\beta$-counting assuming the positron emission probability of 15% per total disintegration. Both values agreed each other within 10%.

Co^{57}—The 122 and 137 KeV γ-ray photopeaks were measured in an 1—3/4 in. dia. ×2 in. high well-type NaI scitillation counter. The photopeak efficiency was estimated as 0.85.

Mn^{56}—The disintegration rate was obtained by counting the β-rays with a calibrated GM counter.

Mn^{54}—The 845 KeV γ-ray photopeak was measured with an 1—3/4 in. dia. ×2 in. high NaI scintillation counter. The disintegration rate was obtained by applying photopeak efficiency to the counting rate as in the case of Co^{58}.

"Note added in proof"

After this work, one of the present authors* has studied the alpha-particle reactions on Ni^{60}. He has compared, after Ghoshal's work, the alpha-particle reactions on Ni^{60} with the proton reactions on Cu^{63}. In the comparison all the cross sections on both reactions which have been measured up to date by many authors are included. He has obtained the conclusion that the energy values in the experiments compared might not be so accurate that it seems inadequate to discuss strictly whether the discrepancy in energy is significant.

Multipolarity of γ-ray Absorption in $U^{238}(\gamma, f)$ Reaction produced by $F(p, \alpha\gamma)$ γ rays

By Eiko TAKEKOSHI

Japan Atomic Energy Research Institute Tokai Laboratory

(Received July 4, 1960)

Multipolarity of γ-ray absorption in $U^{238}(\gamma, f)$ reaction, produced by monochromatic γ rays from $F(p, \alpha\gamma)$ reactions, has been investigated by the analysis of the angular distribution of 1018 tracks of fission fragments in uranium-impregnated nuclear emulsions. It can be explained by mixing two sorts of interaction; *electric dipole* ($E1$) and *electric quadrupole* ($E2$). The ratio of $E2$ to $E1$ absorption cross section, denoted by σ_{fq}/σ_{fd}, has been found to be 0.13 ± 0.05. This value is compared with other results with bremsstrahlung. The angular distribution is consistent with those of Baz *et al.*, however, the analysis and interpretation of the results are different from those of Baz *et al.*.

§ 1. Introduction

As mentioned by A. Bohr[1], the nucleus, which is passing over the saddle point and whose excitation energy is not too far above the fission threshold, is "*cold*", since major part of its energy content is bound in potential energy of deformation. The quantum states available to the nucleus at the saddle point of the "*fission channels*" are then widely separated and represent relatively simple types of motion of the nucleus. These channels are expected to form a similar spectrum to that of observed low-energy excitations of the ground state of the nucleus.

This character of the motion of the nucleus at the saddle point gives rise to a number of regularities in the fission phenomena. Thus, fission process passing through a single channel may exhibit a marked anisotropy in the angular distribution of the fragments, depending on the angular momentum quantum numbers of the channel. Moreover, the wide spacing of the channels implies that the fission threshold may depend significantly on the spin-parities of the compound nucleus. Experimental data on these aspects of the fission phenomenon may thus provide valuable information on the structure of fissioning nuclei at a crucial state of the process.

The case of photofission of even-even nuclei presents some extremely simple features, since in this case the compound nucleus is always produced in a (1–) state, when *electric dipole* absorption is assumed. The lowest (1–) fission channel at the saddle point corresponds to a $K=0$ configuration, with the nuclear angular momentum taken up by rotational motion. For photon energies near the fission threshold, the majority of the fissioning nuclei are therefore expected to pass through this particular channel. In this case the angular distribution of the emitted fragments is expected to be mainly of the type expressed by the following form

$$I(\theta)=b\cdot\sin^2\theta\ , \tag{1}$$

where θ is an angle of nuclear symmetry axis from the photon direction and b is a constant.

As the photon energy increases, other channels of (1–) type representing intrinsic nuclear excitations become available. Those channels having $K=1$ give an anisotropy of opposite character to that of the form (1) and in consideration of the two characters a nearly isotropic distribution is expected for the nuclei passing through the saddle point in a state of intrinsic excitation. Thus, the total angular distribution becomes

$$I(\theta)=a+b\cdot\sin^2\theta\ . \tag{2}$$

According to L. Katz *et al.*[2], the ratio b/a was given by the empirical relation $b/a=x/(E_\gamma-z)^y$, where x, y and z were empirically determined constants equal to 40, 2.6 and 4 respectively for U^{238} nucleus. Therefore, the ratio b/a decreases as photon energy increases.

This circumstance provides an explanation of the observed angular anisotropy of the fission fragments. The experimental studies by E. J. Winhold *et al.*[3] and L. Katz *et al.*, with the bremsstrahlung of maximum energies between 6.0 MeV and 20 MeV produced by a linear accelerator and by a betatron, have shown that the angular distribution is expressed by the form (2) and that γ-ray absorption process can be assumed to be $E1$ absorption only. Winhold *et al.* measured intensities of fission fragments which were emitted at 90° and parallel to incident photons, using a scattering chamber in which fission products were caught on aluminium foils, and thus measuring β activities. Katz *et al.* tried to measure ratios of intensities at various angles to that at incident direction, using a fission chamber in which fission pulses from a uranium target were amplified by linear amplifiers and were introduced to a coincidence circuit gated by expander pulses from betatron.

The situation obtained by V. P. Bannik *et al.*[4] and Baz *et al.*[5] with bremsstrahlung of maximum energies, between 6.5 MeV and 26.5 MeV produced by a synchrotron, has been expressed by a different form from the form (2). The angular distribution is then expressed by the following form

$$I(\theta)=a+b\cdot\sin^2\theta+c\cdot\sin^2\theta\cdot\cos^2\theta\ , \qquad (3)$$

and the γ-ray absorption process can be regarded as the mixture of $E1$ and $E2$ characters. Thus, a detailed angular distribution was shown, in which intensities of fission fragments of various angles to that at incident photon direction were measured by means of uranium-impregnated nuclear emulsion; and the ratio of absorption cross section of $E2$ to $E1$ was discussed.

These experiments were carried out with bremsstrahlung. When this bremsstrahlung is in use, these x-rays have a continuous spectrum extending from zero to the maximum energy of electrons which strike a target. The x-ray spectrum, however, may have various forms, even if these maximum energies have the same value. Thus, the experimental results using bremsstrahlung do not seem to contribute to the explanation of the structure of uranium-238 nuclei. The study obtained by using monochromatic γ rays is rather preferable for this study to bremsstrahlung, because the compound nucleus excited by monochromatic γ rays splits into fission fragments while it passes through a few fission channels; and the analysis of the angular distribution is believed to give a clear information on the structure of the deformed nucleus. The angular distribution of the fission fragments in $U^{238}(\gamma, f)$ reaction, produced by $F(p, \alpha\gamma)$ γ rays, $E_\gamma=6.13$ MeV, is very characteristic for an aspect of the γ-ray absorption process near the threshold in $U^{238}(\gamma, f)$ and $U^{238}(\gamma, n)$ U^{237} reaction.

In the present experiment the angular distribution of the fission fragments for $U^{238}(\gamma, n)$ reaction was measured by using uranium-impregnated nuclear emulsions irradiated by $F(p, \alpha\gamma)$ γ rays under a good geometrical condition. This results shows that the γ-ray absorption process is the mixture of $E1$ and $E2$, and the ratio of $E2$ to $E1$, denoted by σ_{fq}/σ_{fd}, is 0.13 ± 0.05. This result is compared with other results with bremsstrahlung and is discussed.

§ 2. Procedure

Natural uranium-impregnated nuclear emulsions were irradiated for about 10 hours under γ rays produced by proton bombardment of a CaF thick target. The proton beam was accelerated up to 2 MeV by Van de Graaff of the J.A.E.R.I., and the intensity of the magnetically analysed beam was 25 μA. Diameters of the CaF thick target and the proton-beam spot was 8 mm and 3 mm respectively. Sakura NR–M1 uranium-impregnated nuclear plates (1.5″×1″, 200 μ thickness) were used. Each plate was arranged in the manner that the 1″ edges was 12 cm apart from the target and the 1.5″ edges parallel to the γ rays, giving glancing incidence.

The uranium-impregnated nuclear plates were made by immersing the Sakura NR–MI nucler plates (Ilford C2 class) into 25 percent uranyl acetate solution in which the ratio of admixture of glycerine is 3 percent. Immersing of the plates was continued to reach saturation. The immersing time was 3 hours at 25°C. When the plates were immersed into the uranyl acetate solution concentrated over 25 percent, the action of development and fixing of the plates was disturbed by crystallization of the uranyl acetate in the nuclear plates.

The developing procedure of the two bath method[6] was chosen as the most suitable method. For the best condition of the second stage in this procedure of the two bath method, it was found that the developing time is 25 minutes at 17°C. At this condition, very sharp tracks of fission fragments and faint tracks of spontaneous α particles from uranium were obtained, which made the scanning of the plates considerably easier. The microphotographs of the representative type of these very sharp tracks and the faint tracks are shown in Fig. 1.

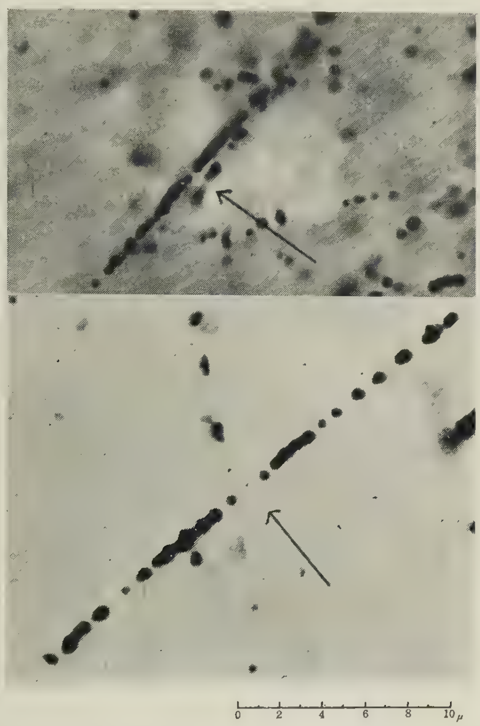

Fig. 1. Microphotographs of typical fission tracks. The arrows show the fission point of U^{238} nucleus.

The very sharp tracks of the fission fragments are dense at the middle and faint at both ends; that is why they are called "*taper track*". The faint tracks of spontaneous α particles from uranium are dotted with black grains in tatters.

The shrinkage factor was obtained by measuring the horizontal and vertical components of the lengths[11] of spontaneous α tracks from uranium in uranium-impregnated nuclear emulsion un-exposed to γ rays. The shrinkage factor was 1.9.

The processed emulsions were scanned using "Tiyoda" and "Nippon Kogaku" microscopes at a magnification of ×1350 and ×1500 respectively. Each depth measurement (mean of three readings) was subject to about $\pm 0.3\,\mu$ standard deviation. Errors in the horizontal projections were $\pm 0.5\,\mu$.

The quantity of the uranium in uranium-impregnated nuclear emulsion was about 0.03 g/cm^3[8].

The total florine γ-ray doses in position of emulsions were about 10^8 quanta/cm^2[9].

Since discrimination between α tracks and fission tracks has ambiguity due to non-uniformity of emulsion sensitivity, it is considered that 1708 fission tracks contain the impurity of spontaneous α tracks from uranium. This impurity was eliminated by using the following method; the uranium-impregnated nuclear plates, un-irradiated by γ rays, were developed intensely in the grade of sharp tracks for α particles. The range distribution of these α tracks and that of fission tracks in these plates are shown in Figs. 2 and 3 respectively.

In the Fig. 2 the peaks at $16\,\mu$ and $19\,\mu$ represent the length of range of α particles from uranium-I and uranium-II+Ac-uranium respectively. From the Figs. 2 and 3, it was pointed out that the fission tracks shorter

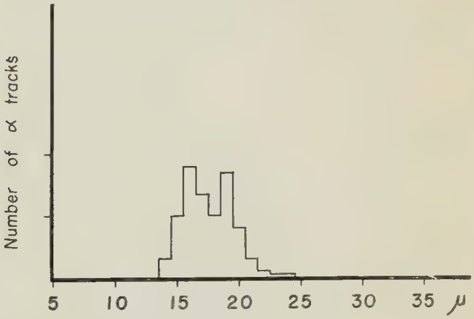

Fig. 2. Range distribution of spontaneous α tracks in uranium-impregnated nuclear plates, un-exposed to γ rays.

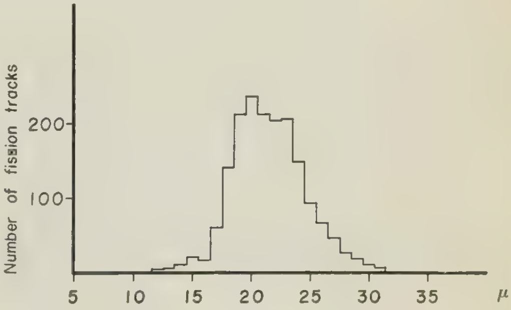

Fig. 3. Range distribution of fission tracks in uranium-impregnated nuclear plates, exposed to γ rays.

than 20 μ may involve the impurity of the spontaneous α tracks. It was very difficult to estimate the fraction of the impurity to fission tracks. However, the difference was not found between the angular distributions for the fission tracks longer than 21 μ and 22 μ.

Thus, by using the angular distribution for the fission tracks longer than 21 μ, the process of $U^{238}(\gamma, f)$ reaction was analyzed. The number of these tracks was 1018.

§ 3. Results and Discussions

The angular distribution for the fission tracks longer than 21 μ is shown in Fig. 4 and that longer than 22 μ is shown in Fig. 5.

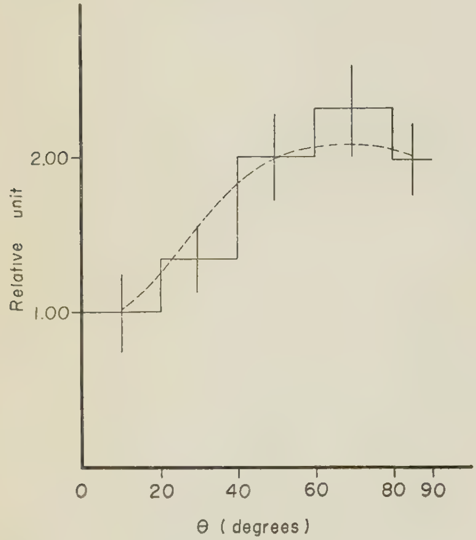

Fig. 4. Angular distribution for the fission tracks longer than 21 μ. Dotted line curve was calculated by least square fitting; this is expressed by

$$I(\theta)=1+(1.02\pm0.49)\sin^2\theta +(1.63\pm0.52)\sin^2\theta\cdot\cos^2\theta\,.$$

The experimental data of the angular distribution were taken at 20° interval. The value at θ° is expressed by a relative number of tracks between θ°−10° and θ°+10° to that between 0° and 20°. Correction for the escape of tracks from the emulsion surface was done. In Figs. 4 and 5 the vertical lines indicate only the statistical standard deviations.

For the purpose of observation of the systematic error in angular distribution measurement, the angular distribution of the tracks from spontaneous α decay of uranium was measured by using uranium-impregnated nuclear emulsions (not exposed to γ rays). This is shown in Fig. 6.

Since this proved to be flat with respect to the angle, as was expected, it was understood that there was no systematic error in the present angular distribution measurement of fission tracks. After the examination of control plates placed outside the γ rays, the

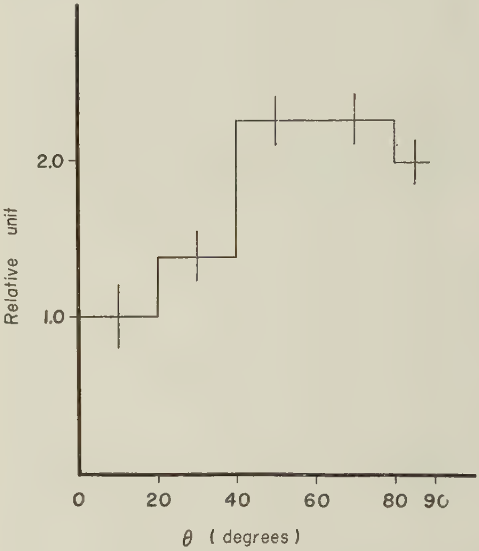

Fig. 5. Angular distribution for the fission tracks longer than 22 μ

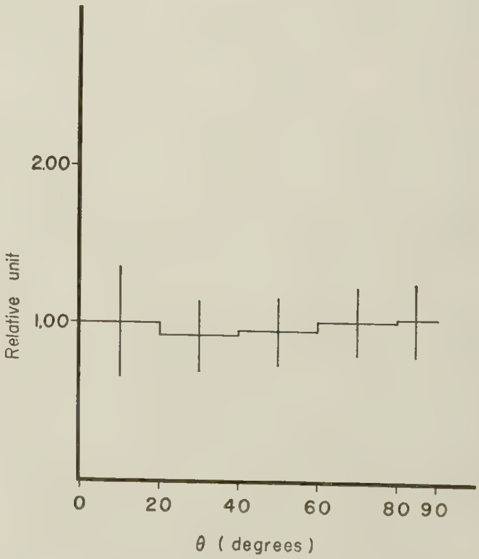

Fig. 6. Angular distribution of spontaneous α tracks in uranium-impregnated nuclear plates (not exposed to γ rays).

fission tracks due to the background neutrons were confirmed to be negligible.

As mentioned in § **1**. there were two experimental results for photon absorption resulting in nuclear fission. In the first, as done by Winhold *et al.* and Katz *et al.*, the photon absorption was assumed to be *electric dipole* character ($E1$). In the second, as done by Bannik *et al.* and Baz *et al.*, the *electric quadrupole* absorption was added to $E1$.

Winhold and Halpern measured only the anisotropy of the angular distribution. They measured only at two angle points, so their results were interpreted by $E1$ absorption alone.

Katz *et al.* measured detailed angular distribution and found that in all cases the data were represented by the form (2). Their results show that the photon absorption is due to $E1$ only and $E2$ process is negligibly small.

Baz *et al.* studied detailed angular distributions by using uranium-impregnated nuclear emulsions, and the change of the angular distribution with energy $E_{\gamma\,\mathrm{max}}$ was studied. In their experimental results, it was pointed out that $E1$ should be mixed with $E2$ and that the ratio $E2$ to $E1$ depend on the energy $E_{\gamma\,\mathrm{max}}$.

In the present experiment the detailed angular distribution was studied by using uranium-impregnated nuclear emulsions irradiated by monochromatic γ ray from $F(p, \alpha\gamma)$ reaction. As shown in Figs. 4 and 5, it was considered that $E2$ must be added to $E1$, since the angular distribution curve at the neighborhood of 90° descend lower than the value given by $I(\theta)=a+b\cdot\sin^2\theta$. Thus, these angular distribution must be described by

$$I(\theta)+I(\pi-\theta)=a+b\sin^2\theta+c\sin^2\theta\cdot\cos^2\theta\,, \tag{4}$$

where the summation $I(\theta)+I(\pi-\theta)$ is done, since it is impossible to distinguish either one of the fissions tracks from the other.

From the present experimental data, the coefficients " a ", " b " and " c " in the form (4) were calculated by using the least mean square fitting. It was given by the following expression;

$$I(\theta)=1+(1.01\pm0.49)\sin^2\theta+(1.63\pm0.52)\sin^2\theta\cdot\cos^2\theta\,.$$

The present results were compared with those of Baz *et al.* and others[2),3)] for (**i**) the graph of angular distribution, (**ii**) the ratios of b/a, c/a and c/b and (**iii**) the b/a ratio calculated in the assumption of the angular dependence to be of the form $I(\theta)=a+b\cdot\sin^2\theta$.

(**i**) The comparison of the angular distributions produced by $F(p, \alpha\gamma)$ γ rays and the bremsstrahlung is shown in Fig. 7. (***a***), (***b***) and (***d***) show the angular distributions produced by bremsstrahlung at $E_{\gamma\,\mathrm{max}}=9.4$ MeV, 8 MeV and 6.5 MeV, respectively, obtained by

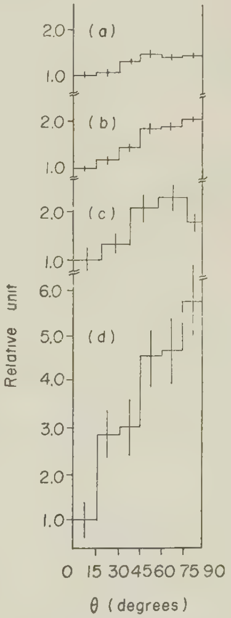

Fig. 7. Comparison of the angular distributions. (***a***), (***b***) and (***d***) show the results obtained by Baz *et al.*, and (***c***) shows the results obtained in the present experiment.

× results obtained by Baz *et al.*

○ results obtained in the present experiment.

These b/a ratios were calculated in the assumption of the angular dependence to be of the form $I(\theta)=a+b\cdot\sin^2\theta$. The discrepancy at each value of the same photon maximum energy may, possibly, be due to difference in the spectrum form of bremsstrahlung and monochromatic γ rays.

§4. Interpretation and Conclusions

Baz *et al.* derived, from the angular distribution of the form (4), the ratio of the $E2$ absorption process to the $E1$ absorption process in the following way. The coefficients "a", "b" and "c" were considered to express isotropic part of angular distribution and the anisotropic parts related to the $E1$ and $E2$ absorption cross section, respectively. Then expressing $E1$ and $E2$ photon absorption cross section in nuclear fission by σ_{fa} and σ_{fq}, respectively, the value of σ_{fq}/σ_{fa} was given by

$$\sigma_{fq}/\sigma_{fa}=c/5b\ . \qquad (5)$$

The values of σ_{fq}/σ_{fa} for each $E_{\gamma\max}$ are also given in Table II, where it is seen that the values increase with increase of E_γ.

Table II. Comparison with the values σ_{fq}/σ_{fa} obtained from the form (5) for data by Baz *et al.* and in the present experiment.

$E\gamma$	σ_{fq}/σ_{fa}	Reference
$E\gamma_{\mathrm{Max}}=6.5$ MeV	0.15 ± 0.14	A. I. Baz *et al.*
$E\gamma_{\mathrm{Max}}=8.0$ MeV	0.11 ± 0.07	〃
$E\gamma_{\mathrm{Max}}=9.4$ MeV	0.49 ± 0.14	〃
F(p, $\alpha\gamma$) γ rays $E\gamma=6.13$ MeV	0.32 ± 0.05	Present Experiment

However, different possibilities are suggested by A. Sugie[10]. According to him, the isotropic part "a" must also be due to either $E1$ or $E2$ or both. The existence of the isotropic part means that the states with K-value one are involved in addition to those with $K=0$. If $K=1$ states are mixed to $K=0$ states in both $E1$ and $E2$ process, we cannot determine the ratios uniquely from the experimentally obtained ratios b/a and c/a. However, we can calculate the ratio σ_{fq}/σ_{fa} by putting several plausible assumptions about the ratio of the processes with different K-values. Then we find that the energy dependence of the ratio σ_{fq}/σ_{fa} changes as follows.

(**i**) As the simplest case; assuming only $K=0$ and $K=1$ contribute to $E1$ and only $K=0$ to $E2$, the value of σ_{fq}/σ_{fa} is given by

$$\sigma_{fq}/\sigma_{fa}=2/15\cdot c/a/(1+2/3\cdot b/a)\ . \qquad (6)$$

The values, calculated from the ratios of "*c*/*a*" and "*b*/*a*" in Table I by using form (6), are represented in Table III; where the values of σ_{fq}/σ_{fa} is nearly constant, when the maximum energies of bremsstrahlung increase.

Table III. Comparison with the values σ_{fq}/σ_{fa} obtained from the form (6) for data by Baz *et al.* and in the present experiment.

E_γ	σ_{fq}/σ_{fa}	Reference
$E_{\gamma\,\mathrm{Max}}=6.5$ MeV	0.11 ± 0.26	A. I. Baz *et al.*
$E_{\gamma\,\mathrm{Max}}=8.0$ MeV	0.05 ± 0.03	〃
$E_{\gamma\,\mathrm{Max}}=9.4$ MeV	0.13 ± 0.03	〃
$F(p, \alpha\gamma)$ γ rays		
$E_\gamma=6.13$ MeV	0.13 ± 0.05	Present Experiment

(**ii**) However, if it is assumed that both $K=0$ and $K=1$ contribute to both $E1$ and $E2$ and that the mixing ratio of $K=1$ to $K=0$ be the same for both $E1$ and $E2$, the ratios of $E2$ to $E1$ increase with increase of photon energy.

(**iii**) Moreover, when an assumption of $K=2$ for $E2$ is added with the same ratio as that of $K=1$ to $K=0$, the similar trend to the above case exist.

(**iv**) However, in case that both $K=0$ and $K=1$ contribute to $E1$ and $K=0$ and $K=2$ to $E2$ and the both mixing ratios are the same, the values σ_{fq}/σ_{fa} are shown to be constant in the region.

Thus, it is found that any unique answer is not drawn as the above discussion, since the values of σ_{fq}/σ_{fa} depend on K-value combination.

As the case stands, however, the author considered that the suggestion given by A. Sugie is reasonable. Therefore, the form (6) is taken for the calculation of the value σ_{fq}/σ_{fa}. As shown in Table III, it is 0.13 ± 0.05. This value, being able to be considered to correspond to that for bremsstrahlung of maximum energy between 8.0 and 9.4 MeV, is consistent with that of Baz *et al.*, after re-calculation by form (6).

The above mentioned consideration must be examined from another point of view, since any unique answer is not drawn from the angular distribution analysis. In other words the competition between $U^{238}(\gamma, f)$ and $U^{238}(\gamma, n)U^{237}$ reaction must be considered, because the energy is somewhat above the threshold of $U^{238}(\gamma, n)U^{237}$ reaction. The relative probability of $U^{238}(\gamma, f)$ and $U^{238}(\gamma, n)$ reaction was studied by Duffield and Huizenga[11] and Gindler *et al.*[12], using radiochemical techniques. They found that the photofission branching ratio, which may be regarded as roughly constant in the region of $E_{\gamma\,\max}=8$ to 11 MeV, was 0.2 for U^{238}. Also Lazareva *et al.*[13] used neutron and fission-counting techniques in order to obtain fission branching ratio. They obtained a value of 0.24 for U^{238}, roughly constant in the region from $E_{\gamma\,\max}=6.5$ MeV to 11 MeV. Thus, it is necessary to consider the photon absorption leading to $U^{238}(\gamma, n)$ reaction near the threshold ($E_\gamma=5.97$ MeV).

The following situation was presented by Baz and Smorodinsky[14]. The $E1$ absorption process leads to $U^{238}(\gamma, n)$ as well as $U^{238}(\gamma, f)$, but the $E2$ absorption process leads only to $U^{238}(\gamma, f)$, not to (γ, n). Then, as the energy becomes higher than the (γ, n) threshold, (γ, f) reaction through the $E1$ process will decrease due to the competition with the (γ, n) reaction, but the (γ, f) reaction through the $E2$ process will not. Thus the ratio σ_{fq}/σ_{fa} increases with increase of photon energy.

However, a different possibility is pointed out by A. Sugie. The photon absorption leading to the $U^{238}(\gamma, n)$ reaction near the threshold is determined mainly by spin-parties of lowlying levels, in U^{237} nucleus disintegrated from $U^{238}(\gamma, n)U^{237}$, since the ground state of U^{238} is 0^+ and neutrons from the $U^{238}(\gamma, n)$ reaction near the threshold may be S-wave. If the ground state of U^{237} is $1/2-$, as suggested by J. O. Rasmussen *et al.*[15] presence of a competing (γ, n) reaction in $E1$ should bring increase of the value of σ_{fq}/σ_{fa} with increase of photon energy. However, if the ground state of U^{237} is $1/2+$, as represented by B. N. Mottelson and S. G. Nilsson[16], the S-wave neutrons of $U^{238}(\gamma, n)$ reaction near the threshold, in case of $E1$ in $U^{238}(\gamma, n)$ reaction, should decay to the levels of excited states of U^{237}. If, in the excited states of U^{237}, the positive parity levels lie close to negative parity levels, the photon absorption of $U^{238}(\gamma, n)$ might be, possibly, given by both $E1$ and $E2$. Thus, without the knowledge of the spin-parities of the levels of U^{237}, both conclusions, σ_{fq}/σ_{fd} is constans or increases with energy, are permissible.

In conclusion, it is not firmly determined whether the ratio of σ_{fq}/σ_{fd} derived from the analysis of angular distribution is constant or increases with increase of photon energy and whether proper value of mixing ratio of $E2$ to $E1$ is found or not, even if the competition between $U^{238}(\gamma, n)$ and $U^{238}(\gamma, f)$ reaction is considered. The author can draw no definite conclusion, since the spin-parities of ground state and excited states of U^{237} are not unambiguously assigned. However, when the spin-parities of levels for U^{237} nucleus is assigned, the aspect of the ratio σ_{fq}/σ_{fd} in $U^{238}(\gamma, f)$ may be proposed from the competition between $U^{238}(\gamma, f)$ and $U^{238}(\gamma, n)$ reactions. Then, an important clue may be given for the levels at the saddle point of the fission, especially for the levels having $K=1$ and positive parity, through the angular distribution analysis.

Acknowledgements

The author wishes to thank Mr. T. Momota and the member of the laboratory for helpful advices. Her thanks are also expressed to Mr. A. Sugie and Mr. K. Moriguchi for valuable theoretical discussion, to Mr. T. Nakajima for chemical analysis and to Miss H. Ishiwa and Miss H. Sasaki for scanning many plates and for numerical calculations.

Search for Weak Gamma-Rays in the Positron Decay of Mn^{51}

Masao NOZAWA*, Hisashi YAMAMOTO and Yasukazu YOSHIZAWA
Department of Physics, Faculty of Science, Osaka University, Osaka
and Yujiro KOH
Department of Physics, Faculty of Science, Osaka City University, Osaka

(Received July 20, 1960)

Weak gamma-rays following the decay of Mn^{51} were investigated by a NaI(T1) scintillation spectrometer. To eliminate the effect of the strong annihilation gamma-ray, a new method was used. Gamma-rays of 0.74 and 1.17 MeV were found and these intensities were 0.4 ± 0.2 and 0.2 ± 0.1 percent of the positrons, respectively. The half-life of Mn^{51} was determined as 44 ± 1 min.

§ 1. Introduction

Mn^{51} having half-life of 44 min decays to Cr^{51} by the emission of 2.16 MeV positrons[1]. No gamma-ray has been found in this decay[2][3]. On the other hand, the investigations of the reaction V^{51} (p, n) Cr^{51} indicated the excited states of Cr^{51} to be 0.74, 1.42 and 1.53 MeV, but the spins and parities of these levels have not been known. The spin and parity of the ground state of Cr^{51} are 7/2−, *i.e.* $(f_{7/2})^{-1}$ in the shell model and those of Mn^{51} are estimated to be 5/2− or 7/2−, *i.e.* $(f_{7/2})^{-3}{}_{J=5/2 \text{ or } 7/2}$. Therefore, if the spins and parities of the excited states of Cr^{51} are 3/2, 5/2, 7/2, or 9/2−, the beta transition from Mn^{51} to those levels may be allowed. Then weak gamma-rays from such a excited state can be found, when log $ft=5\sim7$.

In the case of the investigation of Mn^{52m} (21 min)[4] the weak gamma-ray of about 0.74 MeV with a long half-life was found in the scintillation spectra, and it is estimated to belong to the decay of Mn^{51}. The strong gamma-ray and the annihilation radiation of Mn^{52m} disturbed to detect weak gamma-rays of Mn^{51}. Hence we bombarded the chromium target by low energy deuterons of about 6 MeV which do not produce Mn^{52m} by the $(d, 2n)$ reaction[4]. As the strong annihilation gamma-ray of Mn^{51} and its high energy tail due to the annihilation in flight and the bremsstrahlung of the positrons disturbed the measurement of weak gamma-rays, we devised a new method which decreases above mentioned effect of the annihilation gamma-ray.

In § 2 this method will be introduced. The application of this method to Mn^{51} and the result will be discussed in § 3.

§ 2. A Method for Elimination of the Annihilation Gamma-Ray.

The annihilation radiation often disturbs the NaI scintillation spectrometer measurement for weak gamma-rays, especially, near and lower than 0.5 MeV gamma-rays. If the effect of this radiation is removed, weak gamma-rays, can be easily measured. For this purpose coincidence methods are commonly used. But they are not practical for very weak

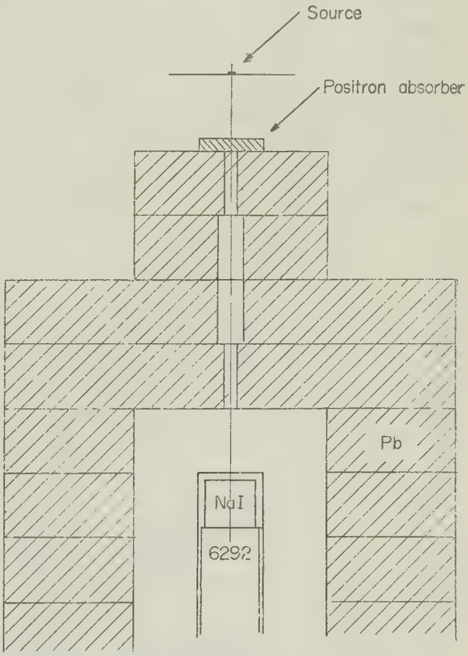

Fig. 1. Schematic diagram of the experimental arrangement for elimination of the annihilation gamma-ray.

* Now at Japan Atomic Energy Research Institute, Tokai, Ibaraki, Japan.

gamma-rays.

In our experiment a new method was adopted. Such thin material as the beta-ray source of no self-absorption must be used for gamma-ray source, in order to decrease the annihilation of positrons near the source. A $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI scintillation probe was shielded by the lead which has a collimation system as shown in Fig. 1. A plastic plate used as the absorber for positrons was put between the lead collimater and the source. The solid angle for the gamma-ray is denoted by ω_γ, that of the effective area of the plastic plate by ω_+ and that for the annihilation radiation converted in the plastic plate by ω_a. Counting rates for the gamma-ray and the annihilation radiation are $N\delta_\gamma\omega_\gamma\epsilon_\gamma$ and $N\delta_+\omega_+\omega_a\epsilon_a$, respectively, where N is the disintegration rate and δ_γ, δ_+, ϵ_γ, and ϵ_a are the branching ratios and the efficiencies of the scintillation counter. In the present experiment ω_γ, ω_a and $\omega_+ < 10^{-2}$. Then the counting rate for the annihilation radiation can be remarkably decreased.

For preliminary experiments Na^{22} deposited on thin mylar film was used. Fig. 2 shows the pulse height spectra for different conditions. The effect of this method can be seen by the comparison with 1.28 MeV gamma-ray. The annihilation gamma-ray was decreased to 10~30 percent. In order to take away the annihilation in air, the source was placed in vacuum chamber, but its effect was not so large.

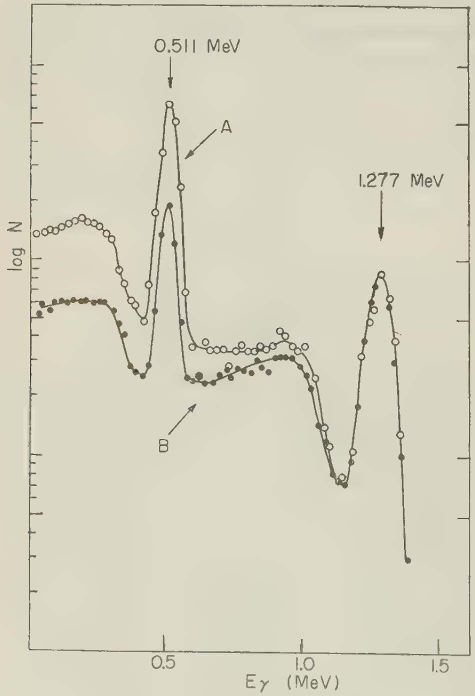

Fig. 2. Scintillation spectra of Na^{22}. Curve A shows spectrum using a gamma-ray source in a thick plastic vessel, and Curve B collimated spectrum with a plastic positron absorber using the thin source (the condition shown in Fig. 1).

The annihilation in the neighbourhood of the source is so small for high energy positrons that this method is more effective than low energy positions. The strong source more than 0.1 mc is necessary, because the small solid angle must be used. A typical case is shown in the investigation of Mn^{52m}4).

§ 3. Experimental Procedure and Result

Chromium foils of about 10 mg/cm^2 thick were bombarded by 6 MeV deuterons of Osaka University cyclotron degraded by aluminum absorber. Target foils were used without

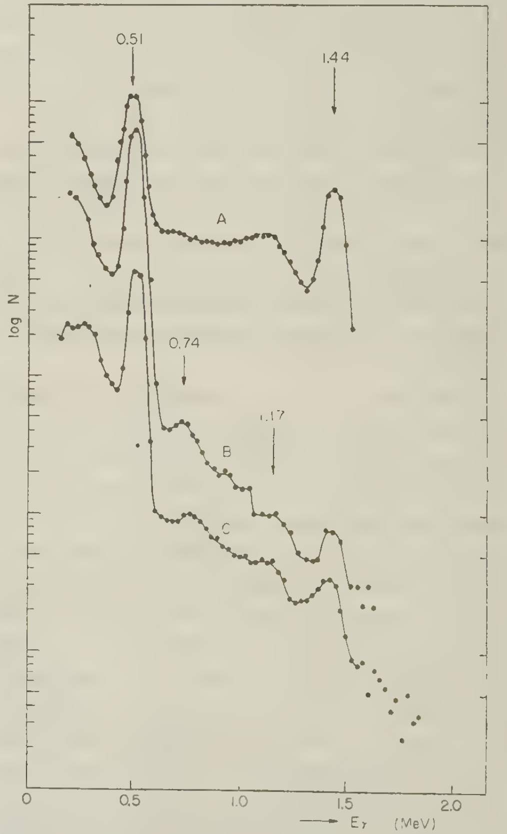

Fig. 3. Scintillation spectra of Mn^{51}. Curve A is the usual gamma-ray spectrum of the source bombarded by 11.4 MeV deuterons, Curve B that by 6 MeV deuterons, and Curve C the spectrum by the new method of the source by 6 MeV deuterons.

chemical process for the gamma-ray sources. The gamma-ray was measured in the worse condition than that as shown in Fig. 1, because the strong enough source could not get. Curve *A* in Fig. 3 shows an usual gamma-ray spectrum from the foil bombarded by 11.4 MeV deuterons. There were the strong 1.435 MeV and the annihilation gamma-rays of Mn^{52m}. Curve *B* is also the usual spectrum from the foil bombarded by 6 MeV deuterons. The spectrum using the new method is shown by Curve *C*. To determine the intensity of positrons, during the measurement of the decay of the spectrum, the source foil was placed between plastic plates. In this arrangement most of positrons are expected to annihilate at the plastic plates.

New gamma-rays of 0.74 and 1.17 MeV were found. A gamma-ray of about 1.4 MeV was estimated to be that of Mn^{52m}, though it is curious that Mn^{52m} was produced at lower energy than (*d*, 2*n*) threshould as Kafaras, *et al.*[5] pointed out. To confirm whether these gamma-rays belong to Mn^{51}, the decay curves are plotted as indicated in Fig. 4. The half-life of Mn^{51} was determined as 44±1 min from these curves. The relative intensities of weak gamma-rays were determined by comparison with the annihilation radiation. Estimated intensities are 0.4±0.2 and 0.2±0.1 percent of the positrons for 0.74 and 1.17 MeV gamma-rays, respectively.

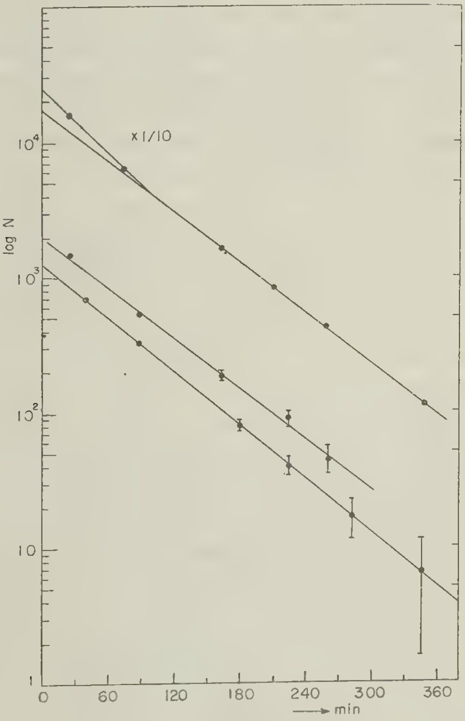

Fig. 4. Decay curves of gamma-ray peak. *A*, *B* and *C* shows annihilation, 0.74 and 1.17 MeV gamma-rays, respectively.

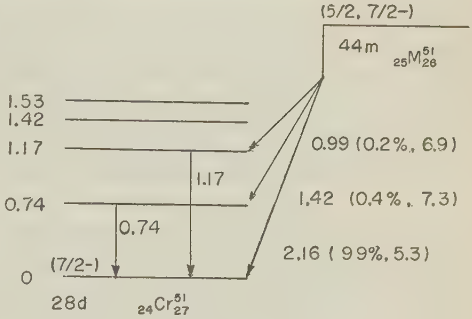

Fig. 5. Decay scheme of Mn^{51}.

The decay scheme is shown in Fig. 5. *EC*/β^+ and log *ft* for the ground state transition are 0.03 and 5.2 from Zweifel[6], Brysk and Rose[7] and Feenberg and Trigg[8]. From these intensities log *ft* are 7.3 and 6.9 for beta-decays to 0.74 MeV and 1.17 MeV levels. These values are large compared with 5.2 for the ground state transition. There is no such a a large log *ft* value except Ca^{47} in the $f_{7/2}$ shell region. The spin and parity of Mn^{51} are 5/2− or 7/2−, *i.e.*, $(f_{7/2})^{-3}{}_{J=5/2 \text{ or } 7/2}$. Then 0.75 and 1.17 MeV levels of Cr^{51} is not expected to have a single particle excited state such as $f_{5/2}$, but to have to more complex configuration. Because there is no even parity configuration and beta transition to these levels cannot be first forbidden.

(Received July 20, 1960)

Excited levels of Cr^{52} were studied by investigating the decays of Mn^{52}(5.7 days) and Mn^{52m}(21 min), produced by $Cr^{52}(d, 2n)Mn^{52,52m}$. By means of a two-directional focusing beta-ray spectrometer, NaI(TI) scintillation spectrometers and a 20-channel pulse height analyzer, following results were obtained: (1) Energies of the main three gamma-rays from Mn^{52} are 746.8±0.2, 938.1±0.4 and 1434.7±0.8 keV. (2) The maximum energies of the positrons from Mn^{52} and Mn^{52m} are 0.572±0.006 and 2.61±0.03 MeV, respectively. (3) The spins and parities of the levels of 3120, 2373 and 1435 keV were determined to be 6+, 4+ and 2+, from measurements of conversion electrons and angular correlations. (4) Several weak gamma-rays were found, which could be inferred to belong to these decays. (5) The half-life of Mn^{52m} is 21±1 min. Its branching ratio $IT/(\beta^+ + EC)$ was determined as 2±1 percent. (6) The energy of isomeric transition is 0.383±0.003 MeV, which was decided as $E4$ from $K/L+M$ and the transition probability.

§1. Introduction

From many investigations[1),2)] it has been well established that Mn^{52} decays with the half-life of 5.7 days through the emission of the positron of 0.58 MeV to a excited level of Cr^{52}, which emits gamma-rays of 0.73, 0.94 and 1.45 MeV in turn. Besides, a isomeric state Mn^{52m} with the half-life of 21 min has been found which decays by the emission of the 2.6 MeV positron to the 1.45 MeV level of Cr^{52}, and in small fraction through the isomeric transition of the 0.39 MeV gamma-ray to Mn^{52}. The values of log *ft* for the positron emission from Mn^{52} and that from Mn^{52m} are 5.3 and 5.6, respectively, and both can be regarded as the allowed transitions. V^{52}(3.8 min) also decays to the 1.45 MeV level of Cr^{52} through the negatron emission. This decay has, however, not yet been reported in detail.

Mazari, Buechner and Sperduto[3)] measured exactly the energy spectra in the reactions $Cr^{52}(p, p')Cr^{52*}$ and $Mn^{55}(p, \alpha)Cr^{52*}$, and found many levels which had not yet been seen in the decays from Mn^{52} and Mn^{52m}. New levels of 2.648, 2.767, 2.965 and 3.161 MeV are shown in Fig. 1.

By Seaborg, *et al.*[2)], the 3.161 MeV level was assigned to be identical as the 3.13 MeV level[3)] in the decay of Mn^{52}. The small difference of energy between them cannot, however, be negligible. According to the K. Way, *et al.*[1)], it is concluded that the three main gamma de-excitation of Cr^{52} are quadrupole transitions and the spins of the concerned levels are 6, 4, 2 and 0. Then the spin of Mn^{52m}, which decays to the 1.45 MeV level, will be 2 or 3. If the 1.45 MeV level is assumed to have the

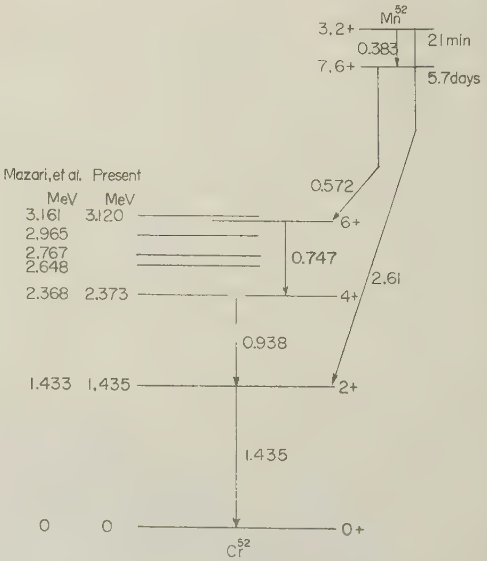

Fig. 1. The decay scheme of Mn^{52} and Mn^{52m}.

---

* Now at Japan Atomic Energy Research Institute, Tokai, Ibaraki, Japan.

even parity according to the systematics of even-even nuclei, Mn^{52m} will have the same parity. Similarly, the spin and parity of Mn^{52} is either 6+ or 7+ from the selection rule of beta-decay. This spin has been also measured by the paramagnetic resonance method[4]. These results are also supported from the conclusion of Huiskamp[5], that the spins and parities of the above-mentioned levels are 6+, 4+, 2+ and 0+, derived from the measurement of gamma-ray directional and polarization angular distributions at low temperature. We have no information concerning spins of new levels found by Mazari, *et al.*, but can infer that they have low spins as they are levels resulting from excitation by the low energy protons. Therefore, a detection of unknown weak gamma-rays between these levels may be possible in the decay of Mn^{52m} rather than Mn^{52}. And it is questionable to consider that the 3.161 MeV level found by Mazari, *et al.* and the 3.13 MeV level in the decay of Mn^{52} are the identical, as they suggested[3].

In this paper, the following results are reported: (1) The energies of three main gamma-rays from Mn^{52} were precisely measured by means of the magnetic beta-ray spectrometer. It was tried to clarify the above mentioned problem from these gamma-ray energies. (2) By measuring the relative total conversion ratios of the three main gamma-rays and those angular correlations, the spins and parities of the concerned levels were re-examined. (3) Unknown weak gamma-rays from Mn^{52} and higher spin levels were looked for. (4) The energy of main gamma-ray from Mn^{52m} was measured, and it was ascertained that it comes from the first excited level of Cr^{52} and is coincident with the annihilation gamma-ray. (5) New weak gamma-rays from Mn^{52m}, especially, the expected from the results of Mazari, *et al.*, were searched. Several weak gamma-rays were found. (6) Beta-ray spectra of Mn^{52} and Mn^{52m} were measured by the beta-ray spectrometer and analyzed. (7) For the isomeric transition of Mn^{52m}, $K/L+M$ and the half-life were measured by the beta-ray spectrometer, and the energy and the intensity of the gamma-ray by the scintillation spectrometer.

Bombarding the natural chromium by 11.4 MeV deuterons of a cyclotron in Osaka University, Mn^{52} and Mn^{52m} were obtained. The cross section of this reaction was reported by Irvin, *et al.*[6].

§ 2. Source Preparation

For the production of Mn^{52} and Mn^{52m} natural metalic chromium was bombarded by the 11.4 MeV deuteron beam of the cyclotron in Osaka University[7], of which the maximum values of beam currents were about 100μA for the internal target and about 50μA for the external. However, the current was limited to 30～50μA and 15～25μA, respectively.

2.1 Mn^{52}

The internal target was mainly used. Target material was natural chromium metal of 100～300 micron thickness electroplated on a copper plate of 1 mm thickness, which was set with ordinary solder to a water-cooled copper pipe of 25 mm diameter.

Impurities in chromium were lower than the spectroscopical limit, except a trace of iron. Considerable products with half-life longer than 5 days are due to $Cr^{50}(d, p)Cr^{51}$ and $Cr^{50}(d, \alpha)V^{48}$ other than $Cr^{52}(d, 2n)Mn^{52}$. The most serious problem in the chemical separation was the removal of V^{48} (16 days). The energies of gamma-rays from V^{48} are 0.99, 1.04 and 1.33 MeV, thus V^{48} and Mn^{52} can be hardly separated by the scintillation spectrometer. Really, the admixture of V^{48} in Mn^{52} brought the ambiguity for weak gamma-rays, angular correlation measurements, etc. The following radiocolloid method was finally adopted by Otozai, *et al.*[8]. The separated sample was tested by observing the positron spectra of V^{48} and Mn^{52} of which the maximum energies are 693 and 572 keV, respectively, and by measuring the half-life difference in the scintillation spectra: (1) The target is treated with 6 N nitric acid to remove base metal from the electroplated chromium, and the resulted chromium foil is then dissolved in 1 ml of concentrated hydrochloric acid. (2) The solution is diluted to about 10 ml with distilled water and added dropwise to the bromine-saturated 2.5 N caustic soda solution (200 ml reagent solution per 100 mg chromium). (3) To this solution, about 5 mg of ammonium vanadate solution containing 20 mg of vanadate is added. (4) The excess bromine is distilled off completely. (5) The solution is filtered with a 3G5 sintered-glass filter to catch manganese activities as radiocolloid. (6) The colloid caught on the filter is washed five times with 2 ml aliquots of water, and successively eluted five times with 2 ml aliquots of concentrated hydrochrolic acid. (7) The eluted solutions are dried up, and carrier-free manganese activities are finally obtained.

The source for the beta-ray spectrometer was carrier free $MnCl_2$ which was deposited on 0.8 mg/cm^2 myler film with insulin solution. Myler film was coated before hand with thin aluminium. Sources for the scintillation spectrometer were also deposited on myler film and padked in Acrylite vessels of about 1 mm wall thickness. Especially the source for the angular correlation was aqueous solution of $MnCl_2$, sealed in an Acrylite pipe of inner diameter 1 mm and wall thickness 1 mm.

2.2 Mn^{52m}

As its half-life is short, the chemical separation was hardly possible and it was practical that chromium foils were bombarded and used without further treatment. Chromium foils were produced by the method of Irvin, *et al.*[5]. Chromium was electroplated on thin copper plates from aqueous solution of chromic acid. Then plates were annealed in vacuum at aboot 200°C within about 5~8 hours, and copper plates were taken away by HNO_3. In the case of sources of the beta-ray spectrometer, chromium foils of 5~10 mg/cm^2 thickness and 5×30 mm^2 dimension were bombarded by external deuteron beam of ~20 μA for 20~30 min. Sources for the scintillation spectrometer were prepared with smaller current and shorter time. As the foils are thin, the ratio of the (d, n) and (d, p) reaction yields to the $(d, 2n)$ yield is relatively small. Because of short bombardments, long life activities of Mn^{52}, V^{48} and Cr^{51} do not cause trouble. Mn^{51}(44 min) was not also an obstacle to observation as shown in § 4.

§ 3. Instruments

The two-directional focusing beta-ray spectrometer was used for observation of beta-spectra and internal conversion electrons. For observations of the gamma-ray single and coincidence spectra and the γ-γ angular correlation, $1\frac{1}{2}'' \times 1\frac{1}{2}''$ and $3' \times 3'$ NaI(Tl) scintillators mounted on 5819 and 6364 photomultipliers were used.

3.1 *Beta-ray spectrometer*

The spectrometer shown in Fig. 2 is of the mushroom type as reported by Hedgran, Siegbahn and Svartholm[9]. The mean radius of electron path is 40 cm, the weight of the magnet 2.2 ton, the diameter 124 cm and the gap at the mean radius 22 cm.

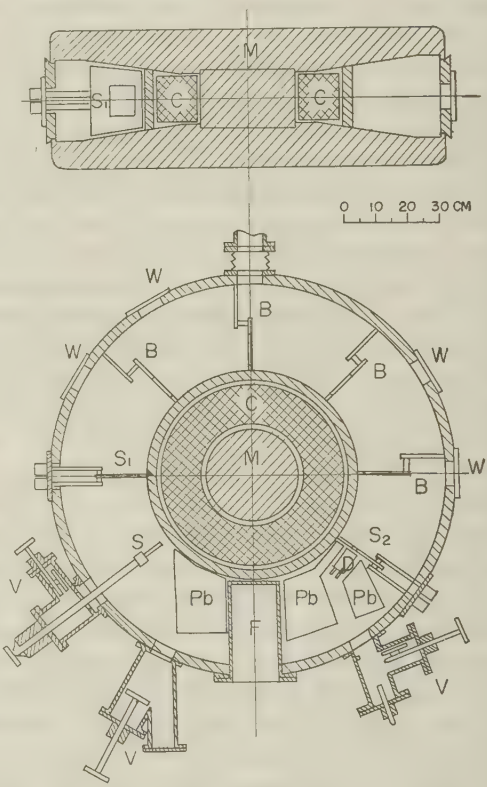

Fig. 2. Two-directional focusing beta-ray spectrometer. M indicates the magnet iron; C, the magnet coil; S, the source; S_1 and S_2, the defining and the exit slits; B, the baffles; D, the detector; V, the valve for the vacuum seals; W, the glass windows; Pb, the lead shield; and F, the chamber for the magnetic field measurement apparatus.

The power source of the magnet is storage batterys of 100 volts and controled by slide resistances. Error due to the hysterisis of the I-B curve can be restricted to less than 0.1 percent, by demagnetization and measurement starting from zero current.

The slit system is made up of two slits and four baffles, as shown in Fig. 2. The defining slit is placed at angular distance 36° from the source, and the exit slit just in front of the GM counter. The slits are adjustable in the directions both radial and vertical. The position of the source is also adjustable in the radial direction. Electrons scattered from inner walls of vacuum chamber are removed by the four aluminium baffles. Upper limit of scattered electrons was about one thousandth. This limit was estimated from counting rates in the energy regions lower than the cut-off energy of the counter window and higher than the maximum energy of various beta sources, e.g. that of Y^{90}.

The GM counter is of the end window type with 3 mg/cm^2 mica. It was seen by measuring the spectrum of Y^{90} that the absorption of the window begins at about 300 keV and its cut-off energy is about 50 keV.

3.2 *Scintillation spectrometer*

Scintillators were the $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI(Tl) covered with lead and graded shields, and their resolutions were 11 percent for 662 keV gamma-ray of Cs^{137}. A $3'' \times 3''$ ascintillator was also used for high energy gamma-rays. Linear amplifiers were of the Higinbotham tybe. Single channel pulse height analyzers of the sweep type and a 20-channel pulse height analyzer were used. Fig. 3 shows the block diagram which was used in the coincidence measurement.

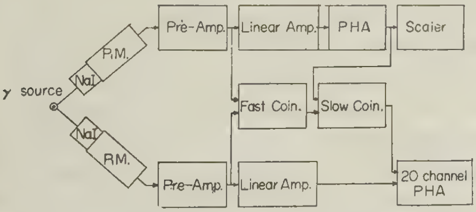

Fig. 3. Blook diagram of the coincidence spectrometer.

For the measurement of the angular correlation were used two single channel P.H.A. and a goniometer made of alminium. The solid angle correction factors for the angular correlation coefficients A_2 and A_4 were 1.07 and 1.25, respectively. The energy dependence of these factor were less than 0.2 percent in the range 0.7∼1.5 MeV.

§ 4. Spectra of Beta-Rays and Internal Conversion Electrons

4.1 Mn^{52}

The source was prepared by the method stated in § 2. The removal of V^{48} was satisfactory. The admixture of Mn^{54} did not cause trouble, because it decays through a electron capture and a 838 keV gamma transition[10].

(1) Beta-ray spectrum. In Fig. 4 is shown the momentum spectrum obtained by our beta-ray spectrometeter. Assuming the $B\rho$ vs. current curve for positrons was the same for negatrons, the energy was calibrated by using the K conversion lines of the 1173 keV gamma-ray of Co_{60} and the 662 keV gamma-ray of Cs^{137}.

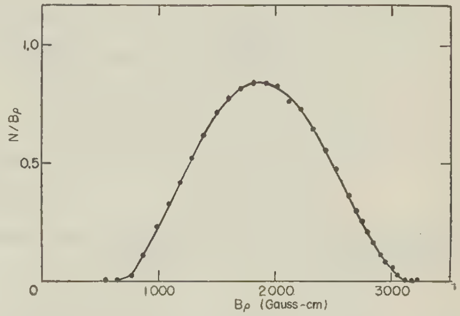

Fig. 4. Momentum spectrum of the positrons emitted in the decay of Mn^{52}.

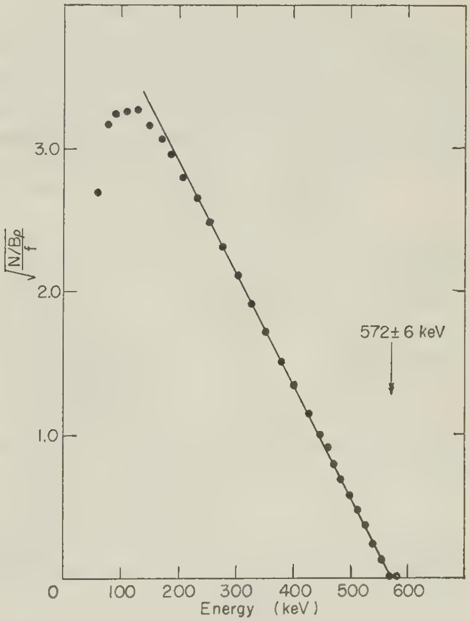

Fig. 5. Kurie plot of the positrons emitted in the decay of Mn^{52}.

Fig. 5 shows the Kurie plot, from which the maximum energy 572±6 keV is determined. As shown in the Figure the Kurie plot is straight from the maximum energy down to about 200 keV, where the absorption

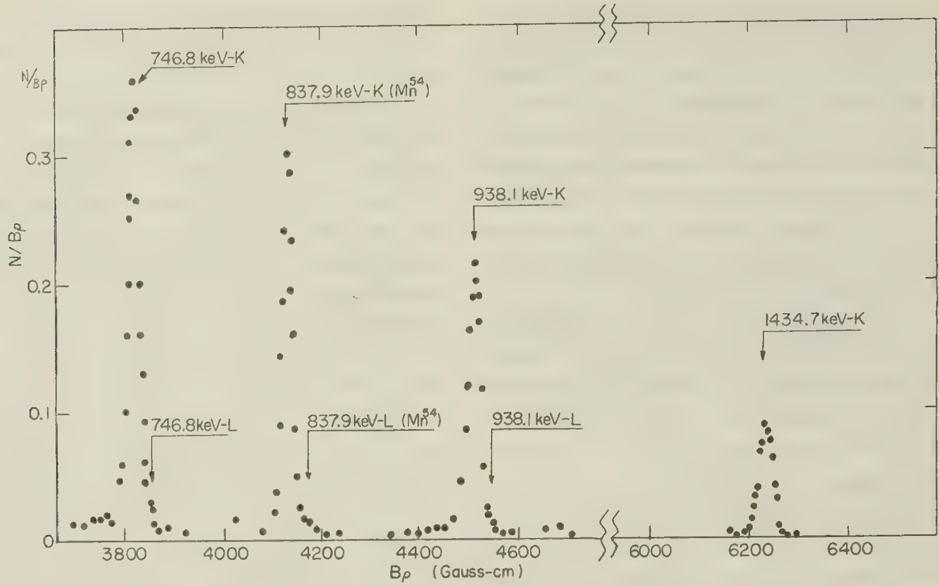

Fig. 6. Spectrum of the Conversion electrons in the 600~1000 keV region and the 1400~1500 KeV region emitted in the decay of Mn^{52}.

by the counter window can be thought to begin. Then if the value of half-life 5.72 days[11] is adopted, the value of log *ft* is 5.4.

(2) Internal conversion electrons Fig. 6 shows the spectrum of the internal conversion lines using the same source as that of beta-ray spectrum. The relative half maximum width of each line is 0.6 percent. The values of energies of each gamma-rays are tabulated in Table I, where energy standards were the *K*-conversion lines of Cs^{137} and Co^{60}.

Theor.	E1	8.3	8.6
	E2	7.8	7.8
	M1	8.0	8.0
	M2	7.8	7.8

The *K*-lines and the $L+M$ lines can be barely separated for 747 and 938 keV gamma-yays. In Table II values of the observed $K/L+M$ ratios are compared with those calculated from the tables of Rose[12]. Here the calculated ratios are taken into consideration only for cases of E1, E2, M1 and M2, because the gamma-rays are restricted to be quadrupole from the results of angular correlation as shown in §6, and ratios other than these four are far from the observed values. The Rose's values for *M*-shell which do not contain the correction for the screening effect should be multiplied by factor about 0.6[13]. The calculated values in Table II were thus obtained and agree well with the observed within experimental error

Instead of measuring the conversion coefficents, the relative intensity ratios of the total conversion electrons of the three gamma-rays were measured. As intensities of weak gamma-rays other than the main three were estimated less than 5 percent (§5), the main three can be said to have equal intensities within the same error. Therefore the ratios of the total conversion electrons are regarded as the ratios of the total conversion coefficients. These ratios compared with calculated

Table III. Relative total conversion ratios of the three main gamma-rays in the decay of Mn^{52}.

	VII	3.20(M1)	2.62(E2)	1(E2)

values for all combinations of E1, E2, M1 and M2 transitions. Table III shows the observed values and some of the calculated ones, normalized for the 1435 keV gamma-ray. It can be concluded that combinations except E2–E2–E2, M2–M2–M2 and E2–E2–M1 are rejected.

4.2 Mn^{52m}

The relatively short half-life of Mn^{52m} necessitated several devices for source preparation of beta-ray spectrometer as stated in § 2.

(1) Beta-ray spectrum Runs of measurements for twenty momentum values were repeated several times until the source decayed out. Decay curves obtained for three momentum values are illustrated in Fig. 7. All decay curves showed the half-life of 21 min. A momentum spectrum derived from these decay curves is shown in Fig. 8. Fig. 9 is its Kurie plot. It shows the maximum energy 2.61±0.03 MeV and the allowed shape down to 0.2 MeV from the maximum energy. Decay curves of the low energy part in Fig. 7 deviate from the straight line with the passage of time. This seems to be the admixture of Mn^{51}(44 min). This effect is, however, negligible as seen from the decay curves.

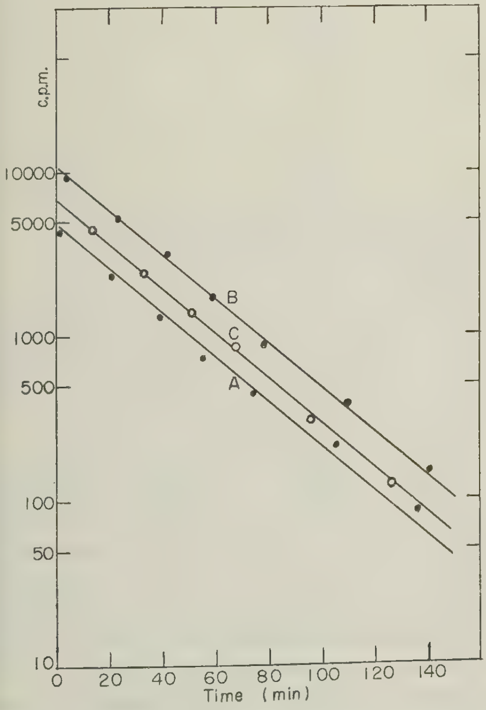

Fig. 7. Decay of the positron spectrum of Mn^{52m}. *A*, *B* and *C* are the decay curves of the points indicated by the same letters in Fig. 8.

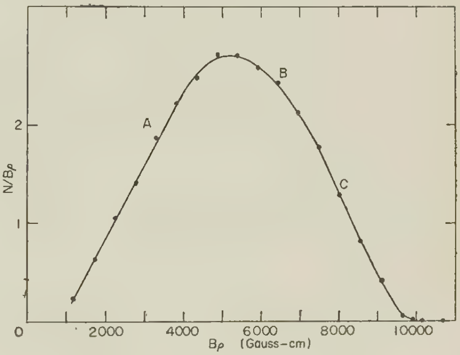

Fig. 8. Momentum spectrum of the positrons emitted in the decay of Mn^{52m}. The intensities of the measured points were normalized at the same time.

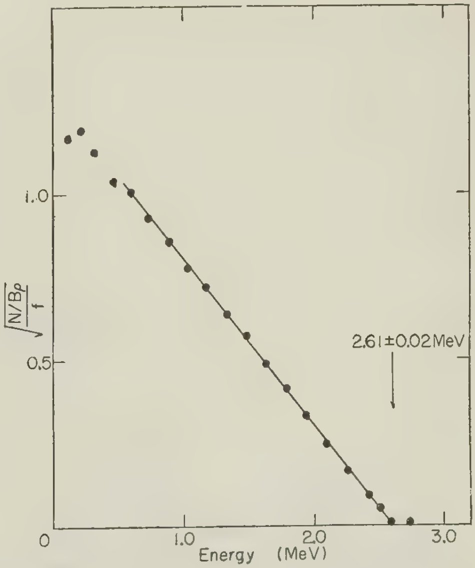

Fig. 9. Kurie plot of the positrons emitted in the decay of Mn^{52m}.

(2) Internal conversion A spectrum of con-

version electrons containing two strong lines was obtained as shown in Fig. 10. Energies of these gamma-rays are tabulated in Table IV. Fig. 11 is the decay plots of the conversion line of 383 keV gamma-ray, which shows the half-life is 24±5 min.

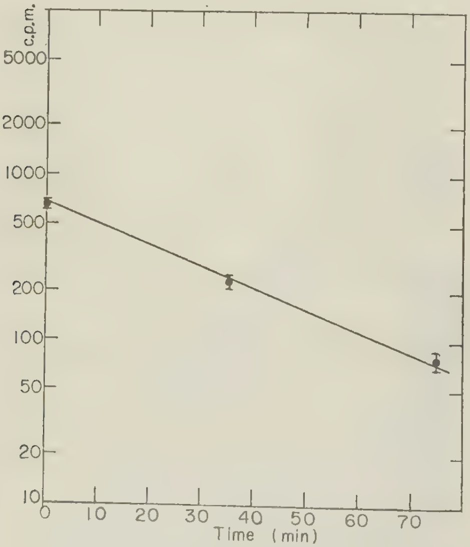

Fig. 11. Decay of the conversion electrons of the 383 keV transition emitted in the decay of Mn^{52m}.

The 1435 keV gamma-ray can be said to be emitted from the first excited state of Cr^{52} as in the case of Mn^{52}. The 383 keV gamma transition can be thought to be isomeric. The observed and the calculated *K*/*L* ratios tabulated in Table V show that it is a *E*4 transition. Besides the above two strong gamma-rays we searched for whether conversion electrons of weak gamma-ray exist between 0.5 and 1.5 MeV, but found nothing. It will be concluded that there is no conversion electron of intensity more than 20 percent of 1435 keV conversion electrons.

§ 5. Scintillation Gamma Spectra

5.1 Mn^{52}

(1) Single spectra Fig. 12 shows the scintillation spectrum of the well-known three gamma-rays of Mn^{52} measured by using the 1½″×1½″ NaI(Tl) scintillator and the single channel pulse height analyzer.

The energies of these three gamma-rays have been reported by Peacock and Deutsch and others. Table I contains some of these values. The preceding values for 938 keV gamma-ray agree well with the present values but values for other two gamma-rays do not well. Here, we reexamined the energies of these two gamma-rays by means of the scintillation spectrometer calibrated with the annihilation and 938 keV gamma-rays, and obtained the values of 0.746 and 1.433 MeV. The fact that present results from two dif ferent methods are not contradictory means hat there is no such a gamma-ray in the eighbourhood of these gamma-rays as to ause a deviation of a peak in the scintillation spectrum. It can be concluded that the 3.161 MeV level found by Mazari, *et al.* differs from the 3.121 MeV level in the decay of Mn^{52} over the experimental errror as shown in Fig. 1. Therefore, the positron decay to the 3.161 MeV level from Mn^{52} is estimated to be forbidden.

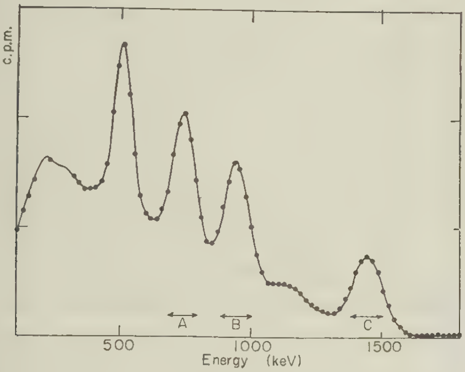

Fig. 12. Gamma spectrum of Mn^{52}. A, B and C indicate the gate-windows for the angular correlation.

The intensities of the three gamma-rays were estimated to be nearly equal, using the energy-efficiency curve of the scintillation counter. Besides, the levels of 2.648, 2.767, 2.965 and 3.161 MeV found by Mazari, *et al.* and shown in Fig. 1 may cause weak gamma-rays other than the main three, if they have appropriate spins and parities. We attempted the search of weak gamma-rays between 0.94~1.43 MeV, comparing the shape of the 1.435 MeV gamma-ray spectrum with that of the 1.12 MeV gamma-ray of Zn^{65} and estimated their intensities less than 10 percent at most.

The energy range higher than 1.435 MeV was swept carefully, using the $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI(Tl) scintillator and 20-channel P.H.A. A weak 1.73 MeV gamma-ray was found in this way. Fig. 13 is the result of the more detailed measurement of this gamma-ray by use of the $3'' \times 3''$ scintillator and the single channel P.H.A. The intensity is estimated as about 0.5 percent of the main gamma-rays from Fig. 13.

(2) Coincidence spectra Coincidence spectra were observed using 20-channel P.H.A. Opening a gate window at the full width of the 1.435 MeV photo-peak, the coincidence spectrum of the annihilation, 0.747 and 0.938 MeV gamma-rays were observed in the range lower

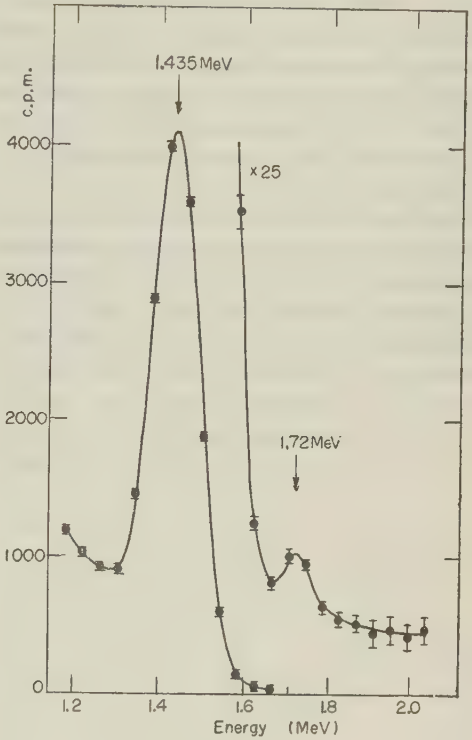

Fig. 13. Weak high energy gamma-ray of Mn^{52}.

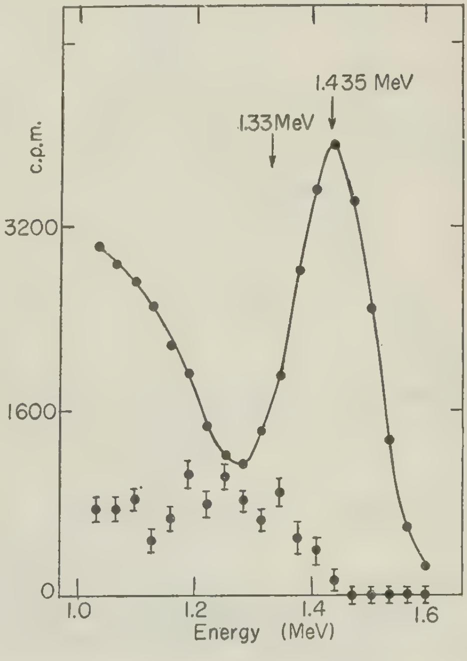

Fig. 14. Gamma-ray spectrum coincident with the 1.435 MeV gamma-ray of Mn^{52}.

than 1 MeV. The coincidence of the 0.747 MeV gamma-ray with 0.938 MeV was also confirmed. These facts show the main three gamma-rays are successive. Fig. 14 is a coincidence spectrum with a gate window opened at the higher side of the photo-peak of 1.435 MeV gamma-ray. This shows weak 1.33 and 1.2 MeV gamma-rays about 5 and 3 percent of the main three, respectively.

5.2 Mn^{52m}

(1) Single spectra Fig. 15 shows single and summing spectra of chromium foils bombarded by deuterons as stated in § 2. The NaI(Tl) scintillators were of 1½″×1½″ and 3″×3″. The latter was placed at 30 cm as well as 0.5 cm in front of the sources for the purpose to identify summing peaks.

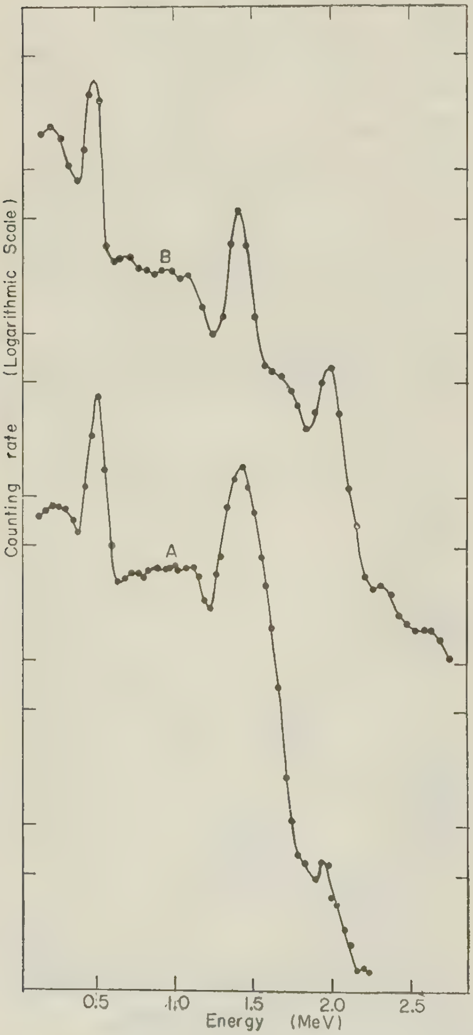

Fig. 15. Gamma-ray spectra of Mn^{52m}. A indicates single spectrum, and B summing spectrum.

Both the 1.435 MeV and the annihilation gamma-rays decayed with the half-life of Mn^{52m} at the start, and with the half-life of Mn^{52} after a few hour. The decay curves of these two gamma-rays are shown in Fig. 16, from which the half-life of Mn^{53m} 21±1 min is obtained.

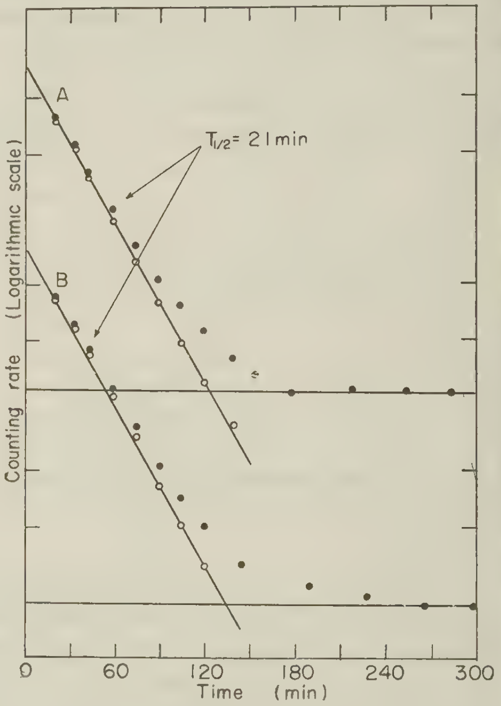

Fig. 16. Decay curves of the 1.435 MeV and the annihilation gamma-rays of Mn^{52m}. A indicates the decay curve of the 1.435 MeV gamma-ray, and B the decay curve of the summing peak of the two gamma-rays.

The search of weak gamma-rays was tried with the two methods corresponding to the energy regions lower and higher than the energy of the annihilation gamma-ray. For the higher region shapes of spectra were compared with those of known single gamma-rays, and several weak gamma-rays were found between 0.511 and 1.435 MeV, but they could not be said to be conclusive. For the lower region, on the other hand, the method of such simple comparison as the above-mentioned is practically impossible, because the region is covered by the strong Compton peak of the annihilation gamma-ray. We eliminated the effect of the annihilation gamma-ray with the same method as used for the detection of weak gamma-rays from the positron emitter Mn^{51} [14].

The annihilation of positrons was avoided in the vicinity of the source foil as carefully as possible. The $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI (Tl) scintillator was covered by the lead shield of 20 cm thickness with a collimating hole of 1 cm diameter. The sourse was placed at 30 cm in front of the scintillator and the positrons were stopped just before the hole by the plastic plate of 1 cm thickness. Fig. 17 is the obtained result, which shows distinctly the 0.383 MeV gamma-ray, in comparison with the spectrum of the source in a glass vessel without the lead shield which is shown in Fig. 15. The half-life 23±4 min of this gamma-ray was also checked. From the relative intensity to the 1.435 MeV gamma-ray, the branching ratio of the 0.383 MeV gamma-ray to the positron decay plus the electron capture could be estimated as 2±1 percent considering the efficency of the detector, and the partial half-life of gamma transition not containing conversion electrons as 18 hours.

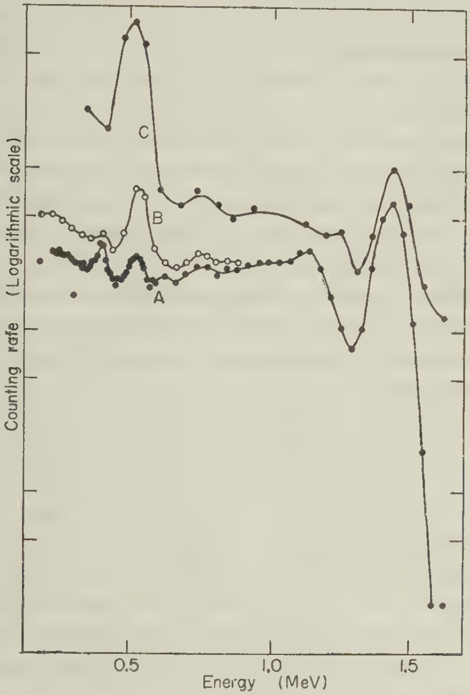

Fig. 17. Gamma-ray spectrum of Mn^{52m}. Curve A shows the spectrum measured with the plastic plate, Curve B the spectrum without the plate, and Curve C the ordinary spectrum of the source in a glass vessel without the lead shield.

(2) Coincidence spectra Coincidence spectra were observed using the $1\frac{1}{2}'' \times 1\frac{1}{2}''$ scintillators. The gate-windows were opened at the full width of the photo-peaks of 1.435 and 0.511 MeV as well as the high energy and the low energy sides of the photo-peak of 1.435 MeV and near 1.2 MeV. Fig. 18 is the result of the former case, shows the some of these coincidence spectra compared with the single.

From those experiments, the coincidences of the positrons with the 1.435 MeV gamma-ray were confirmed and several weak gamma-rays were found as follows: 0.70(3%), 0.94(4%), 1.02(3%), 1.15(2%), 1.37(%) and 1.52 MeV(2%). The percentages in parentheses are ratios of those intensities to the intensity of the 1.435 MeV gamma-ray. However, statistial errors were large, the decisive conclusions were difficult.

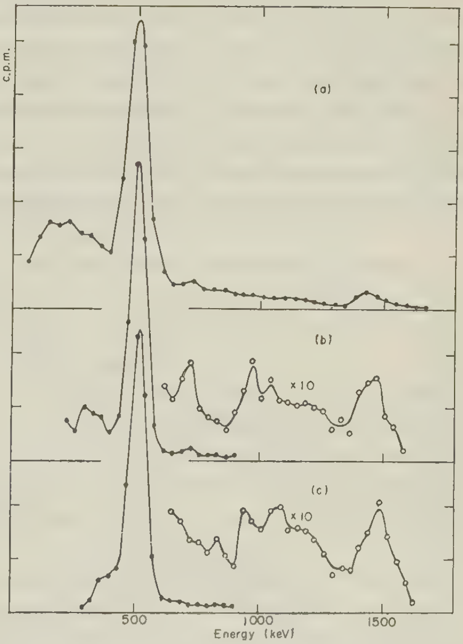

Fig. 18. Single and coincidence gamma spectra of Mn^{52m}. (a) Single spectrum. (b) Coincidence spectrum with the 1.435 MeV photo-peak. (c) Coincidence spectrum with the 1.2 MeV region.

§ 6. Directional Angular Correlation

6.1 *Experimental results*

The directional angular correlation among the three gamma-rays were observed. As mentioned in § 2, the admixture of V^{48} is a serious obstacle, especially for the observation of the angular correlations. The source of present measurement was prepared carefully in this point.

The gate-windows were set at the full width of the respective photo-peaks indicated by arrows *A*, *B* and *C* in Fig. 12. Combinations of the gate-windows are denoted by *B-C*, *A-C* and *A-B*. Of the three combinations, *B-C* of the two higher energy gamma-rays are not questionable in the following means. But the combinations *A-C* and *A-B* are not simple. Some parts of the Compton-peaks of the higher energy gamma-rays always pile up on the photo-peaks of the lower energy gamma-rays. Therefore, the counting rates of *A-C* and *A-B* are complex ones which are dependent upon the Compton as well as the photoelectric cross sections of the three gamma-rays. Though the correction in this point is difficult, it can be said that, in a special case where the observed three angular correlations are equal to each other, the correlation functions of three gamma-rays themselves are common and this correction becomes unnecessary. The results in Fig. 19 and Table 6 show that the observed correlations differ only slightly with each other and are relatively close to the theoretical for the spin-multipole sequence $J+2(2)J(2)J-2$. However it will be noticeable that the combination *B-C*, which is expected to be not disturbed by other gamma-rays, deviates from the other two observed and the theoretical correlations beyond the experimental error.

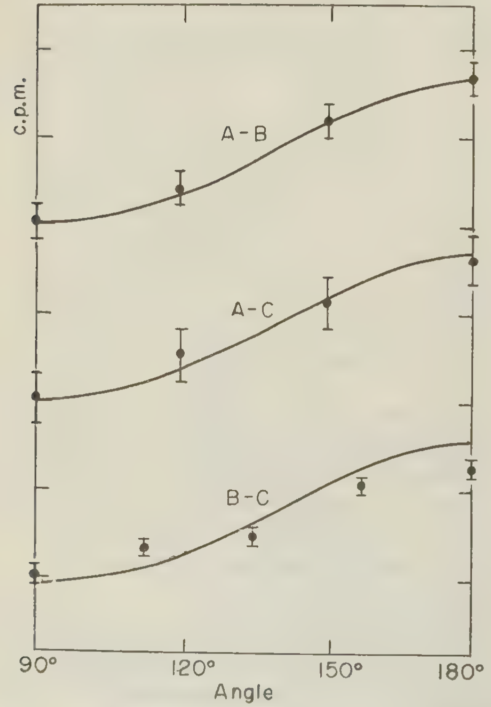

Fig. 19. Angular correlations of the three gamma-rays of Mn^{52}.

6.2 *Analysis*

Generally, for three quadrupole gamma-rays γ_1, γ_2 and γ_3 emitted succesively with dipole mixing it can be said as follows. Measurements of the three combinations of them γ_1-γ_2, γ_1-γ_3 and γ_2-γ_3 are possible. Assume each of three has a correlation function close to the theoretical one for $J+2(2)J(2)J-2$, as the present case of Mn^{52}. It is noticed that two sequences $J\pm1(1+2)J(2)J-2$ and $J(1+2)J(2)J-2$ give same correlation functions as that of $J+2(2)J(2)J-2$ within the usual experimental error, if the mixing ratios are appropriate. However, in the case of the triple cascade with the same correlation functions the possibilities of the mixed transitions can be excluded, except for the case where the only first gamma-ray is mixed, similarly the only third is so.

Table VI. Angular correlation coefficients of Mn^{52}.

		A_2	A_4
Teor.	$J+2(2)J(2)J-2$	0.1020	0.0091
Exp.	0.938−1.435	0.079±0.013	0.003±0.018
	0.747−1.435	0.102±0.019	−0.003±0.036
	0.747−0.938	0.114±0.018	0.005±0.034

In the case of Mn^{52}, the spin and parity of the ground state of Cr^{52} is 0+, and then γ_3 must be a pure multipole. Hence γ_2 and γ_3 are pure quadrupole transition from Table IV, but γ_1 is a pure or mixed quadrupole transition and the spin of the third excited level is not determined uniquely. As a consequence it can be concluded that following four sequences are left as possible, 6(2)4(2)2(2)0, 5(2+1)4(2)2(2)0, 4(2+1)4(2)2(2)0 and 3(2+1)4(2)2(2)0. In § 7 we shall compare these results with the values of the internal conversion coefficients and determine the third level spin.

Far the fact that the coefficients A_2 and A_4 of the combination γ_2-γ_3 are slightly smaller than those of the other combinations and the calculated, several reasons can be considered as follows: (1) The half-life of the 1.435 MeV level may be relatively long. (2) The atomic excited or ionized state after the decay may have a sufficiently long life and an intense field of the extranuclear effect. This effect is often remarkable for the electron capture. (3) Some weak gamma-rays other than the main three cause A_2 and A_4 to attenuate. The first and the second reasons are unnatural. Because, estimated half-lives of excited levels of about 1 MeV in nuclei near Mn^{52} are so short that they can not cause small A_2 and A_4 unless perturbing field is extremely intense. It is confirmed by the observed half-life of order 10^{-13} sec by the method of the resonance fluorescence[15]. It is also difficult to consider that the extranuclear field due to atomic excited levels perturbes the first excited level only and does not the second and the third levels. The third reason seems to be relatively natural. As stated in § 5, we found weak gamma-rays of 1.33 and 1.2 MeV which were coincident with the 1.435 MeV gamma-ray. If an appropriate decay scheme was assumed, the explanation of this attenuation was possible.

§ 7. Discussions

According to the *j-j* coupling shell model, ${}_{24}Cr^{52}_{28}$ is the nucleus, of which neutrons fill the $f_{7/2}$ orbit and protons leave four holes in the same orbit. Therefore, low lying excited states of this nucleus seem to be attributable to the proton excitation. Levels of the neutron excitations will come higher than a few MeV. The application of the shell model is considerably successful in the region near Cr^{52}. From the viewpoint of the collective model Cr^{52} is a neutron magic number nucleus for which vibration of spherical core may be considered to be pertinent. This model, however, has not yet succeeded in the Cr^{52} region. The nuclear structure of this region is not discussed here in detail, but will be an interesting problem in future.

${}_{25}Mn^{52}_{27}$ is the odd-odd nucleus, of which neutrons and protons have one and three holes in the $f_{7/2}$ shell respectively. Thus the ground state spin of Mn^{52} must be larger than zero, obeying the Nordheim's weak rule.

7.1 *Beta-decay*

Using our values of maximum energies of positron spectra, the log *ft* values of Mn^{52} and Mn^{52m} were determined as 5.4 and 5.3 respectively. For the half-lives, 5.72 days reported by Backofen and Herber[11] for Mn^{52} and 21 min of the present measurement for Mn^{52m} were adopted. From the values of log *ft* and the shapes of the spectra shown in Figs. 5 and 9, both transitions are allowed, i.e., $\Delta J=0$, ± 1 and no parity change.

In addition, we can estimate that low energy components of the beta-rays are less than 10 percent from the shapes of both spectra.

7.2 *Isomeric transition*

The energy and intensity of the gamma-ray of the isomeric transition were measured. The transition is $E4$, $E5$ or $M5$ from $K/L+M$, as shown in Table V. The partial half-life of the gamma-transition were estimated as 6×10^4 sec. Compared with the single particle estimate the transition is $E4$ or $M4$. As mentioned in § 4.1 the three combinations of multipolarities are possible for the three gammma-rays. For any one of these combinations the 1435 keV and 3120 keV levels have same parities. Thus the parities of Mn^{52} and Mn^{52m}, which decay to the levels of same parities through the allowed transitions, should be the same. Therefore, the isomeric transition is concluded to be $E4$.

If the first excited state of Cr^{52} has even parity, it can be decided the parities of Mn^{52} and Mn^{52m} are even.

7.3 *Excited states of* Cr^{52}

The energies of the gamma-rays from Mn^{52} were precisely measured. The obtained levels except the 3120 keV level agree well with those of Mazari, *et al.* The 3120 keV level differs from 3160 keV level of Mazari, *et al.* beyond the experimental error.

We conclude that there are close lying two levels. The 3120 keV level was not excited in the experiment of Mazari, *et al.* It is interesting that protons of a few MeV do not excite such a high spin level, as infered from the multipolarities of the triple cascade gamma-rays.

The spins and parities of the levels 1435, 2373 and 3120 keV were decided as follows. The relative ratio of the internal conversion coefficients and $K/L+M$ of the three gamma-rays led to the conclusion that their multipolarities are restricted to the three combinations: $E2$–$E2$–$E2$, $M2$–$M2$–$M2$ and $E2$–$E2$–$M1$(§ 4.1). By the experiment of the angular correlation, the gamma-ray from the first excited level was decided to be quadrupole, using the ground state spin of zero[16]. The three gamma-rays was restricted to either $E2$–$E2$–$E2$ or $M2$–$M2$–$M2$. This was consistent with the result of the angular correlations (§ 6.2). The correlation experiment can decide uniquely the spin values of the excited levels except that of the 3120 keV level. Besides, from the well-established systematics that both the first excited and ground levels of even-even nuclei have even parities, the combination $M2$–$M2$–$M2$ is excluded and the spins and parities become (3, 4, 5 or 6)+, 4+, 2+ and 0+.

As the positrons from Mn^{52m} decay to the first excited level but do not to the ground level, the spin and parity of Mn^{52m} will be 2 or 3+. As the transition from Mn^{52m} to Mn^{52} is $E4$ (§ 7.2), the spin and parity of Mn^{52} is 6 or 7+. On the other hand the 0.94 MeV gamma-ray of about 4 percent which is presumably emitted from the second excited level was present in the coincidence spectra (§ 5.2). This gamma-ray can be considered to follow the beta transition to the second excited level, of which the weak positron spectrum was not observed because of its low intensity. If it is so, long ft for the beta transition to the second excited level is 5.8, and the spins and parities of Mn^{52m} and Mn^{52} are reasonably assigned to be 3+ and 7+ rather than 2+ and 6+. 2+ and 6+ cannot, however, be excluded from the discussion in § 7.4. In addition, Jeffries, *et al.*[4] obtained the spin 6 for Mn^{52} from the paramagnetic resonance measurement. Then, the spin and parity of 3120 keV level of Cr^{52} is restricted to 5, 6, 7 or 8+ by the above-mentioned spin and parity of Mn^{52} and the selection rule of beta-decay. Combining above two discussions, the spins and parities of the levels of Cr^{52} are concluded to be (5 or 6)+, 4+, 2+ and 0+. 5+ of the 3120 keV level is excluded from a following reason. If 5+ is assumed the mixing ratio $E2/M1 \approx 0.08$ of the 747 keV gamma-ray is necessary in order to explain the angular correlation experiment. Such a dominance of $M1$ is inconsistent with the result of the relative internal conversion ratio.

It should be emphasized that the above arguments are based upon our observed results using only two assumptions, the even parities of the first excited and ground states of the even-even nuclei. Our final results agree well with the experiment of Huiskamp, *et al.*[5] for the distribution of the gamma-ray from polarized nuclei.

7.4 *Week gamma-rays*

As stated in § 5, many weak gamma-rays other than the main three were found. As preliminary interpretations, it is tried to connect these gamma-rays with levels found by Mazari, *et al.*

The 1.73 MeV gamma-ray from Mn^{52} can be regarded as the transition between the 3161 and 1435 keV levels. Considering the 1435 keV level of 2+ and the selection rule of beta-decay, the spin of the 3161 keV level is presumably 3 or 4.

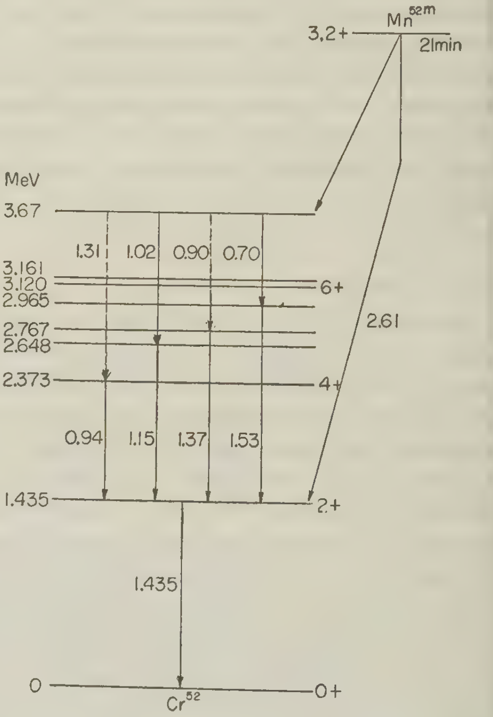

Fig. 20. Tentative decay scheme for the weak gamma-rays of Mn^{52m}.

The 1.2 and 1.33 MeV gamma-ray of Mn^{52} which are coincident with the 1.435 MeV gamma-ray can be interpreted to be the transitions trom the 2648 and 2767 keV level to the 1435 keV level. Assuming that the transitions from the 3120 keV level to both levels are $E2$, the observed branching ratios of the two weak gamma-rays to the 0.747 MeV gamma-ray from the 3120 keV level are agree with the single particle estimate. Then the assignment of 4+ to the both levels found by Mazari, *et al.* seems to be reasonable.

For Mn^{52m} the transitions of the 1.52, 1.37, 1.15 and 0.94 MeV gamma-rays, which are coincident with the 1.435 MeV gamma-ray, can be interpreted as those from the 2965, 2767, 2648 and 2373 keV levels to the 1435 keV level. The left weak 0.70 and 1.02 MeV gamma-rays cannot be explained by use of the known levels. Assuming a new level of 3.67 MeV, it is considered that these gamma-rays are due to transitions to 2965 and 2647 keV levels, as shown in Fig. 20. The intensities of the gamma-rays are consistent within experimental error. The beta transition to the 3.67 MeV level gives rather small log *ft* value 4.

One the other hand the low energy gamma-rays from Mazari's level to the 2767 and 2373 keV levels were observed within the upper limit of 1 percent. The gamma-rays from the 3.67 MeV level to the 2767 keV and 2373 keV levels could not be distinguished from the 1.37 and 0.94 MeV gamma-rays which were assumed to be emitted in the transition from these two levels to the 1435 keV level. Thus the decisive conclusion could not be obtained for the beta transition to the 2373 keV level as mentioned in § 7.3.

Acknowledgement

The authors would like to thank Prof. S. Kikuchi, Prof. T. Wakatsuki, Prof. J. Itoh and the members of the cyclotron group in Osaka University for their helps and interests. They are also indebted to Dr. J. Sanada for his contribution to the construction of the spectrometer and to Prof. K. Otozai, Mr. S. Kume, Mr. S. Iwata, Mr. Y. Yamamoto and Mr. I. Fujisawa for the chemical separation.

Polarization of Protons Scattered from Complex Nuclei

By Shotaro YAMABE, Michiya KONDO, Shohei KATO,
Takashi YAMAZAKI, and Jian-zhi RUAN

Department of Physics, Osaka University, Osaka, Japan

(Received August 4, 1960)

The experimental results for the angular dependence of polarization of elastically scattered protons from carbon at 14 and 16 MeV, and the polarization at 45° laboratory angle in the elastic scattering by 12 target nuclei at the energy of 12~17 MeV are described. Qualitative agreement with the calculation in terms of optical potential with spin-orbit interaction is obtained for elastic scattering of protons by carbon.

§ 1. Introduction

In recent years the measurements[1)–9)] of the polarization of nucleons scattered from nuclei have been performed at low energy region. From these experiments large amounts of polarization have been observed which are unexpected from the extrapolation of some high energy experiments[10)]. This indicates that the spin-orbit interaction plays an important role in nucleon scattering phenomena as in bound nuclei, and some analyses[11),12)] in terms of optical potential with spin-orbit component have been performed.

The experimental results for the angular dependence of polarization of elastically scattered protons from carbon at 14 and 16 MeV, and the polarizations at 45° laboratory angle in the elastic scattering by 12 target nuclei at the energy of 12~17 MeV are described in this paper.

§ 2. Experimental Procedure

This experiment was performed using the INS 160 cm variable energy cyclotron of University

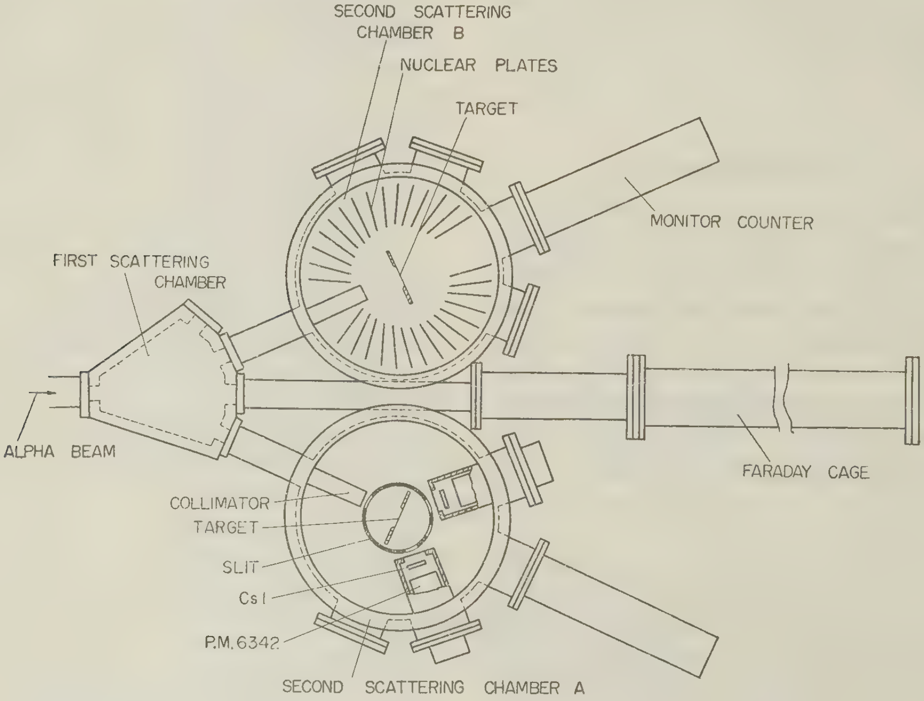

Fig 1. The second scattering chamber A is for the measurements of the left-right asymmetries by cesium-iodide scintillation counters. The chamber B shows a part of the arrangement used for the measurements of the angular dependences of the left-right asymmetries by nuclear emulsion. The details such as the shield and the pumping system are not shown in this figure.

of Tokyo. The experimental arrangement is shown in Fig. 1. 30~40 MeV α particles were extracted from cyclotron, focused by a pair of quadrupole magnets and a sector magnet, and led through the vacuum pipe to the first scattering chamber in the next room. The entrance window of the first scattering chamber was stainless steel foil of 30 mg/cm^2 and its diameter was 2.0 cm. The beam spread in the scattering volume of the first scattering chamber was adjusted to 8 mm width and 10 mm height by a pair of slits in front of the chamber. The beam, passed through the first scattering chamber and exit window of a stainless steel foil, entered into a system of Faraday cage. The beam current, about 0.3 μA, was integrated by a conventional integrator circuit, and a small fraction of this beam was led through a aluminum foil to outside of the vacuum system and its energy was determined by measuring the range in aluminum.

The first scattering chamber was filled with tank hydrogen gas 5 to 10 atmospheric pressures. Protons recoiled to ±25° with respect to the direction of the incident α particles, passed through the stainless steel foil (30 mg/cm^2) and collimator system, were led to the evacuated second scattering chamber. The energy of these recoil protons was varied from 12 MeV to 17 MeV by changing the primary energy of α particles and the pressure of hydrogen gas of the first scattering chamber. These protons are expected to be nearly completely polarized from the phase-shift analysis of the p-He scattering experiments(7),(13).

At the center of the second scattering chambers the foil targets (Be, C etc.) were placed. The recoiled beams were collimated to 10 mm × 20 mm at the target position. These second scattering chambers and collimator systems were carefully aligned within ±0.5°.

Changing the energy of the recoiled protons, excitation functions of the left-right asymmetries of the second scattering were measured by cesium-iodide scintillation counters combined with 6342 photomultiplier tubes which were set at ±45° to the direction of the recoiled proton in the second scattering chamber. The scintillation counters could be exchanged to each other, and no systematic error could be found in this system. The target and the slit system were set in ditches which were concentrically machined in the bottom of the chamber. This slit system was a cylinder of 11 cm dia. which had four windows in the middle of its height, entrance and exit holes and two circular slits of 1.5 cm dia. Geometrical asymmetries were check-

Pb			−0.8±1.1		−0.9±2.1

ed by inversing this cylinder, and satisfactory results were obtained. Pulses from the counters were amplified and analyzed by 20 channel pulse height analyzers.

A small fraction of the recoiled proton beam, which entered into the second scattering chamber, was led through a aluminum foil at the end of this chamber to outside of the vacuum system, and the energy spectrum of the recoil protons was measured by a scintillation counter and is shown in Fig. 2.

The angular dependences of the left-right asymmetries of the second scattering were measured by nuclear emulsion, in this case plate holders were placed in the second scattering chambers. We used two plate holders the one is for both forward and backward angle, the other is for around ±90°. The angular range covered was ±30° to ±160° by an interval of 10° in the laboratory system. The glancing angle of the plates was 10° and overall angular resolution was ±3°. We used Ilford C-2 200 μ plates of 1″×3″.

3. Results and Discussion

The measured left-right ratio R of the scat-ered intensities in the second scattering is xpressed by the product of the polarization f the first and the second scattering as the ollowing relation

$$\frac{R-1}{R+1}=P_1\cdot P_2\ ,$$

vhere P_1 and P_2 are the polarization of the irst and the second scattering, respectively. The sign convention for the polarization is hat the positive direction is that of $k_{\rm inc}\times k_{\rm sc}$, where $k_{\rm inc}$ and $k_{\rm sc}$ are the incident and scattered wave vectors, respectively. We assumed that P_1 was equal to $+100\%$ which was not contradictory to both a direct measurement[14] and a calculation from the value of the scattering phase-shift, then P_2 could be obtained.

The results obtained for elastically scattered protons using scintillation counters are listed in Table I and typical pulse height spectra are shown in Fig. 3. Errors indicated are only statistical ones throughout this article. The scattering angle was 45° in the laboratory system and the values of the proton energy were expressed approximately at the center of the target. It is noticeable that all the values except the one for Ti at 16.9 MeV have negative sign. In Figs. 4 and 5 excitation functions for C and Be are shown with other results in this energy region.

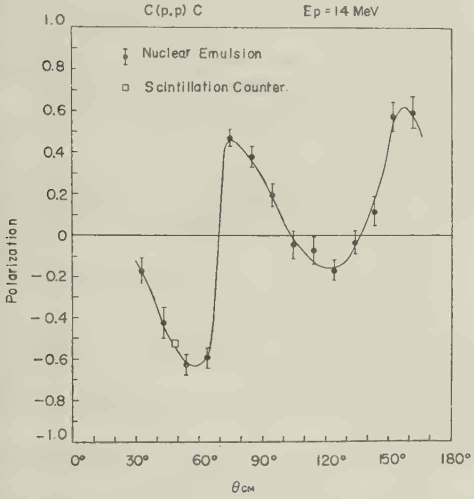

Fig. 7. The angular dependence of the polarization for C at 14 MeV.

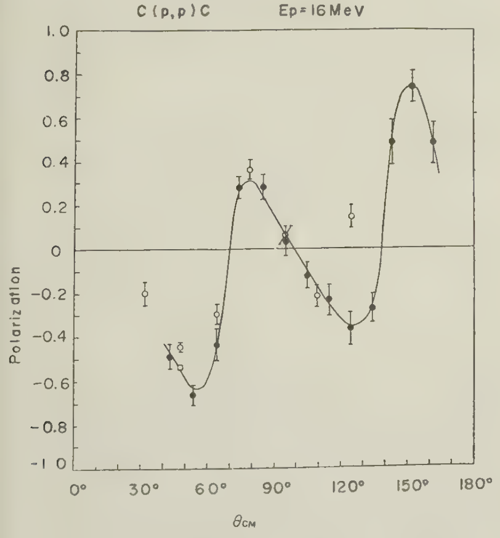

Fig. 8. The angular dependence of the polarization for C at 16 MeV. The open circles represent the result obtained by Brockman at 17.7 MeV.

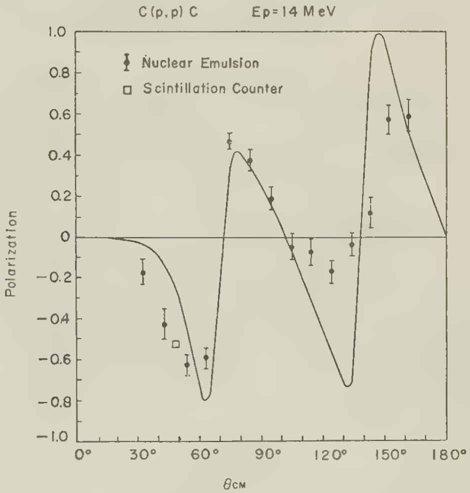

Fig. 9. Comparison with optical model calculation. Theoretical prediction given by Erickson and Cheston is indicated.

The angular dependence of the polarization for elastically scattered proton from C at 14 and 16 MeV was measured by nuclear emulsion. A typical histogram is shown in Fig. 6.

The results of the angular dependence of the polarization are shown in Figs. 7 and 8. These angular dependences were very similar in shape to each other. The result obtained by Brockman[7] at 17.7 MeV was also very similar to our present results, and these circumstances are shown in Fig. 8. From these facts we may conclude that the energy dependence of the polarization of protons elastically scattered from C is not so remarkable in this energy region.

Theoretical calculation using the optical model with spin-orbit potential for 14 MeV proton on C was given by G. W. Erickson and W. B. Cheston[12)], and our result at 14 MeV can be fitted qualitatively with this calculation, as shown in Fig. 9. In this figure, theoretical prediction by Erickson and Cheston is shown by solid curve. The optical potential adopted in the calculation is

$$V(\vec{r},\vec{\sigma}) = V_c(r)+[(V+iW)+(v+iw)\vec{\sigma}\vec{L}]\frac{1}{1+e^{(r-R)/a}},$$

where $V_c(r)$ is the Coulomb potential. The values of the parameters are as follows, $R=2.845\times10^{-13}$ cm, $a=0.5\times10^{-13}$ cm, $V=-50$ MeV, $W=-8.5$ MeV, $v=-2$ MeV and $w=0$.

Table II. The left-right asymmetries (%) for inelastically scattered protons from $C^{12}(Q=-4.43$ MeV).

Ep (MeV)	14.8	15.9	16.9
asymmetry	-32.4 ± 2.6	-32.6 ± 3.3	-41.3 ± 2.5

The left-right asymmetries at 45° laboratory angle for inelastically scattered protons from C^{12} ($Q=-4.43$ MeV) are listed in Table II. As to the angular dependence we could not obtained reliable data because of the large background of neutron and γ-radiation.

Acknowledgments

We are indebted to the INS cyclotron group of University of Tokyo for the very reliable operation of the machine. We also wish to express our gratitudes to Professor T. Wakatsuki for his guidance and to Dr. J. Sanada for his helpful discussions throughout this work.

Reactions of Nickel with Alpha-Particles

By Shigeo TANAKA

Institute for Nuclear Study, University of Tokyo,
Tanashi-Machi, Tokyo

(Received August 5, 1960)

Excitation functions for the alpha-particle induced reactions on Ni^{58}, Ni^{60}, Ni^{61}, Ni^{62} and Ni^{64} have been measured at incident energies up to 40 Mev. The sum of the measured cross sections for Ni^{58} appears to agree with the total reaction cross section calculated from the continuum theory for $r_0=1.7\times10^{-13}$ cm. The sum almost agrees with the optical-model analysis of reaction cross section for alpha-particles by Igo, but his prediction seems to give a little higher value. In the excitation function for the $(\alpha, \alpha n)$ reaction on Ni^{58}, there is a small "knee" immediately after the effective threshold (around 23 Mev). The alpha-particle reactions on Ni^{60} have been compared with the proton reactions on Cu^{63}, the compound nucleus Zn^{64} being the same for two cases. The prediction from the compound nucleus theory seems to hold roughly, and it seems inadequate to discuss strictly whether the discrepancy in energy is significant. The same is observed in the comparison between the alpha-particle reactions on Ni^{62} and the proton reactions on Cu^{65}.

§1. Introduction

Present author and his colaborators[1-4] are studying systematically the cross sections of alpha-particle reactions on medium-weight nuclei at intermediate energies. As a part of their systematic study, the excitation functions for the reactions listed in Table I have been measured in this study for alpha-particle energies up to 40 Mev.

Table I. List of the reactions studied.

Target Nuclide	Type of Reaction
Ni^{58}	$(\alpha,\ p+\alpha,\ n)$, $(\alpha,\ pn+\alpha,\ 2n)$, $(\alpha,\ \alpha p)$, $(\alpha,\ \alpha n)$, $(\alpha,\ \alpha pn)$, $(\alpha,\ \alpha 2n)$
Ni^{60}	$(\alpha,\ n)$, $(\alpha,\ pn)$, $(\alpha,\ 2n)$, $(\alpha,\ \alpha pn)$, $(\alpha,\ p2n+\alpha,\ 3n)$
Ni^{61}	$(\alpha,\ p)$
Ni^{62}	$(\alpha,\ n)$, $(\alpha,\ pn)$, $(\alpha,\ \alpha p)$
Ni^{64}	$(\alpha,\ p)$, $(\alpha,\ 3n)$

Recently, Houck and Miller[5] measured the excitation functions for the $(\alpha, \alpha p)$, $(\alpha, \alpha n)$, $(\alpha, \alpha pn)$ and $(\alpha, \alpha 2n)$ reactions on Ni^{58} for alpha-particle energies up to 40 Mev. They compared the ratios of $\sigma(\alpha, \alpha p)/\sigma(\alpha, \alpha n)$ and $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ for Ni^{58} with those of $\sigma(\alpha, p)/\sigma(\alpha, n)$ and $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ for Fe^{54}, respectively. They themselves and also Dostrovsky, Fraenkel and Friedlander[6] discussed their results in terms of the evaporation theory of compound nucleus. The $(\alpha, p+\alpha, n)$ and $(\alpha, pn+\alpha, 2n)$ reactions on Ni^{58} have been also measured in this study. The sum of the measured cross sections has been compared with the total reaction cross section predicted by the continuum theory and by the optical model analysis.

The alpha-particle reactions on Ni^{60} and the proton reactions on Cu^{63} were previously measured by Ghoshal[7]. They gave the experimental evidence for the Bohr's compound nucleus hypothesis to the medium energy region. It has been pointed out, however, by Eastman, Isenor, Bainbridge and Duckworth[8] and also by John[9] that the energy shift required to fit Ghoshal's experiment to the compound nucleus theory is not exactly equal to the value derived from mass measurement The measurement of the alpha-particle reactions on Ni^{60}, after Ghoshal's work, would be of use to examine this discrepancy. The similar discrepancy was shown, very recently, by the present author and his colaborators[4] for the comparison between the alpha-particle reactions on Fe^{56} and the proton reactions on Co^{59}. Further, the comparison between the alpha-particle reactions on Ni^{62} in this study and the corresponding proton reactions on Cu^{65} would be of use for the test of this discrepancy.

Very recently, McGowan, Stelson and

Smith[10] measured the cross sections for the reactions $Ni^{58}(\alpha, n)Zn^{61}$, $Ni^{58}(\alpha, p+\alpha, n+\alpha, \gamma)$, $Ni^{60}(\alpha, n)Zn^{63}$ and $Ni^{62}(\alpha, n)Zn^{65}$ up to $E_\alpha=11.0$ Mev. And present results are compared with theirs.

§ 2. Experimental

The bombardments were performed with the external alpha-particle beam from the 160 cm INSJ variable energy cyclotron by means of a stacked-foil technique. The stack of the target foils was placed at the bottom of the long cylindrical cup which was served also as a Faraday cup. The beam was measured by a 100% feed-back type current integrator. Each stack generally consisted of 10 to 12 target foils which were interspaced with aluminum absorbers. The value of the energy loss of alpha-particles in aluminum absorber was taken from the works of Bichsel, Mozley and Aron[11], Burkig and MacKenzie[12] and of Sternheimer[13], whereas that in nickel target was calculated from the stopping power formula of Bethe et al. using the estimated mean excitation potential; $I=13Z$ (ev) and $Z=28$. In different experiments, the initial alpha-particle energies were 40.0, 38.5, 32.0 and 31.3 Mev, and energy region was overlapped in different runs by a few Mev. After the bombardment, the target foil was dissolved in acid and nickel, cobalt, copper and zinc were chemically separated by means of an anion exchange resin. Each fraction was then submitted to counting. For the shorter-lived nuclides (mainly for Cu^{60}, Cu^{62} and Zn^{63}) short time irradiation (from 30 seconds to a few minutes) was performed several times with 5 to 6 target foils in the stack. The shorter-lived activities were counted, with and without a chemical separation. Copper and zinc were separated from nickel and other constituents by means of an organic co-precipitation method.[14,15] The chemical process completed within 25 minutes. A more detailed description of the bombarding system is given in the previous reports[1,16], and that of the chemical procedure in the Appendix.

The targets consisted of natural-nickel foils (8.7±0.2 mg/cm²) whose impurities were chemically analyzed.

Table II. Impurities of natural-nickel target.

Impurity	C	Si	Mn	Co	Fe	Mg
Content (%)	0.02	0.03	0.05	0.05	0.01	0.11

The disintegration rates of the residual nuclides were determined with a calibrated GM counter, a $4\pi\beta$-counter and an (1−3/4 in. dia. ×2 in. high, 1−1/2 in. dia. ×1 in. high and well-type) NaI scintillation counter. The counting technique and the calibration method are presented in detail in the Appendix.

§ 3. Results and Discussion

Reactions of Ni^{58}

The excitation functions for the alpha-particle reactions on Ni^{58} are shown Fig. 1 and Fig. 2, which also include the estimated error of the magnitude of cross section and the energy spread in target foil for some experimental points. The cross sections measured by McGowan, Stelson and Smith[10] for the low-energy part of the $(\alpha, p+\alpha, n+\alpha, \gamma)$ reaction agree well with the present results. (See: Fig. 1) Natural-nickel was used as target material; hence the $(\alpha, p+\alpha, n)$ cross section for Ni^{58} and the $(\alpha, p2n+\alpha, 3n)$ cross section for Ni^{60} could not be obtained separately, above the threshold for the latter reaction.

● $Ni^{58}(\alpha, p)Cu^{61}+Ni^{58}(\alpha, n)Zn^{61}$.

○ $Ni^{58}(\alpha, pn)Cu^{60}+Ni^{58}(\alpha, 2n)Zn^{60}$.

–·– $\sigma(\alpha, p+\alpha, n+\alpha, \gamma)$ measured by McGowan et al.[10]

- - - - Estimated curve of $\sigma(\alpha, p+\alpha, n)$ after subtraction of the contribution from the reactions $Ni^{60}(\alpha, p2n)Cu^{61}$ and $Ni^{60}(\alpha, 3n)Zn^{61}$.

The excitation functions for the reactions (α, αp), (α, αn) and (α, αpn) obtained by Houck and Miller[5)] and by the present author agree completely with each other. (See: Fig. 2)

The sum of the measured cross sections is compared with the total reaction cross section calculated from the continuum theory (according to Shapiro's calculation[17)]) and from the optical model analysis (according to Igo's calculation[18)]). A shallow minimum around 22 Mev in the sum of the measured cross sections may reflect a substantial contribution of the unmeasured cross sections. The most probable reactions which are missed in this experiment may be the (α, $\alpha\gamma$) reaction and particularly the (α, $2p$) reaction. The threshold for the (α, $2p$) reaction is lower than that for the (α, pn) reaction by about 8.1 Mev (Quisenberry et al.[19)]), thus the (α, $2p$) reaction may be quite important in spite of the Coulomb barrier of the proton emission. According to Shapiro's calculation, a value of $r_0=1.7\times10^{-13}$ cm appears to give a reliable fit to the sum of the measured cross sections. Igo's prediction almost agrees with the present experiment, but seems to give a little higher value.

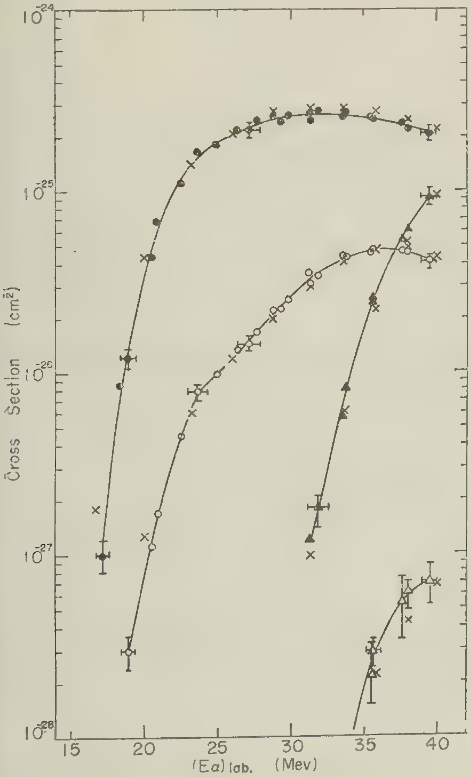

Fig. 2. Excitation functions for the alpha-particle reactions on Ni^{58}. (Part 2)

- ● $Ni^{58}(\alpha, \alpha p)Co^{57}$ ▲ $Ni^{58}(\alpha, \alpha pn)Co^{56}$
- ○ $Ni^{58}(\alpha, \alpha n)Ni^{57}$ △ $Ni^{58}(\alpha, \alpha 2n)Ni^{56}$
- × The cross sections measured by Houck and Miller[5)] for each corresponding reaction.

The next value is not shown in the Figure.
$\sigma(\alpha, \alpha n)$ at 33.5 Mev = 6×10^{-29} cm².

It can be seen that there is a small "knee" immediately above the effective threshold (around 23 Mev) in the excitation function for the (α, αn) reaction. (See: Fig. 2) The "knee" was carefully determined by two different runs. The contamination of cobalt into nickel fraction was reduced below $\sim1\times10^{-5}$ by careful procedures. It is thought that this "knee" is beyond experimental errors. This anomaly was also observed in the excitation function for the (α, 2n) reaction on Fe^{54} by the present author and his colaborators[3)] and also by Houck and Miller[5)], the reason remains uncertain.

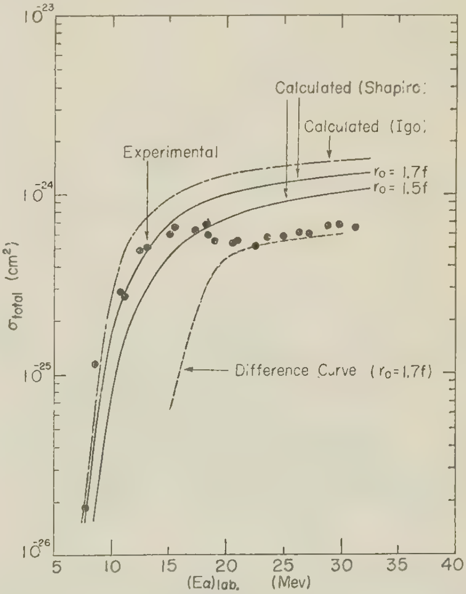

Fig. 3. The total reaction cross section for the alpha-particle reactions on Ni^{58}.

- ● Sum of the measured cross sections.
- —— Total reaction cross section calculated from the continuum theory of $r_0=1.7\times10^{-13}$ cm and of $r_0=1.5\times10^{-13}$ cm. (According to Shapiro's calculation[17)])
- —·— Total reaction cross section predicted from Igo's optical model analysis.[18)]
- ---- Difference curve between continuum theory of $r_0=1.7\times10^{-13}$ cm and sum of the measured cross sections.

The energy dependences of the ratios of $\sigma(\alpha, \alpha p)/\sigma(\alpha, \alpha n)$ and $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ for Ni^{58} are shown in Fig. 4. The predominance of proton emission over neutron emission has been reported for the cross section ratios of various reactions resulting the isobaric pairs of Co^{57}–Ni^{57} and Co^{56}–Ni^{56}.[3,5,20–24] The shallow concave which can be seen around 23 Mev in the ratio curve of $\sigma(\alpha, \alpha p)/\sigma(\alpha, \alpha n)$ is a consequence of the "knee" observed in the $(\alpha, \alpha n)$ excitation function.

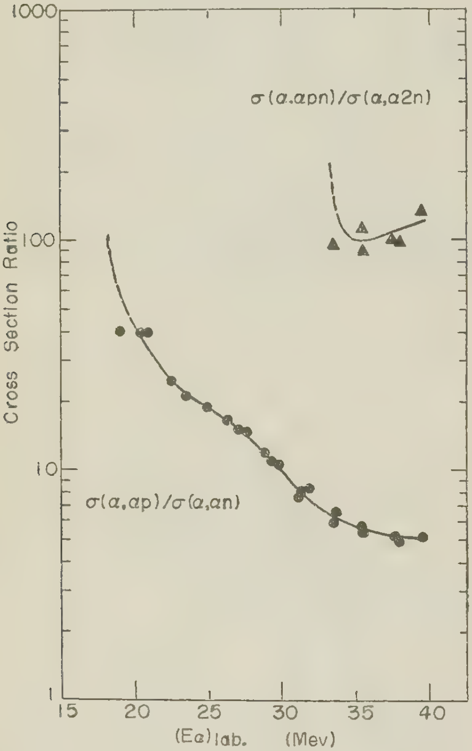

Fig. 4. The energy dependences of the cross section ratios of $\sigma(\alpha, \alpha p)/\sigma(\alpha, \alpha n)$ and $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ for Ni^{58}.

Reactions of Ni^{60}

The excitation functions for the (α, n), (α, pn) and $(\alpha, 2n)$ reactions on Ni^{60} are shown in Fig. 5 together with the data of Ghoshal.[7] The present results do not entirely agree with Ghoshal's, especially for the energy dependences of the (α, n) and the (α, pn) reaction. The low-energy part of the (α, n) excitation function measured by McGowan et al. agrees rather with the present experiment than with Ghoshal's. The experiment of McGowan et al. is considered to be most accurate among the three for the energy values at the low-energy part. The disagreement in energy between Ghoshal's and the present experiment may have an influence on the discussion made by Eastman et al.[8] and John.[9] They have pointed out that the energy shift to fit Ghoshal's experiment to the compound nucleus theory is not exactly equal to the value derived from mass measurement.

* With regard to the interfering reactions of Ni^{61}, no corrections is applied to the present results.

The comparison between the alpha-particle reactions on Ni^{60} and the proton reactions on Cu^{63} is illustrated in Fig. 6. All the available cross sections of both reactions are compared schematically with the excitation energy of the compound nucleus, Zn^{64}. The binding energies of an alpha-particle to Zn^{64} and of a proton to Zn^{64} are deduced from the mass values which have recently been measured with high precision by Quisenberry, Scolman and Nier[19];

B_α=3.93 Mev and B_p=7.71 Mev. The magnitude of cross section obtained by Ghoshal is somewhat larger than that obtained by other authors in every case. And the energy values in the experiments of both Ghoshal and Meadows might not be so accurate that it seems inadequate to discuss strictly whether the discrepancy in energy is significant. However, it seems certain that the (α, n) and the (p, n) excitation function disagree in energy with each other by about 1 Mev. Further accurate experiment is desirable to see whether the discrepancy is significant. On the whole, this comparison is not necessarily in disagreement with the prediction from the compound nucleus theory; i.e. the relation $\sigma(\alpha, n):\sigma(\alpha, pn):\sigma(\alpha, 2n)=\sigma(p, n):\sigma(p, pn):\sigma(p, 2n)$ is roughly satisfied provided that the excitation energy of compound nucleus is the same.

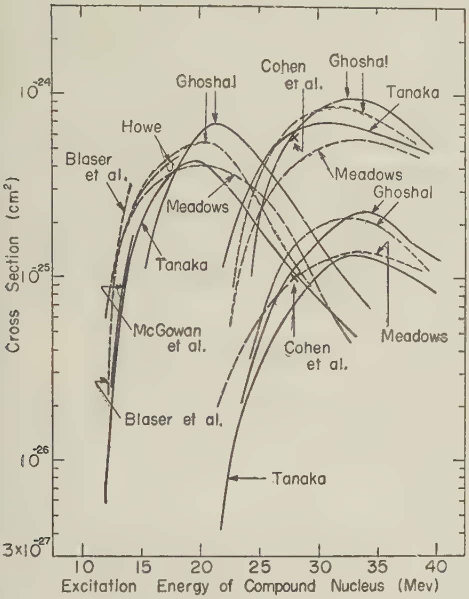

Fig. 6. The comparison between the alpha-particle reactions on Ni^{60} (solid curves) and the proton reactions on Cu^{63} (dashed curves), the compound nucleus Zn^{64} being the same for two cases.

- ○ $Ni^{60}(\alpha, p2n)Cu^{61}+Ni^{60}(\alpha, 3n)Zn^{61}$
- ---- Estimated curve of $\sigma(\alpha, p2n+\alpha, 3n)$ after subtraction of interfering reaction. (See: text)

The energy dependence of the ratio of $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ for Ni^{60} is shown in Fig. 7.

The excitation functions for the $(\alpha, \alpha pn)$ and $(\alpha, p2n+\alpha, 3n)$ reactions on Ni^{60} are also shown in Fig. 8. The $(\alpha, p2n+\alpha, 3n)$ cross section was estimated by subtracting the contribution of the $(\alpha, p+\alpha, n)$ cross section for Ni^{58}. (Dashed curve in Fig. 8)

Reactions of Ni^{62}

The excitation functions for the (α, n), (α, pn) and $(\alpha, \alpha p)$ reactions on Ni^{62} are shown in Fig. 9. The use of natural-nickel as target material made it impossible to distinguish between the $Ni^{62}(\alpha, n)Zn^{65}$ and the $Ni^{64}(\alpha, 3n)Zn^{65}$ cross section above the threshold for the latter reaction. And, what is worse, the $Ni^{62}(\alpha, pn)Cu^{64}$ and the $Ni^{61}(\alpha, p)Cu^{64}$ cross section could not be distinguished exactly. The yield of producing Cu^{64} was classified into two reactions assuming a smooth curve of each excitation function. The estimated excitation functions are indicated by the dashed curves in Fig. 9 and Fig. 11. The rough estimation may not cause much ambiguities.

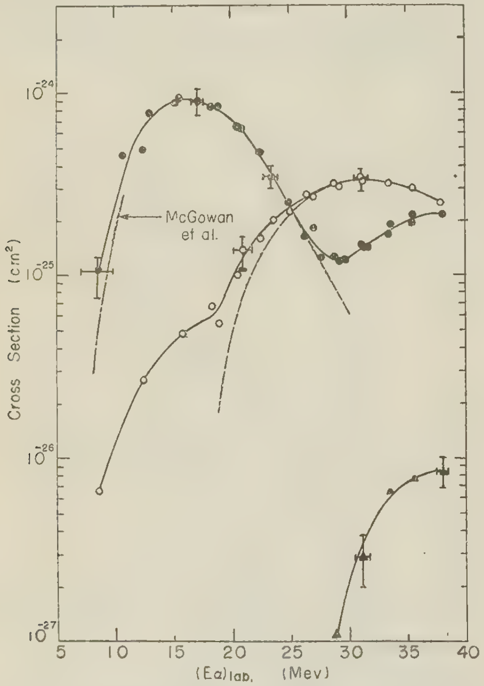

Fig. 9. Excitation functions for the alpha-particle reactions on Ni^{62}.

● $Ni^{62}(\alpha, n)Zn^{65}$ ○ $Ni^{62}(\alpha, pn)Cu^{64}$
▲ $Ni^{62}(\alpha, \alpha p)Co^{61}$
---- Estimated curve after subtraction of interfering reaction. (See: text)

The present results for the alpha-particle reactions on Ni^{62} are compared in Fig. 10 with the corresponding proton reactions on Cu^{65}, with the excitation energy of the compound nucleus, Zn^{66}. The binding energies of an alpha-particle to Zn^{66} and of a proton to a Zn^{66} are assumed 4.56 Mev and 8.90 Mev, respectively. These values are deduced from the mass values measured by Quisenberry et al.[19] The prediction from the compound nucleus theory seems to hold roughly and the discrepancy in energy between the experiment and the theory can not be observed. However, the difference between the value of cross section for the $Ni^{62}(\alpha, pn)Cu^{64}$ reaction and that for the $Cu^{65}(p, pn)Cu^{64}$ reaction

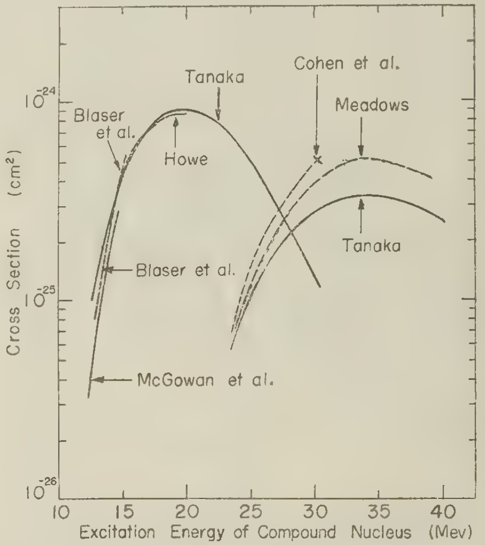

Fig. 10. The comparison between the alpha-particle reactions on Ni^{62} (solid curves) and the proton reactions on Cu^{65} (dashed curves), the compound nucleus Zn^{66} being the same for two cases.

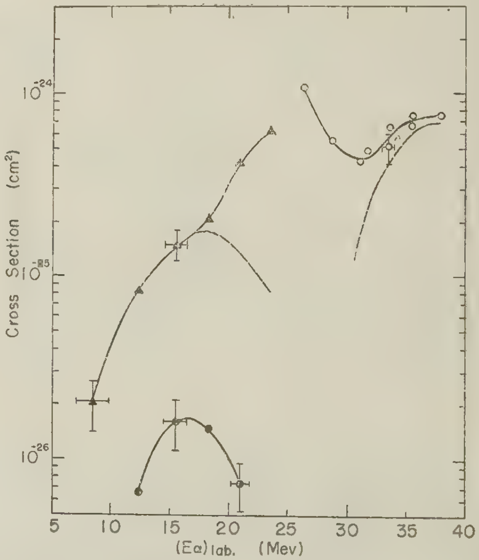

Fig. 11. Excitation functions for the alpha-particle reactions on Ni^{61} and Ni^{64}.

● $Ni^{64}(\alpha, p)Cu^{67}$
---- Estimated curve after subtraction of interfering reaction. (See: text)

should be again checked experimentally.*

Reactions of Ni^{61} and Ni^{64}

The results of the reactions on Ni^{61} and Ni^{64} are shown in Fig. 11. The excitation functions for the $Ni^{61}(\alpha, p)Cu^{64}$ and the $Ni^{64}(\alpha, 3n)Zn^{65}$ reaction were estimated by subtracting the contribution of the $Ni^{62}(\alpha, pn)Cu^{64}$ and the $Ni^{62}(\alpha, n)Zn^{65}$ reaction, respectively.

All the excitation functions measured in this study may be useful in the comparison with the evaporation calculation based on the statistical theory of nuclear reaction. However, such a discussion is not made in this paper.

Acknowledgements

The close association with Messrs. M. Furukawa, S. Iwata, M. Yagi and Dr. H. Amano has contributed immeasurablly to this work, and their continued colaboration and helpful advice are gratefully acknowleded. Thanks are also due to Prof. I. Nonaka and the other members of staff of Low Energy Division in this Institute for their constant interest and encouragement. The cyclotron bombardments could not have been done without the co-operation and help of Messrs. T. Karasawa, A. Suzuki, H. Ogawa and the other Cyclotron Crew of this Institute. The continued assistance of Messrs. T. Ando, A. Iguchi and M. Chiba throughout this work are also acknowledged.

Appendix

A. Chemical Procedures

For shorter-lived nuclides

The target foil was dissolved in 2 ml of conc. HCl with the aid of 10 drops of 30% H_2O_2. The excess of H_2O_2 was decomposed by adding 25% $NaHSO_3$. After the addition of zinc carrier (200 γ of Zn), 6N–NH_4OH was added to the solution until the blue color of Ni-ammin complex appeared. The solution was neutralized to methyl orange with 1N–HCl. 5 ml of 5% NH_4I and 3 ml of 3% methyl violet were added. The Cu-precipitate was separated by centrifuge and washed with 10 ml of 0.5% NH_4I. The precipitate was dissolved in ethyl alcohol and submitted to counting. The united solution of supernatent and washing was adjusted to pH 10～12 by adding 6N–NH_4OH drop by drop, and then 5 ml of 5% NH_4SCN and 3 ml of 3% methyl violet were added. The zinc precipitate was separated by centrifuge, and dissolved in alcohol.

For longer-lived nuclides

The target foil was dissolved in aqua regia.

* *Note added in proof*—H. P. Yule and A. Turkevich [Phys. Rev. **118** (1960) 1591] measured the $Cu^{65}(p, pn)Cu^{64}$ cross section in the energy range 82–426 Mev. Their result is lower than Meadows's by a factor of about 0.6. The value of Yule and Turkevich reduces the discrepancy in the magnitude of cross section between the proton and the alpha-particle reaction.

the solution was evaporated nearly to dryness and the residue was dissolved in 1 ml of 8N–HCl. The solution was then passed through a column (13 mm dia. × 150 mm high) of anion exchange resin Dowex-1X 8 (200～400 mesh) followed by washing with about 25 ml of 8N–HCl. Nickel was eluted with 8N–HCl, cobalt with 4N–HCl, copper with 2.5N–HCl and zinc with 2N–HNO_3.

B. Counting and Calibration Procedures

The nuclear data shown in Table III were used for the calculation of disintegration rates. These data were obtained mainly from the compilation of Strominger et al.[29]

Co^{56} The γ-rays above 1.6 Mev were measured in a well-type NaI scintillation counter to discriminate against other activities. The disintegration rate was obtained by comparing the sample with a calibrated Co^{56} standard source. (See: reference 3 for the detailed calibration procedures)

Co^{57} The 122 and 137 kev γ-ray photopeaks were counted in an 1−3/4 in. dia. × 2 in. high well-type NaI scintillation counter. The counting efficiency was assumed as 0.85. (See: reference 1)

Co^{58} The 810 kev γ-ray photopeak was counted in a well-type NaI scintillation counter. The contribution of Co^{56} was subtracted by comparing the sample with a Co^{56} standard source. (See: reference 1 for the detailed subtraction procedure). The disintegration rate was obtained by applying the intrinsic photopeak efficiency to the counting rate. (See: reference 4)

Co^{61} The decay of cobalt fraction was followed with the GM counter whose efficiency had been calibrated with various β^--emitters of known disintegration rates.

Ni^{56} After Ni^{56} was allowed to decay to Co^{56}, the disintegration rate of Ni^{56} was measured as Co^{56}.

Ni^{57} After Ni^{57} was allowed to decay to Co^{57}, it was counted as Co^{57}.

Cu^{60} Immediately after the bombardment, the target foil was sandwiched by two brass plates of sufficient thickness to stop the positrons, and the two 0.51 γ-rays were detected in coincidence with two 1−1/2 in. dia. × 1 in. high NaI scintillation counters positioned 180° from each other with respect to the source. The decay was followed for about 10 hours to distinguish Cu^{60} from Cu^{61}, Cu^{62} and Zn^{63}. The counting efficiency of the instrument was calibrated by the Na^{22} standard source, the absolute activity of which had been determined by both the γ-γ coincidence and the $4\pi\beta$-counting method. In the experiment with chemical separation, copper fraction counted similarly. The counting with a calibrated GM counter was also performed.

Cu^{61} After chemical separation, the positrons were counted with a calibrated GM counter. The decay was also followed with a $4\pi\beta$-counter to determine the disintegration rate. In the experiment with short time irradiation, the decay was followed by measuring the coincident annihilation radiation. (See: Cu^{60}) The disintegration rates from the different experiments agreed with each other within 10%.

Cu^{62} Without chemical separation, the coincident annihilation radiation was measured. (See: Cu^{60})

Cu^{64} and *Cu^{67}* The disintegration rates were obtained by following the decay of copper fraction with a calibrated GM counter.

Zn^{62} The decay of zinc fraction was followed with a calibrated GM counter. A $4\pi\beta$-counting was also performed.

Zn^{63} After chemical separation, an aliquot of zinc fraction was counted with a calibrated GM counter and another aliquot was submitted to counting the coincident annihilation radiation. (See: Cu^{60})

Zn^{65} The 1.11 Mev γ-ray photopeak was counted in a well-type NaI scintillation counter. The photopeak efficiency was obtained by comparing the sample with a Zn^{65} standard source.

Excitation Function for the Reaction $B^{11}(p, n)C^{11}$ up to E_p=15 MeV and Energy Levels of C^{12}

By Michiaki FURUKAWA, Yoshihide ISHIZAKI, Yoshihiro NAKANO*,
Tadashi NOZAKI**, Yoshio SAJI and Shigeo TANAKA
Institute for Nuclear Study, Universty of Tokyo, Tanashi-machi, Tokyo

(Received August 5, 1960)

Excitation function for the $B^{11}(p, n)C^{11}$ reaction was measured by the activation method with improved energy resolution for the proton energies ranging from 4.7 to 15.0 MeV. The excitation function exhibited rather clear peaks at proton energies of 8.5, 9.9, 10.9, 11.5 and 13.6 MeV in the laboratory system and a broad peak at the energy region between 13.8 MeV and 14.5 MeV. A considerable number of uncertain peaks were also observed. The excitation function for the $O^{16}(p, \alpha)N^{13}$ reaction was also obtained above E_p=9.7 MeV.

§1. Introduction

The excitation function for the $B^{11}(p, n)C^{11}$ reaction was measured using a stacked-foil method by Blaser *et al.*[1] for the proton energies up to 6.7 MeV; by Kalinin, Ogloblin and Petrov[2] up to 12.2 MeV; and by Hintz and Ramsey[3] up to 100 MeV. The excitation function below 5.5 MeV was also confirmed by Gibbons and Macklin[4] from the measurement of total neutron yield. The energy levels of C^{12} were compiled by Ajzenberg-Selove and Lauritsen[5].

Some of the present authors[6] are under study about the angular distributions of neutrons from the $B^{11}(p, n)C^{11}$ reaction at various incident proton energies from 8 to 15 MeV. For this work, it is desirable to obtain more precise information on the energy dependence of the cross sections over the region $E_p=8\sim15$ MeV.

In the experiment reported here, the excitation function for the (p, n) reaction on B^{11} was measured by the activation method for the proton energies ranging from 4.7 MeV to 15.0 MeV. Borax was used as a target material, so that the excitation function for the $O^{16}(p, \alpha)N^{13}$ reaction above $E_p=9.7$ MeV was simultaneously obtained.

§ 2. Experimental

The external beam from the 160 cm INSJ variable energy cyclotron was used to irradiate the targets. The deflected beam was focused by a pair of quadrupole magnets and a sector-type focusing magnet, and was collimated successively by narrow graphite slits. The energy dependence of the cross sections for the reaction $B^{11}(p, n)C^{11}$ was measured by a stacked-foil technique in which every ten target foils were stacked. In different seven bombardments, the initial energies were 15.0, 14.0, 13.0, 11.5, 10.0, 8.5 and 7.5 MeV which were calculated from the cyclotron frequencies. Each stack covered a range of from 1.5 to 2.8 MeV and this range overlapped that of adjacent stacks by about 0.5 MeV. The bombardments were generally performed with the protons of 75 μC for 3.5 minutes. The energy uncertainty of the incident beam was estimated to be less than ±1%. The beam was monitored by a Faraday cup and the total charge of the beam was measured by a 100% feed-back type current integrator.

The targets were of sodium borate bihydrate ($Na_2B_4O_7 \cdot 2H_2O$) prepared as follows. The powdered pure borax ($Na_2B_4O_7 \cdot 10H_2O$) was suspended in acetone with polyvinyl acetate as a binding material, and deposited onto a thin aluminum backing fail after evaporation of acetone. Then, it was heated in an oven at about 80°C in order to convert $Na_2B_4O_7 \cdot 10H_2O$ into $Na_2B_4O_7 \cdot 2H_2O$. The boron contents in some targets were chemically analyzed

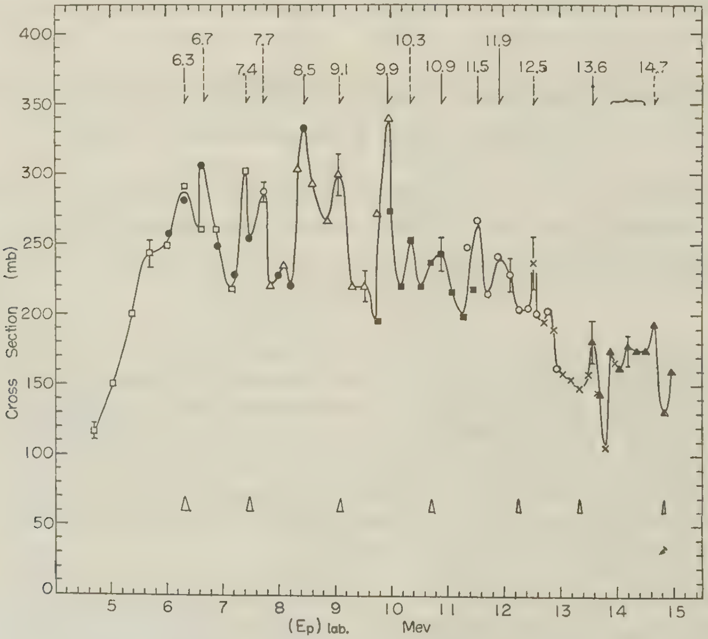

Fig. 1. Excitation function for the reaction $B^{11}(p, n)C^{11}$. The different marks of points represent the results from the separate bombardments, while the solid line is the composite curve for the excitation function. The peaks are pointed out by the arrows with the energies in the laboratory system. (The arrows with dashed lines indicate the peaks less certain than those indicated by solid lines.) The vertical bars at some experimental points indicate the estimated errors of relative cross sections. The wedges show the energy resolution in the targets.

after bombardments and they were consistent with the form of $Na_2B_4O_7 \cdot 2H_2O$. The thicknesses of targets were almost about 2 mg/cm^2 and the inhomogeneity in thickness was estimated to be less than 10%. The energy loss in 1 mg/cm^2 of $Na_2B_4O_7 \cdot 2H_2O$ was 30 keV for the 15.0 MeV protons and 62 keV for the 6.0 MeV protons.

After the bombardment, the target was sandwiched by brass plates of appropriate thickness, and the two 0.51 MeV γ-rays from positron annihilation were detected in coincidence by two 1-1/2 in. dia. ×1 in. high NaI scintillation counters positioned 180° from one another with respect to the source. The decay was followed for about 2 hours in order to distinguish between the activity of C^{11} from the $B^{11}(p, n)C^{11}$ reaction and that of N^{13} from the $O^{16}(p, n)N^{13}$ reaction. The disintegration rate was obtained by applying the counting efficiency calibrated with a Na^{22} standard source, the absolute activity of which had been determined by both the γ-γ coincidence and the 4π β-counting method.

§ 3. Results

The excitation function for the $B^{11}(p, n)C^{11}$ reaction is shown in Fig. 1.

The prominent peaks occur at energies of 8.5 MeV and 9.9 MeV in the laboratory system. These two peaks appeared already in the previous work of Kalinin *et al.*[2] and were confirmed in this experiment with improved energy resolution. There is also evidence that fairly clear peaks might be present at 6.3, 6.7, 7.4, 7.7, 9.1, 10.3, 10.9, 11.5, 11.9, 12.5, 13.6 and 14.7 MeV, among which the four peaks at 10.9, 11.5, 11.9 and 13.6 MeV might be most reliable. It is not certain whether there are separate peaks at 6.3 and 6.7 MeV or whether there might be one resonance instead of two. And it is similarly situated for the peaks at 7.4 and 7.7 MeV. An improved resolution was not attained for the low-energy portion of the excitation function. It can be seen that a broad peak appears at the energy region between 13.8 MeV and 14.5 MeV. In this broad peak a few overlapping resonances must be involved. Further experiment is desirable for the confirmation of a number of uncertain peaks in this experiment.

The absolute cross section obtained here agrees well with that reported by Kalinin *et al.*[2], but differs rather greatly from those of Blaser *et al.*[1] and of Hintz and Ramsey[3].

The enegy levels of C^{12} derived from this experiment are shown in Fig. 2, together with the references of Blaser *et al.*[1] and Kalinin *et al.*[2]

The exciation function for the reaction O^{16}

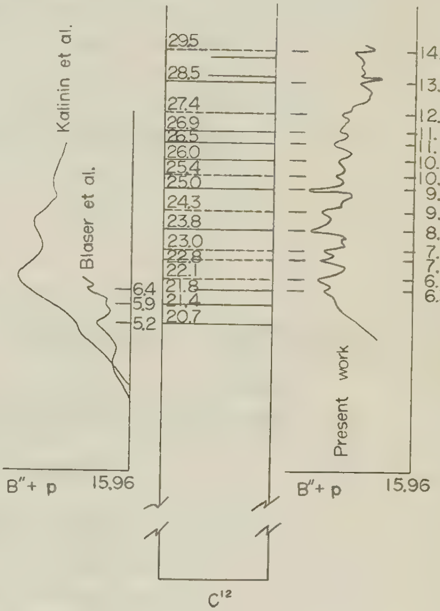

Fig. 2. Energy levels of C^{12} derived from this experiment. Energy values are plotted vertically in MeV. Uncertain levels are indicated by dashed lines; broad levels are cross-hatched. Excitation functions for the $B^{11}(p, n)C^{11}$ reactions are shown schematically, with the yield plotted horizontally and the bombarding energy vertically. Bombarding energies are indicated in laboratory coordinates and plotted to scale in centre-of-mass coordinates.

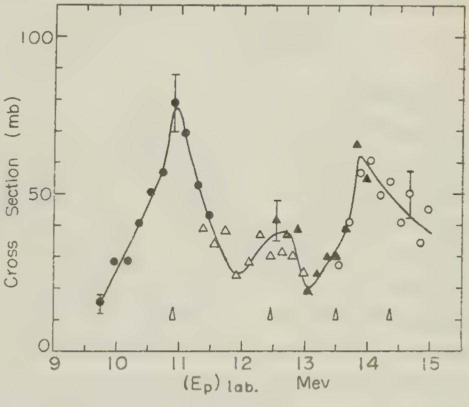

Fig. 3. Excitation function for the reaction $O^{16}(p, \alpha)N^{13}$.

$(p, \alpha)N^{13}$ is also shown in Fig. 3. This agrees well with the previous work of Whitehead and Foster[7].

Acknowledgements

Authors are indebted to Mr. A. Iguchi for his help in preparing the targets. They are also grateful to Dr. K. Saito for his help in chemical analysis and to Mr. A. Suzuki for his assistance in cyclotron operation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 12, DECEMBER, 1960

The $N^{14}(d, n)O^{15}$ Reaction in the Energy Range from 1.5- to 2.9-MeV

By Susumu MORITA, Nawoyuki KAWAI, Yorio GOTÔ,
Takashi MAKI, and Masahiro MUKAE.

Department of Physics, Faculty of Science,
Kyushu University, Fukuoka.

(Received August 8, 1960)

The angular distributions of neutrons emitted from the $N^{14}(d, n)O^{15}$ reation were investigated by means of the neutron detector made of a thin plastic scintillator to eliminate the gamma ray background, at the deuteron energies of 1.53-, 1.72-, 1.96-, 2.24-, 2.54-, 2.65_5-, and 2.90-MeV.

The results were compared with the stripping theory including the heavy particle stripping, and qualitative agreements were obtained. The excitation curve of this reaction was also estimated and compared with those of the $N^{14}(d, p)N^{15}$ and $N^{14}(d, \alpha)C^{12}$ reactions. The excitation curves of the $N^{14}(d, n)$ and $N^{14}(d, p)$ reactions show similar resonance-like structures, while that of the $N^{14}(d, \alpha)$ reaction shows somewhat different behavior.

§ 1. Introduction

In our previous experiment[1], the angular distribution of the $N^{14}(d, n)O^{15}$ reaction at the deuteron energy of 1.96 MeV was measured and a sharp increase in the backward directions, besides the forward peak was found. And also, one of the authors[2] observed the excitation curves of this reaction at the directions of 0°, 90°, and 165° to the deuteron beam in the energy range of deuteron from 1.0- to 2.2-MeV. These results suggested that the angular distributions change remarkably with deuteron energy. J. L. Weil and K. J. Jones[3] observed the excitation curve at the direction of 0° at deuteron energies 1.0- to 5.5-MeV.

The aim of this experiment is to observe in detail the angular distributions in the energy range of deuterons from 1.5- to 2.9-MeV with small intervals of deuteron energy and to obtain informations concerning the reaction mechanism, by comparing the angular distributions and excitation curve with theory, Retz-Schmidt and Weil[4] have made the same measurements in the energy range of deuteron from 0.91- to 5.27-MeV with larger energy intervals than in this work.

§ 2. Experimental Procedure

The magnetically analyzed deutron beam from the Van de Graaff accelerator of Kyushu University passed through a window of 0.00005- or 0.0001-in. thick nickel foil, and entered into the target chamber filled with nitrogen gas. Fig. 1 shows a sectional view of the target chamber and beam duct. The amount of materials constructing the beam duct and the target chamber was minimized to reduce the scattering and absorption of neutrons in these materials, and the inner surface of the wall exposed to the deuteron beam was covered with silver plates to avoid neutron production. The target chamber, 2.0 cm in depth, was filled with commercial nitrogen gas to the pressure of 20.0 cm Hg and the energy loss of deuteron of 2 MeV in the nickel foil was estimated to be 120- and 320-KeV for the two foils respectively, and the energy loss in the nitrogen gas was estimated to be 140 KeV.

A disk of thin plastic scintillator of 1 mm in thickness and 10 mm in diameter was used for neutron detection at bombarding deuteron energies below 2.24 MeV and that of 1.5 mm in thickness and of the same diameter was used at deuteron energies above 2.54 MeV.

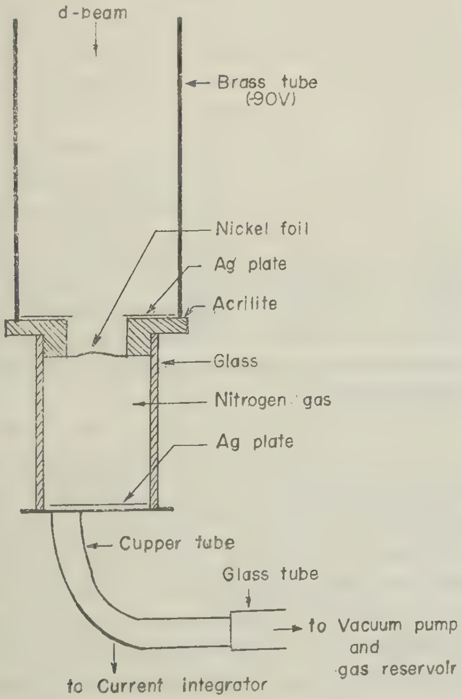

Fig. 1. Sectional view of the target chamber and the beam duct.

The plastic scintillator was mounted on a EMI 6097 photomultiplier tube, and output pulses from this tube were linearly amplified and fed to a 20-channel pulse-height analyzer. The pulse-height spectra obtained by this manner are similar to those shown in the previous paper[2]. The principle of discrimination of the associated gamma rays by means of a neutron detector of this type, has been described previously.

The background due to scattered neutrons was measured by inserting an iron absorber between the target chamber and the detector, and that due to *d-d* neutrons produced in deuterium contaminants on the inner surface of the chamber wall was measured by deuteron bombardment of the empty chamber, and they were found to be negligible.

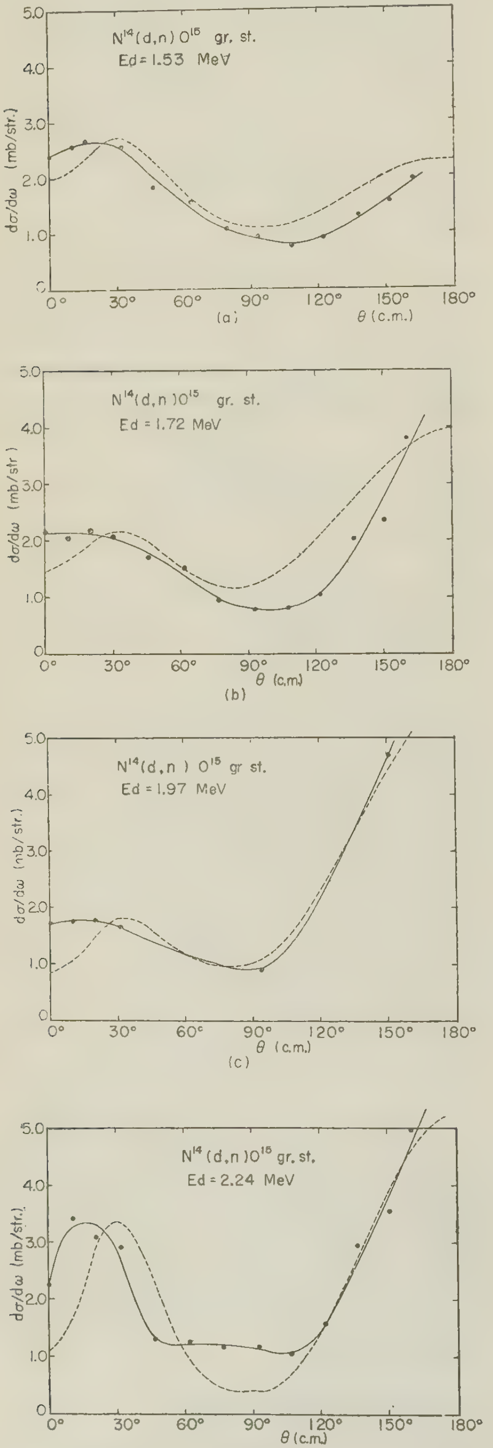
The pulse-height spectra obtained by the 20-channel pulse-height analyzer, were corrected for escapes of recoil protons from the scintillator, add then transformed to the energy spectra using the pulse-heigot vs. proton-energy relation for the plastic scintillator. Then, the energy spectra were integrated from the energies of 85% of maximum energies to the maximum energies, to give the measures of neutron intensities, since this portion of the spectrum represents the energy distribution of recoil protons in the plastic scintillator and include no γ-ray background.

Either of the two plastic scintillators of 0.1 cm and 0.15 cm in thickness, having same diameters of 1.0 cm, mounted on a DuMont 6291 photomultiplier tube was used as a monitor counter according as energies of neutrons to be counted. The monitor counter was placed at the direction of 90° and at a distance of 14.0 cm from the center of the target.

In order to obtain the angular distribution, the above mentioned integrals of energy spectra of recoil protons obtained at different detector angles and at a certain deuteron energy, were corrected for the variation of the *n-p* scattering cross section with neutron energy and normalized to a definite number of monitor counts.

§ 3. Results and Discussion

Fig. 2 shows the seven angular distributions obtained at the deuteron energies of 1.53-, 1.72-, 1.96-, 2.24-, 2.54-, 2.68-, and 2.90-MeV. The angular resolutions ranged from ±4° at the detector angle of 0°, to ±6° at 90°. The errors shown in the figure are statistical ones, which range from 5% to 2%. Besides the statistical uncertainties, uncertainties in the evaluation of neutron intensities from the pulse-height spectra of recoil protons in the plastic scintillator, and those in the estimation of neutron scatterings in materials present between the target and detector, and so on, were considered and the over-all relative uncertainties of every experimental points in angular distribution were estimated to be less



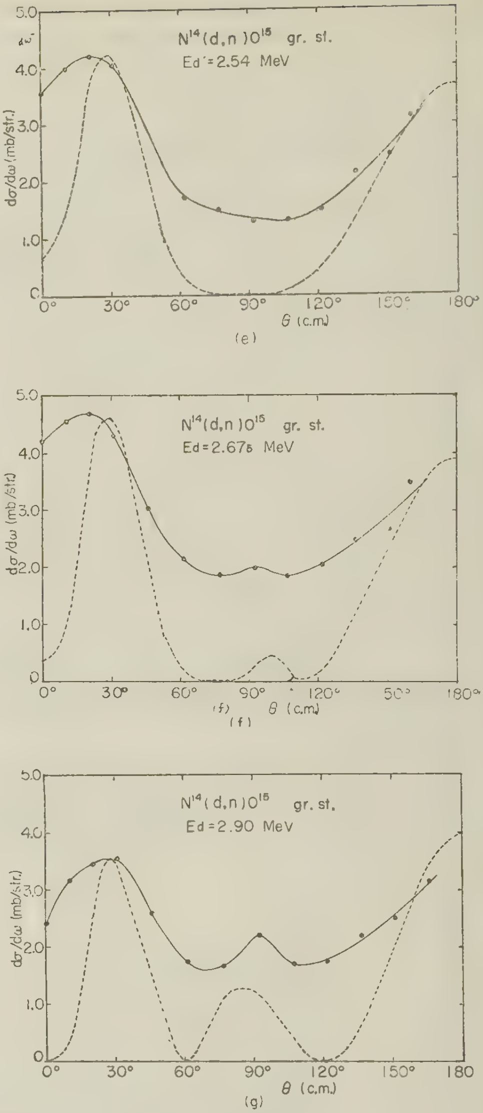


Fig. 2. The angular distributions of the neutrons from the N^{14}(d, n)O^{15} reaction. The energy of deuteron is shown for each distributions. Solid curves are experimentals, and dotted curves are the theoreticals, calculated by the heavy particle stripping process.

than 10%. The relative uncertainties of the total cross sections derived from the angular distributions were thought to be about to be about 15%.

These angular distributions are consistent with those obtained by Retz-Schmidt and Weil[4] at the deuteron energies of 1.50_7-, 1.88_1-, and 3.13_1-MeV, although some discrepancies are found between the angular distribution obtained by us at $E_d=2.54$ MeV and that obtained by Retz-Schmidt and Weil at $E_d=2.58$ MeV. At this deuteron energy, their result shows smaller rise in the backward directions than ours. As was expected from the previous work[2], the shape of the angular distribution at the backward directions varies remarkably with the deuteron energy, but the forward peak does not. Moreover, it must be noted that this behavior of angular distribution of neutrons from the $N^{14}(d, n)O^{15}$ ground state reaction shows a strong resemblance to that of protons from the $N^{14}(d, p)N^{15}$ ground state reaction in the same range of deuteron energy, obtained in our laboratory[5]. We attempted to analyze these angular distributions of the $N^{14}(d, n)O^{15}$ ground-state reaction with the heavy particle stripping theory of Owen and Madansky[6]. Although this theory includes some inconsistency, as was pointed out by Hasegawa and Ichikawa[7], we used the formula of Owen and Madansky because of its simplicity. Their formula would be sufficient for qualitative discussions.

The heavy particle stripping means the stripping of neutron from the target N^{14} nucleus and the capture of N^{13} by the deuteron. The orbital angular momentum of captured N^{13} are limited by the conservation of angular mementum and parity. The ground state of O^{15} has been known to have spin of 1/2 and odd parity, the deuteron has spin of one and even parity, and the N^{13} core has odd parity. So that the orbital angular momentum l_c of the captured N^{13} must be limited to 0 or 2. Since the d-wave penetrability is much less than that for s-wave, we can neglect the $l_c=2$ terms.

According to Owen and Madansky,

$$\frac{d\sigma}{d\omega}\propto\left|G_D(K_1)j_1(k_1R_1)+\frac{\lambda_2}{\lambda_1}G_H(K_2)j_0(k_2R_2)\right|^2 ,$$

where,

$$G_D(K_1)=\frac{1}{K_1^2+0.0529\times10^{26}} ,$$

$$G_H(K_2)=\left[\frac{1}{1.423\times10^{26}-K_2^2}+\frac{1}{0.5098\times10^{26}+K_2^2}\right]\times[0.1423\sin(K_2r_N)+j_1(K_2r_N)] ,$$

λ_2/λ_1 is the ratio of the amplitude for the heavy particle stripping to that of the ordinary deuteron stripping. Other symbols have usual meanings as quoted in reference[6]. This ratio is assumed to be a function of deuteron energy and was adjusted to get the fit with experimental results. The radius and depth of the potential well used to determine the neutron wave function for the calculation of $G_H(K_2)$, were 3.37×10^{-13} cm and 40 MeV, respectively, and to assume these values means

$$\alpha_N r_N=\left[\frac{2M}{\hbar^2}|E-V|\right]^{1/2}r_N=4.03 ,$$

$$\beta_N r_N=\left[\frac{2M}{\hbar^2}|E|\right]^{1/2}r_N=2.41 .$$

The value of 7.0×10^{-13} cm was chosen for both interaction radii, R_1 and R_2.

Although these interaction radii, as well as the ratio of amplitudes λ_2/λ_1, can be taken as adjustable parameters depending on the deuteron energy, we could obtained, as can be seen in Fig. 3, qualitative agreements with the experimental angular distributions with this constant value of interaction radii.

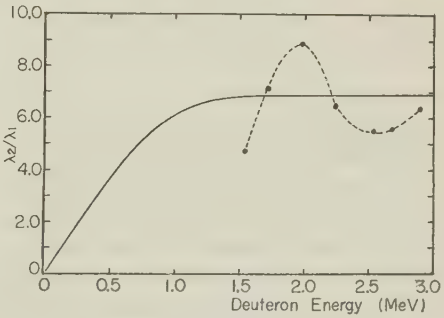

Fig. 3. The ratio of amplitude λ_2/λ_1 of the heavy particle stripping to that of the ordinary stripping.

In the analysis of the reaction $B^{11}(d, n)C^{12}$ [6], these interaction radii were assumed to be constant independent of deuteron energy but Weil and Jones[3], and Hasegawa and Ichikawa[7] used energy dependent interaction radii. In the formula of Ichikawa and Hasegawa, one more adjustable parameter was introduced in the interference term of the both stripping processes. Accordingly, much better fit to the experimental distributions would be obtained by using Ichikawa's formula. The values of λ_2/λ_1, which were adopted in the calculation of the curves in Fig. 2, were plotted against the deuteron energy and are shown in Fig. 3 connected with a broken line. As was pointed out by Retz-Schmidt and Weil, λ_1/λ_1 does not show monotone increase with deuteron energy, in contract to the cases of reactions $B^{11}(d, n)$ and $N^{15}(d, n)$, where the ratio increases gradually up to the deuteron energy corresponding to the height of Coulomb barrier, which is 2.2 MeV and then becomes nearly flat, as is shown by the full curve in this figure. Anomalously large value of λ_2/λ_1 was found at the deuteron energy of 2 MeV, where the excitation curve shows a small peak and the angular distribution has a remarkable rise in the backward direction.

In order to obtain some information on the reaction mechanism, the excitation curve of this reaction is shown in Fig. 4, together with the data obtained by Retz-Schmidt and Weil and also with the excitation curves of the $N^{14}(d, p)N^{15}$ and $N^{14}(d, \alpha)C^{12}$ ground-state reactions, which were obtained in our laboratory[5].

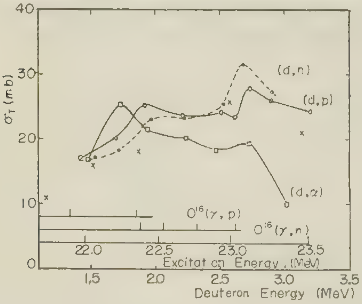

Fig. 4. Excitation curves of the reactions $N^{14}(d, n)$, $N^{14}(d, p)$[8], and $N^{14}(d, \alpha)$[8] reactions. Retz-Schmidt and Weil's results on the $N^{14}(d, n)$ reaction are also shown with crosses.

The absolute valve of cross section of the $N^{14}(d, n)$ reaction in the present experiment, was determined by normalizing the angular distribution to the absolute cross section obtained at the direction of 30° by Retz-Schmidt and Weil.

As the reactions $N^{14}(d, n)O^{15}$ and $N^{14}(d, p)N^{15}$ are considered to be mirror reactions, it may be natural that the angular distributions of these reactions behave quite similarly, whether the reactions proceed through the compound nucleus formation or the striping process. Moreover, it must be noted that the excitation curve of the $N^{14}(d, n)$ reaction shows similar behavior to that of the $N^{14}(d, p)N^{15}$ reaction and some resonance-like structures were found in these excitation functions. We can not decide whether these structures are due to the compound nucleus formation or the distortion effects of the wave function in the stripping reaction. As for the (d, α) reaction, such a surface direct interaction has been considered as double pick-up process. However, it will be reasonable to consider that in the lower energy range of deuteron the compound nucleus formation is more predominant than in the (d, n) and (d, p) reactions, and in fact, the angular distributions of α-particles from the $N^{14}(d, \alpha)C^{12}$ ground-state reaction have quite different behavior, showing rapid change with deuteron energy[8]. Nevertheless, in the excitation curve of the $N^{14}(d, \alpha)$ reaction, the resonances are less predominant than in the other two curves, and the dip in this curve, observed at deuteron energy of 2.7 MeV, corresponds to the peaks in the excitation curves of (d, p) and (d, n) reactions. This fact will suggest that the resonance-like structures found in the excitation of (d, p) and (d, n) reactions are to be interpreted by the distortion effect of wave function in the stripping reaction. But, the effects of compound nucleus formation on the (d, p) and (d, n) reactions can not be entirely excluded.

The level structure of the compound nucleus O^{16} obtained from other reactions[9] are shown in the lower insert of Fig. 4. Most of these were observed in the breaks of the yield curves of induced activity. However, the levels, observed in the photo-reactions, are not necessarily found in the present excitation curves because of the isotopic spin selection rule. As the isotopic spins of N^{14} and deuteron are equal to zero ($T=0$), the levels of compound nucleus O^{16}, excited by the deuteron bombardment of N^{14}, must have the isotopic spin of zero. On the other hand, the levels of O^{16}, excited by photon, are expected to have the isotopic spin of unity.

The authors express their cordial thanks to Prof. I. Nonaka for his discussions and all the other members of the nuclear laboratory of Kyushu University for their cooperation throughout this work.

Gamma Radiation Following the Decay of Dy^{165}

By Akira HASHIZUME, Tan TAKAHASHI, Yoshihiko TENDO
and Yohko ENOMOTO

The Institute of Physical and Chemical Research, Bunkyo, Tokyo

(Received June 16, 1960)

The transition of gamma-rays in Ho^{165} emitted in the decay of Dy^{165} (140 min) has been studied with γ-γ coincidence and sum coincidence techniques. In addition to previously reported gamma-rays, (178), ~483, and ~515 keV gamma-rays are found in coincidence experiment. About 1 MeV gamma-rays is resolved into 998 and 1055 keV gamma-rays. A proposed decay scheme is presented. The measured half-life of Dy^{165} is 142.4 ± 0.5 min.

§ 1. Introduction

The strong radioactivity of dysprosium induced by slow neutrons was first observed by Marsh and Sugden[1] and independently by Hevesy and Levi[2]; its half-life was reported to be 2.5 hours. Later, this activity was assigned to mass 165 by Inghram *et al.*[3], and the most accurately measured half-life was 139.19 ± 0.14 min.[4] The activity with a half-life of 1.25 min. was first reported by Flammersfeld[5] and was assigned to a metastable state of Dy^{165} by Inghram[6]. Since then, the decay of Dy^{165} has been investigated by a number of authors[7]–[12], yet its decay scheme cannot be regarded as thoroughly investigated.

The beta-ray energies measured by Slätis[8] with a magnetic spectrometer were reported to have the values 0.24, 0.42 and 0.88 MeV, while, according to Bonhoeffer *et al*[12], they are 0.305, 1.00, 1.22 and 1.3 MeV which were found by the use of the beta- and gamma-ray coincidence technique with scintillation counters. In addition to the several gamma-ray previously reported[11], Bonhoeffer found 555 keV gamma-rays. The largest energy value of the gamma-rays reported is nearly 1 MeV, and the authors have resolved this into two gamma-rays, 998 and 1055 keV in the investigation of gamma-ray transitions with a sum coincidence technique, and the decay scheme of Dy^{165} is considered.

§ 2. Experimental Procedure

The gamma-ray sources of dysprosium were produced in the research reactor JRR-1* by neutron irradiation of dysprosium oxide** of the spectrographic purity of 99.9%. After one or two hour irradiation the samples were left to decay for few hours to allow the short lived activities to die away.

---

* Japan Atomic Energy Research Institute at Tokai.

** Obtained from Société des Terres Rares, Paris.

The gamma-rays were investigated with a NaI(Tl) crystal of 1″ diameter and 1″ height, optically coupled to a 6292 DuMont photomultiplier, together with a sum conincidence[14] and a coincidence scintillation spectrometers. A schematic diagram of the sum coincidence spectrometer is shown in Fig. 1. The output pulses from White cathod-followers (CF-1, CF-2) are clipped by 1 m of RG/65-U cable and make to either into a linear adding network. The linear adding network and the adjustment of the height of the pulses from two counters with potentiometers are nearly the same as described by Hoogenboom[13]. The accidental coincidence is examined by a delay line either connected to the adding network or inserted between the output of a single channel pulse height analyzer and the gate input of a multichannel analyzer. Pulse heights are analyzed with a 256 channel pulse height analyzer which is gated with 2 μsec pulses of the output of a single channel pulse height analyzer. The energy resolution of the sum coincidence spectrometer examined with Co^{60} was 5.6% at 1.33 MeV. The gamma-sources used to calibrate the energy scale of the spectrometer over the range from 75 to 2500 deV were Co^{60}, Se^{75}, Cs^{137} and Hg^{203}.

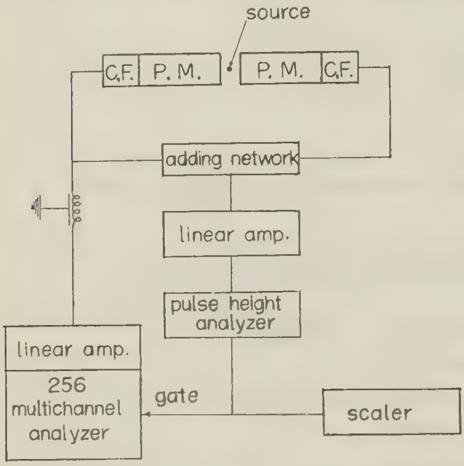

Fig. 1. Block diagram of the sum coincidence spectrometer.

§ 3. Experimental Results and Conclusions

Fig. 2 shows the gamma-ray spectra of dysprosium obtained with a single crystal scintillation spectrometer. The curve 1 shows the spectrum obtained with the distance of 20 cm between the source and the surface of the crystal and the curve 2 that with the distance of 3 mm to indicate the summing effect. Previously reported 1 MeV gamma-ray was resolved into two photopeaks of 998±5 and 1055±5 keV gamma-rays. It is evident from the curve 1 and 2 that the 998 keV gamma-ray reveals the summing effect. This indicates that the gamma-rays emitted from the level of this energy decay partly in cascade to the ground state. The decay of these two peaks were followed for 16 hours, the half-life of which was found to be 144 min proving that the peaks are caused by the gamma-rays from decaying Dy^{165}. The other gamma-ray energies were 95±2, 277±5, 364±6, 577±6, 627±4, 714±4 keV. The gamma-ray spectrum was also examined by using a large NaI(Tl) crystal (4″φ×1″1/2), and it is concluded that the 557 keV peak is neither Compton peak nor a scattering peak but a photopeak. The 1 MeV gamma-ray did not resolve into two peaks when the large crystal was used.

A least-square analysis of the decay curve obtained with the total counts of a scintillation counter yielded for Dy^{165} the half-life of 142.4±

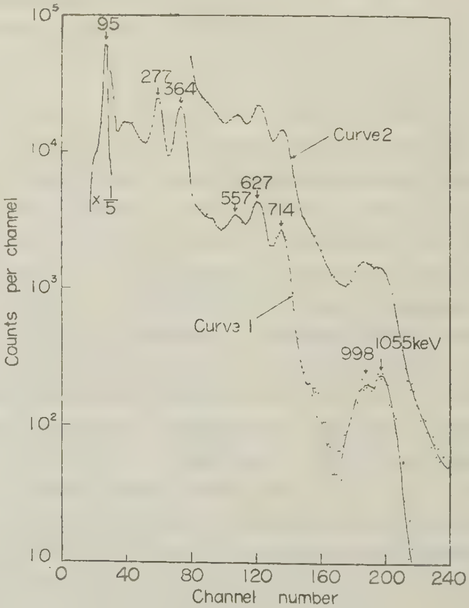

Fig. 2. The scintillation spectra was measured with 1″φ×1″ NaI (Tl) crystal. The curve 1 shows the spectrum with the distance of 20 cm between the source and the crystal, and the curve 2 that with the distance of 3 mm.

).5 min. The contribution of long lived activities due to impurities was found to be egligible. The half-life reported by Slätis is 145±3 min[8] and by Sher 139.17±0.14 min[4] nd recently by Mayquez 143.0±2.6 min[15].

As the spectra of single scintillation counter uggest the presence of the aforementioned oublet near 1 MeV, a careful search was ade in the 1 MeV region with the technique of the sum coincidedce. The gate of the sum coincidence was set from 990 to 1150 keV at intervals of every 3 keV. The typical sum coincidence spectra of gamma-rays obtained with the channel settings of the differential discriminator at 1055 and 998 keV are shown in Figs. 3 and 4. With the gate set at 998 keV (Fig. 4), the previously reported[11] 714–277, 627–364 keV cascade gamma-rays are clearly shown. Furthermore there occurs a broad peak at 500 keV, which suggests the presence of another cascade gamma-rays. The small rises of about 200 and 800 keV are due to Compton scattering. With the gate set at 1060 keV, there appeared no significant peaks (Fig. 3), that is there is no cascade gamma-rays.

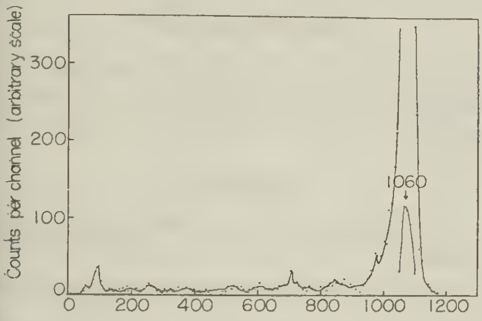

Fig. 3.

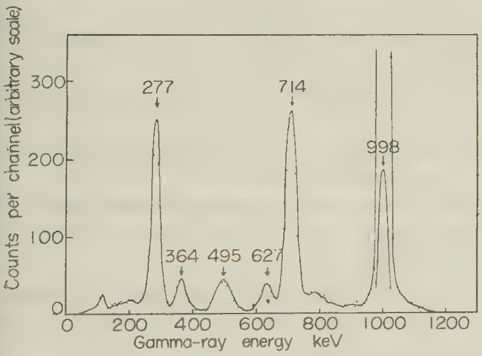

Fig. 4.

Fig. 3 and 4. The sum coincidence spectra of dysprosium. The sum-channel settings are at 1060 and 998 keV.

The coincidence spectra gated with 714, 627 and 557 keV photopeaks are shown in Figs. 5, 6 and 7 by dashed lines. For comparison a spectrum of single crystal scintillation counter normalized at 277 keV is shown in Figs. 5 and 6 and at 178 keV in Fig. 7. The width of coincidence gate is shown on the direct gamma-ray spectrum by arrows with oblique lines. With the coincidence gate opened at 714 keV, a strong peak at 277 keV is seen (Fig. 5) and when opened at 627 keV, the 364 keV peak rises (Fig. 6) and another peak of 277 keV observed is thought to be coincident with Compton scattered 714 keV gamma-rays. When opened at 557 keV, there appeared 178 keV peak (Fig. 7). Other peaks observed at 277 and 364 keV may also due to the Compton scattered 627 and 714 keV gamma-rays. From these considerations the coincidences of 277–714, 364–627 and (178–557) keV are concluded. The

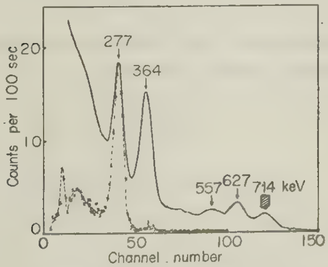

Fig. 5. Coincidence spectrum with 714 keV photopeak.

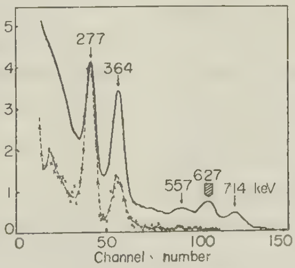

Fig. 6. Coincidence spectrum with 627 keV photopeak.

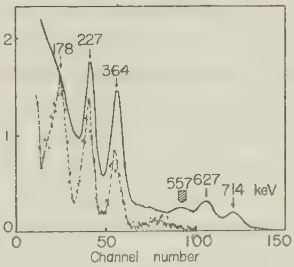

Fig. 7. Coincidence spectrum with 557 keV photopeak.

The dashed lines represent coincidence spectra which are normalized at the 227 keV photopeak of single crystal gamma-ray spectrum in Fig. 5 and Fig. 6. In Fig. 7 the coincidence spectrum is normaliged at 178 keV. The width of each coincidence gate is shown on the single crystal gamma-ray spectrum by arrows with obligue lines.

coincidences of 277–714 and364–627 keV gamma-rays correspond with sum coincidence results of Fig. 4.

From the results of single crystal gamma-ray spectra and of the sum coincidence experiment, about 1 MeV level is composed of two levels is composed of two levels of 998 and 1055 keV. Cork[11)] reported the existence of 515 keV level from the decay of Dy^{165m}, and the 495 keV peak in Fig. 4 is presumed to be the unresolved peak composed of two peaks of 483 and 515 keV by assuming that the 988 keV level decays in two-step cascade, first to 515 keV level second to the the ground level. For an interpretation of the coincidence between 178–555 keV gamma-rays, 733 keV level may be suggested.

From the Nilsson model, the estimated values of the spins and parities of the ground states of Dy^{165} and Ho^{165} and are 7/2+ and 7/2−. The gamma-ray transition from the first excited level to the ground state is M1 M1+E2[7),10)], that is, $\Delta l=1$ with no parity change. From the Coulomb excitation experiment[14)] this level is known as rotational level hence the spin and parity of the first excited state are 9/2−. The proposed nuclear energy level scheme is shown in Fig. 8. The energy and intensity of beta-rays for this scheme were taken from the results of Bonboeffer *et al.*[12)]

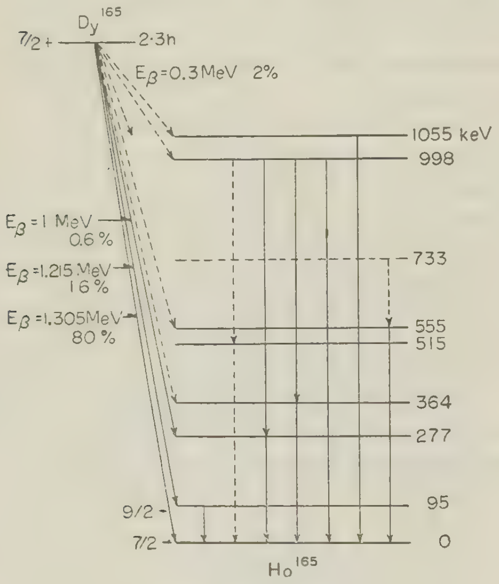

Fig. 8. Proposed decay scheme of D_y^{165}.

Decays of Photoreaction Products of Selenium

By Tokihiro KUROYANAGI*

Department of Physics, Tohoku University, Sendai

(Received June 21, 1960)

The decay properties of Se^{73m}, Se^{81} and As^{79} have been studied by scintillation methods. Gamma-ray spectra showed lines of energy 170, 275, 335, 410, 480, 550, 650 and 840 KeV belonging to the decay of Se^{81}. The decay scheme of Se^{81} was proposed with the aid of single and coincidence measurements of radiations. The mass difference between the ground states of Se^{81} and Br^{81} is represented by the 1.56-MeV beta ray. In As^{79}, new gamma rays of 360, 440, 725 and 890 KeV were found. Beta-gamma and gamma-gamma coincidence measurements confirmed that a 44-min activity in selenium is attributed to Se^{73m}. It is found that the beta-decay energy is 1.86-MeV and that there is no appreciable gamma ray.

§ 1. Introduction

Natural selenium consists of the stable isotopes of mass number 74, 76, 77, 78, 80 and 82. When a selenium sample is irradiated by 25-MeV bremsstrahlung, many radioactive isotopes of selenium and arsenic are produced by (γ, n) and (γ, p) reactions. If the time of irradiation is comparatively short (several tens minutes), the radiations from Se^{73}, Se^{73m}, Se^{77m}, Se^{79m}, Se^{81}, Se^{81m}, As^{79} and As^{81} are expected to be observed. Since the activities of Se^{77m}, Se^{79m} and As^{81} have short halflives of 17.5 sec, 3.9 min and 32 sec, respectively, the dominant radiations at about ten minutes after the termination of the bombardment may be caused by Se^{73}, Se^{73m}, Se^{81}, Se^{81m} and As^{79}. The decay characteristics of these isotopes have been known in some extent but not with good accuracy, although the isotopes of Se and As region with long half-lives are very well studied. It, therefore, seemed to be worth while studying the decays of Se^{73m}, Se^{81} and As^{79}.

Using an internal bombarding technique[1] recently developed in our laboratory and scintillation spectrometers, such unknown radiations were investigated.

§ 2. Experimental Arrangement

The gamma-ray spectrometer consisted of a $1\frac{1}{2}$-inch in height and $1\frac{1}{2}$-inch in diameter NaI(T1) crystal attached to the end of a DuMont type 6292 photomultiplier tube. In order to eliminate the beta background, it was necessary to place a 2 g/cm² polystyrene absorber between the sample and the crystal. Pulses from the photomultiplier tube were fed through a cathode follower and linear amplifier to a 100-channel pulse-height analyzer.

Because of the complexity of gamma-ray spectra to be analyzed with the scintillation spectrometer, a careful analysis of resolution and respone function was necessary. The energy calibrations were done using all or some of the following gamma-ray sources: In^{114}, Hg^{203}, Au^{198}, Cs^{137}, Zn^{65} and Na^{22}. The errors in energy measurements of gamma rays were within ±5 KeV.

The energy resolution as a function of energy E was determined from the full width ΔE at the half maximum of the various monoenergetic photopeaks of Hg^{203}, Cs^{137}, Zn^{65} and Na^{22} corresponded fairly well to the formula:

$$\frac{(\Delta E)^2}{E} = AE + B$$

with $A = -0.011$, $B = 15$ KeV. Measured pulse-height spectra were resolved with the aid of the reference spectra obtained using standard sources of Hg^{203}, Au^{198}, Cs^{137} and Zn^{65} under conditions similar to this experiment. A contribution due to bremsstrahlung of beta rays was subtracted from the pulse-height spectra using the spectra of bremsstrahlung of beta-ray sources of P^{32} and Sr^{90} which have no gamma ray. A calibration of the photopeak efficiency vs energy was obtained by the coincidence method using sources of Se^{75}, Na^{22} and In^{114} (Fig. 1). In order to determine the intensities of the gamma rays $I(\gamma)$, use is made of the following eqation:

---

* Now at Japan Atomic Energy Reserch Institute, Tokai-Mura, Ibaraki-ken, Japan.

$$I(\gamma)=\epsilon_p(\gamma)\Omega(\gamma)A(\gamma)\exp(-\mu d),$$

where $\epsilon_p(\gamma)$ and $\Omega(\gamma)$ are the photopeak efficiency and the solid angle for the detection of γ, $\exp(-\mu d)$ is the fraction of transmitted through the beta absorber. $A(\gamma)$ is the photopeak area which was calculated by assuming a Gaussian shape as photopeak shape, and by using the energy resolution of the crystal and the observed maximum height of the peak. The errors of the obtained intensities were few tens percents.

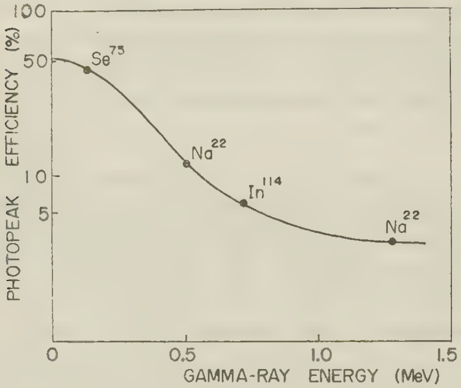

Fig. 1. Photopeak efficiency *vs* energy.

The beta-ray counter consisted of an anthracene scintillator 0.6-cm thick and 2-cm in diameter, attached to a DuMont 6292 photomultiplier tube and protected from light by a 2 mg/cm² aluminum foil. The electronic system was identical with that of the gamma-ray spectrometer. In order to obtain the energy calibration curve of the spectrometer, the end points of well known sources, In^{114}, P^{32} and Au^{198}, were determined using the Kurie plots without correction of the resolution of the phosphor. It has been proved that such a calibration without correction of the resolution is quite enough for our purpose. The errors in measured end-point energies were within ±50 KeV. The irradiated samples were melted and spread on an aluminum foil 2 mg/cm² thick to make thin beta-ray sources. The average thickness of the sources was about 50 mg/cm².

In order to determine which of the observed gamma rays is in coincidence with beta rays, beta-gamma coincidence measurements were made using a conventional "fost-slow" coincidence circuit whose resolving time $2\tau=80$ mμ sec in the energy range between 0.07 and 1.3 MeV. The radiations were viewed by a 1½-inch×1½-inch NaI(T1) crystal and a 0.6-cm×2-cm anthracene crystal which were mounted on DuMont 6291 photomultiplier tubes. To determine the coincidence ralationship of the gamma-rays, the beta-ray counter was replaced with a second gamma-ray spectrometer. In the gamma-gamma coincidence experiments, the same "fast-slow" coincidence circuit mentioned previously was employed. In all the coincidence measurements, a correction for the accidental coincidence counts was neglible because of the fast resolving time of the coincidence circuit.

§ 3. Results and Discussion

A sample of natural selenium metal of 300 mg was exposed to the 25-MeV betatron bremsstrahlung for twenty minutes and displaced in front of the gamma-ray spectrometer the spectrometer was turned on for an appropriate time interval and the measurement was continued successibly for seven hours after the irradiation. Fig. 2 shows the spectra counted at 4, 36 and 513 min after the termination of the bombardment. In this spectrum, there are seven outstanding peaks at 100, 275, 345, 410 485, 725 and 875 KeV. Following the decays of these peaks, it was found that the gamma rays displayed on the spectrum contained

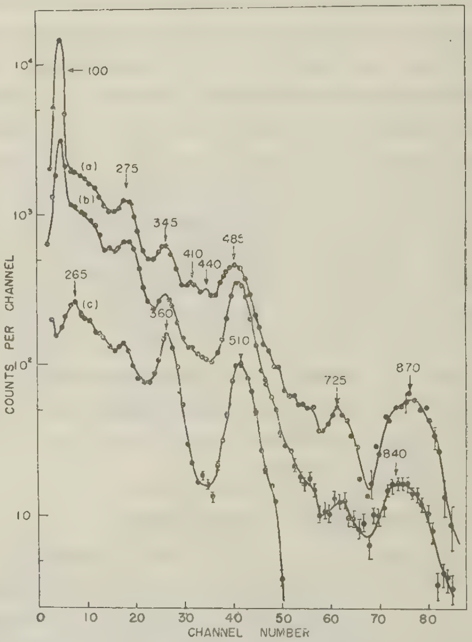

Fig. 2. Gamma-ray spectra of irradiated selenium sample with 25-MeV bremsstrahlung. (a), (b) and (c) show the spectra at 4, 36 and 513 min after the termination of bombardment.

radiations of the isotopes, Se^{73}, As^{79} and Se^{81}, and the isomers, Se^{73m} and Se^{81m}. The spectra were not disturbed by the (γ, p) product (As^{81}) of Se^{82}, since the activity has a short half-life of 32 sec[2]. In order to assign the decay properties of Se^{73m}, As^{79}, Se^{81} and Se^{81m}, radiations of the activities were studied separately.

3.1 Se^{73m}

The radioactive decay of Se^{73} has been investigated by F. Scott[3] and R. W. Hayward and D. D. Hoppes[4]. In selenium, the 44-min radioactivity[5] having the beta-decay energy of 1.7±0.2 MeV has been proposed to Se^{73m}.

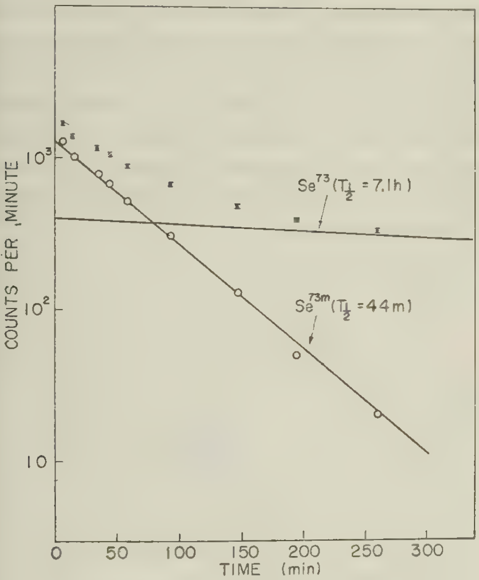

Fig. 3. Decay curve of gamma rays in coincidence with 510-KeV annihilation radiations.

In order to verify the existence of the 44-min isomer without disturbance of other background radiations, the gamma rays in coincidence with the 510-KeV annihilation quanta were measured. A natural selenium metal was irradiated with 25-MeV bremsstrahlung for twenty minutes, and the decay of the coincidence gamma ray was followed for about six hours. The decay curve consisted of two components of 44-min and 7.1-hour half-lives as shown in Fig. 3. The gamma-gamma coincidence spectrum between 10 min and 80 min after a 20 min bombardment was compared with the coincidence spectrum of Na^{22} taken under conditions similar to this experiment, which is shown in Fig. 4. Moreover, no intensive gamma rays were found when the coincidence spectrum was observed with two spectrometers at 90° each other. These results show that an upper limit of the gamma-ray intensity ratio for annihilation quanta does not exceed 1%. It is supported from these evidences that the radiation with the 44-min half-life belongs to the positron decay of Se^{73m}.

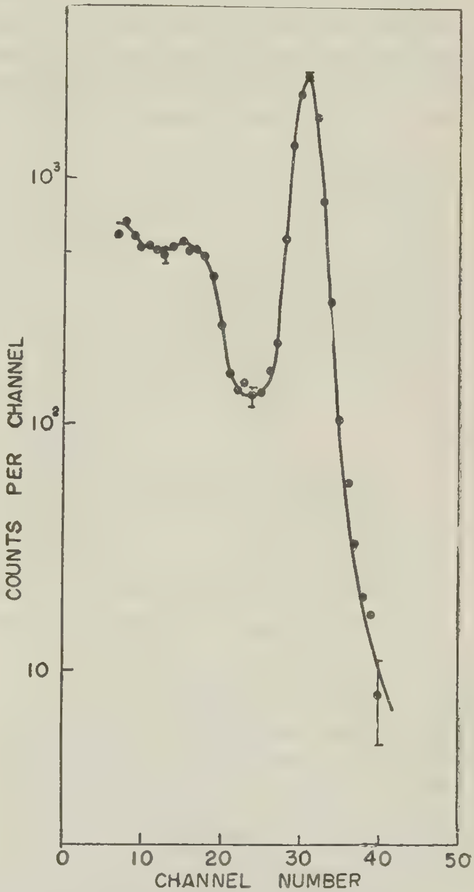

Fig. 4. Gamma-rey spectrum in coincidence with annihilation quanta. The solid line shows coincidence spectrum of Na^{22} taken under similar conditions.

Using the beta-gamma coincidence method, the positron decay energy of the isomer was measured. In this measurement coincidence gates were opened with the pulses corresponded to the photopeak of the 275-KeV gamma ray for an investigation of Se^{81} decay characteristic. However, the beta rays emitted from Se^{73m} could be mearured for the existence of Compton pulses of the annihilation quanta in this gate. The Kurie plot of the obtained beta-ray spectrum is shown in Fig. 5. In this Kurie plot three beta-ray groups having the end point energies of 1.01, 1.32 and 1.86 MeV were found. Following the decays of each beta-ray group, the 1.86-MeV beta group was identified as positrons of Se^{73m} with the half-life of 44 min, and the beta rays of the 1.32-MeV end point was found to belong to the wellknown 7.1-hour decay of Se^{73}. (The 1.01-MeV beta group will be disscused in the later section of Se^{81}). The energy of this isomeric level was determined to be 130±50 KeV from the beta-ray end-point energy of 1.86 MeV and the decay scheme of Se^{73}.

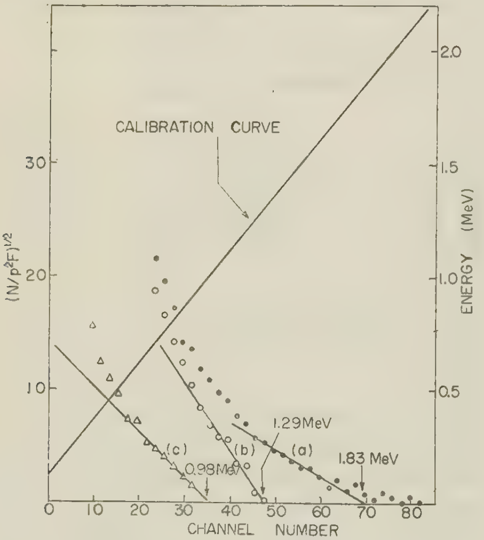

Fig. 5 (a). Fermi analysis of the beta-ray spectrum in coincidence with Compton pulses of annihilation quanta. (b). Fermi analysis of the positron group of Se^{73}. (c). Fermi analysis of the beta group in coincidence with the 275 KeV gammr-ray. The second and third groups obtained by the subtraction method. The self-absorption corrections are not yet applied.

The nuclear shell model predicts that for nuclei with 39 neutrons the two lowest lying states will be $p\,1/2$ or $g\,9/2$ levels with nearly the same energy. From the knowledge that Zn^{69} and Ge^{71} with 39 neutrons have an isomer of $M\,4$ type, and that the ground state spin of Se^{73} is $g\,9/2$, the isomeric state of Se^{73} should be expected to be $p\,1/2$. The isomeric transition of $M\,4$ type in Se^{73} will be expected. However, according to Weisskopf's single particle estimate with correction for the internal conversion process a partial half-life of such an $M\,4$ transition must have an order of 10^8 hours, which makes the branching of such a transition negligible. Since the isomer has no gamma ray, the log ft value is determined to be 4.9, which suggest an allowed transition. Therefore, it is concluded that the positron group leads to the ground state of As^{73} which has a $p\,3/2$ single particle state, and that the isomeric level is a $p\,1/2$ state. A $p\,3/2$ state cannot be expected, since its isomeric transition must be E 3 type and then the partial halflife must have an order of second. A systematic change of the energy splitting between $p\,1/2$ and $g\,9/2$ states in each of three isomers of Zn^{65}, Ge^{71} and Se^{73} is shown in Fig. 6.

Using the decay curve of the annihilation quanta, the yield ratio of the ground and isomeric states of Se^{73} by the photo-neutron emission was calculated to be 1:0.3 with the correction of the K electron capture decay which was done using the table of Wapstra Nijgh and van Lieshout[6]. Again, the value is one of the supports of the assignment of this activity to Se^{73m}.

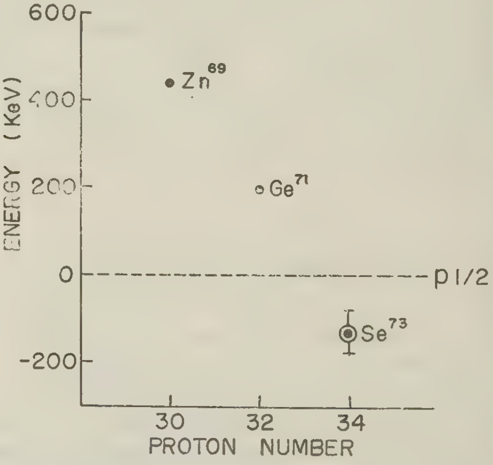

Fig. 6. Change of the energy splitting between $p1/2$ and $g9/2$ states in $n=39$ isomers.

3.2 As^{79}

Butement, Cuningham and Ythier[7] pointed out in their studies that As^{79} decayed to the 96-KeV isomeric level of Se^{79} with the half-life of nine minutes without any appreciable gamma ray.

In the present investigation, chemical separations were performed in order to see the gamma-ray associated with As^{79} without confusing radiations. Selenium dioxide powder was irradiated for ten minutes and then dissolved into hot 10N HCl with arsenic carrier and the arsenic was extracted by CCl_4.

Fig. 7 shows the gamma-ray spectrum which was taken from 4 min to 24 min after the termination of the bombardment. As shown in Fig. 7, there are four outstanding peak at 95, 360, 440 and 510 KeV. Following the decays of these peaks, the former three lines were found to be the radiations associated with As^{79}. The 510-KeV gamma ray was assigned to O^{15} activity from the decay period. Moreover, it was found that weak gamma rays of energies of 725 and 890 KeV belong to As^{79}. These results were consistent with the spectrum (Fig. 2) obtained from the photoactivated selenium sample which was not treated chemically.

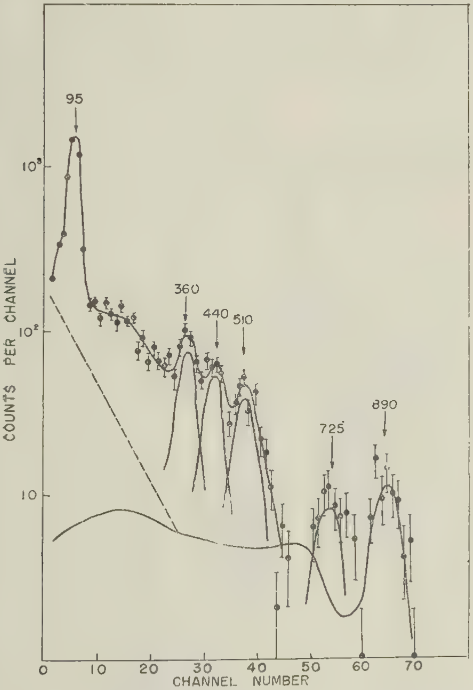

Fig. 7. Gamma-ray spectrum of As^{79}. The dashed line shows the contribution by bremsstrahlung of the beta rays.

Since the ground state of As^{79} is expected to be 3/2− and the ground and isomeric states of Se^{79} have been identified to be 7/2+ and 1/2−, respectively, it is considered that the observed gamma rays are the cascade transition with the 96-KeV isomeric transition. Consequently, the total disintegration of As^{79} should be obtained from the number of the 96-KeV transition correcting for the 3.9-min half-life of Se^{79m}. From these spectra, the intensity ratios per total decay were calculated, which is shown in Table I.

Table I. Relative intensities of the gamma radiations of As^{79}

Energy (KeV)	Percent of total decay
360	2.5
440	2.5
725	1.0
890	1.5

3.3 Se^{81}

The radioactive decay of Se^{81} has been investigated by several experimenters7), and a 57-min isomeric level7) has been found. The beta ray spectrum of Se^{81} has been studied with a 180° type spetrometer by Bergström and Thulin8), Rutledge, Cork and Burson9), who reported the the beta-ray endpoint energies of 1.38 and 1.5 MeV, Respectively. However the respective gamma rays have not been reported previously.

Heydenburg and Temmer10), Wolicki, Fagg and Geer11) reported the 275-KeV level of Br^{81} by means of Coulomb excitation. In 1958 and 1959, Duffield and Vegor12), Goodman and Schardt13) found the 550-KeV level with 37 μ sec half-life of Br^{81} by the reactions (γ, γ') and (p, γ).

In order to determine the beta decay energy and gamma rays of Se^{81}, a natural selenium sample was irradiated by 12-MeV bremsstrahlung for twenty minutes. Only the Se^{81} activity was produced by bremsstrahlung of this energy, since the threshould energies in the (γ, p) reactions are above 12 MeV, and Se^{74} and Se^{82} have the neutron binding energies of 12.1 and 9.4 MeV, respectively.

The Kurie plot (Fig. 8) of the beta-ray spectrum yielded a value of 1.56±0.05 MeV as the beta-decay energy. This agrees with the results by Rutledge etal within the experimental error. In this Kurie plot the energy parts higher than 0.5 MeV were linear, and the summing of Compton electrons from gamma rays causes considerable distortion in the lower energy parts. The gamma rays of the sample were measured by a single crystal scintillation spectrometer. The peaks were found at 103, 170, 275, 410, 480, 550, 640 and 840 KeV, and these gamma rays except the 103-KeV gamma ray of Se^{81m} were assigned to Se^{81} by following the decay periods.

In order to determine the decay from the isomeric level of Se^{81} (57 min), the gamma ray spectrum of an irradiated sample by 25-MeV bremsstrahlung for sixty minutes was measured. No drastic change was seen. Beta-gamma coincidence spectrometry was also very helpful in determining the position of gamma rays in a decay scheme. Fig. 5 shows the Kurie plot of the beta-ray spectrum in coincidence with the gamma ray of 275 KeV which is one of the most strong gamma rays. A beta-ray group of 1.01 MeV was found besides 1.3- and 1.8-MeV beta groups belonging to Se^{73} and Se^{73m}, which were mentioned previously. A beta-ray group in the energy region lower than 500 KeV may be questionable, since backscattering from the source and counts of electrons probably introduced a considerable Compton distortion of the low energy beta-ray spectrum.

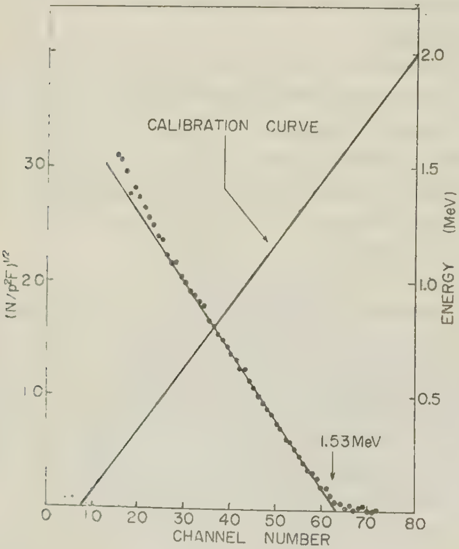

Fig. 8. Kurie plot of the beta spectrum of Se^{81}. Self-absorption correction is not yet applied.

To determine the decay scheme, gamma-gamma coincidence measurements were made. The gamma rays of 105 and 275 KeV were found in coincidence with 170-KeV gamma ray. The 105- and 275-KeV gamma rays were in coincidence with the 275-KeV gamma ray. Besides these gamma rays, weak coincidence gamma rays of 170, 205 and 410 KeV were seen by a careful analysis of the spectrum. The 170- and 275-KeV gamma ray was in coincidence with the 410-KeV gamma ray. Fig. 9 shows one of examples of the coincidence gamma-ray spectra. In this figure the peak at 510 KeV is due to the annihilation radiation of Se^{73} in coincidence with its Compton pulses, which was verified by following the decay. When the coincidence gates were opened by the pulses from the gamma rays of 550, 650 and 840 KeV, no intensive photopeaks were observed. In the case of the 550-KeV gate, the radiations were viewed with two spectrometers at 90° each other in order to avoid the suprious coincidence by the annihilation quanta in the Se^{73} decay and the Se^{73m}. In this coincidence spectrum, a weak gamma ray of 290 KeV was observed. In all measurements, no gamma ray which is in coincidence with the 335-KeV gamma ray was observed.

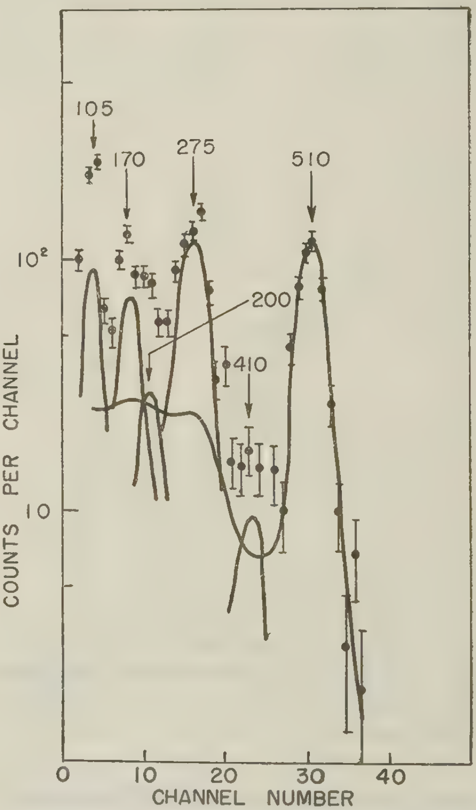

Fig. 9. Se^{81} gamma-ray spectrum in coincidence with the 275 KeV gamma rays.

From the gamma-gamma coincidence measurements and the single crystal spectrometer result which is analyzed to each gamma ray (Fig. 2), the intensity ratios of the gamma rays were calculated. The spectrum of Fig. 10 was obtained from Fig. 2(a), from which

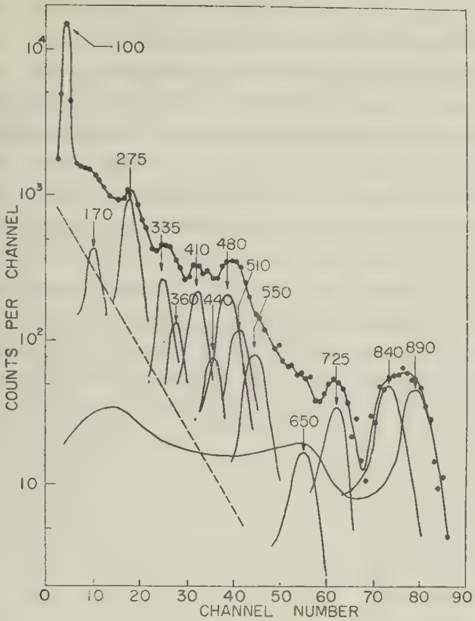

Fig. 10. Analyzed gamma-ray spectrum of irradiated selenium sample with 25-MeV bremsstrahlung. The dashed line shows the contribution by bremsstrahlung of the beta ray.

Table II. Relative intensities of the gamma ray of Se^{81}

Energy (KeV)	Percent of total decay
105	0.1
170	1.4
205	0.5
275	1.8
275	1.2
335	0.9
280	?
290	0.1
410	1.0

550	0.9
650	0.3
840	0.9

the contribution of the gamma radiations belonging to Se^{73} has been subtracted. The results are summarized in Table II.

3.4 Decay Scheme of Se^{81}

The above results indicate that the radioactive decay of Se^{81} is accompanied by the gamma rays of energies of 105, 170, 275, 410, 480, 550, 650 and 840 KeV. The measurements of the half-lives in all experiments and the measurements of the radiation of the source irradiated by 12-MeV bremsstrahlung also indicated that these gamma rays must be attributed to Se^{81}. The Kurie plot of beta-ray spectrum measured by the single crystal beta-ray spectrometer shows that the beta-decay energy of Se^{81} is 1.56 MeV. and that there is no intensive branching since the Kurie plot is quite linear over the region from the end-point energy to about 0.5 MeV.

The beta-gamma coincidence measurement indicates that the gamma ray of 275 KeV is fed by the beta ray of 1.01 MeV. A difference between this energy and the 1.56 MeV beta-decay energy propose that there is a level at 550 KeV in Br^{81}. On the other hand, the 275-KeV level in Br^{81} has been known as a 5/2− state from the Coulomb excitation, (p, γ) and (γ, γ') reaction experiments, and the ground state of Se^{81} has been assigned to be a 1/2− state. Since a beta decay between the 1/2− state and the 5/2− comes to be a second forbidden transition, a beta ray populating the 275-KeV level of Br^{81} will not compete with other transitions. The information from the gamma-gamma coincidence spectrum gated by the photopeak pulses of 275-KeV gamma ray strongly suggests that there is a level at 550 KeV which feeds two equal energy gamma rays of 275 KeV. It is supported by the fact that there is the gamma ray of energy of 550 KeV in the spectrum measured by the single crystal spectrometer. The gamma-gamma coincidence spectra in coincidence with 275- and 170-KeV gamma rays suggest the energies of four levels at 170, 275, 550 and 690 KeV in Br^{81}. It is consistent with the gamma-gamma coincidence result gated by the 410-KeV gamma ray, and the intensity relations are consistent with the fact that the 275-KeV level is not populated by a beta ray as found in the beta-gamma coincidence experiment. Since the coincidence counts with the 410-KeV gamma ray are very small, it is considered that there is a level at 410-KeV. An absence of strong gamma rays in coincidence with 550, 650, and 840 KeV shows the levels at 550, 650 and 840 KeV. The weak gamma ray of 290 KeV in coincidence with the 550-KeV gamma ray may be a transition between levels at 840 and 550 KeV.

The relative intensity ratios of the beta rays were calculated to see if the intensity ratios of the gamma rays might be interpreted to be consistent with each other. Then the intensities of each beta ray per total disintegration of Se^{81} were determined from the comparison between the intensities of the 103–KeV gamma ray (isomeric transition of Se^{81m} with the 57–min half-life) and the 57–min component of each gamma ray. In this determination, the intensity of the 103–KeV transition was corrected by the internal conversion coefficient of the value of $\alpha=11$, and the number of disintegration of the Se^{81} ground state made from the Se^{81m} isomeric transition was calculated. The branching of the beta group having the 1.01–MeV end-point energy and populating the 550–KeV level of Br^{81} was obtained to be 2% for the total disintegration of Se^{81}. According to verification of the branching ratio, the gamma-ray spectrum and the beta-ray counts of a source were simultaneously measured by a NaI(T1) spectrometer and a Geiger Muller counter. The source was irradiated by 12–MeV bremsstrahlung for 20 minutes. The branching ratio of the beta ray feeding the 550–KeV level of Br^{81} was obtained to be 2%, which was in good agreement with the previous result. The obtained intensities of various beta groups are listed in Table III together with their associated log *ft* valus which are computed from Moszkowski's nomographs. The relative intensities of gamma radiations were normalized to total decay due to the similar way. A tentative decay scheme which is consistent with the observations is shown in Fig. 11. The 335–KeV gamma ray cannot be illustrated on the decay scheme, since any gamma ray has not been observed in coincidence with the 335–KeV gamma ray.

Table III. Relative intensities and log *ft* values of the various beta-ray transitions in the decay of Se^{81}

Energy (MeV)	Percent of total decay	log *ft*
1.56	92	5.2
1.39	1.3	6.6
1.15	1.0	6.2
1.08	1.8	5.9
1.01	2.0	5.7
0.88	0.5	6.1
0.72	1.0	5.6

In the experiment of (p, γ) and (γ, γ') reactions, a level at 550 KeV has been assigned to be a 9/2+ state which is an isometric state with the half-life of 37 μsec. However, the 550–KeV level in this experiment must not be the 9/2+ state, since the log *ft* value of the 1.01–MeV beta ray is 5.7 which suggests that the 1.01–MeV beta decay is either allowed or first forbidden transition. Therefore, it is concluded that the 550–KeV level in the present investigation is a new level near the 9/2+ state, and has a low spin value and an odd parity.

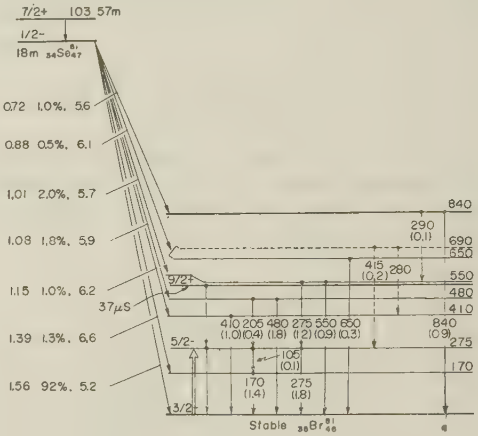

Fig. 11. Tentative decay scheme of Se^{81}.

The 550–KeV level of the 9/2+ state may be populated directly from Se^{81m} having the spin and the parity of 7/2+, since the beta transition is expected to be an allowed type. Therefore, the decay of the 275–KeV photopeak must contain a component with the half-life of 57 min. However, the experimental results shows an absence of this component. An upper limit of the beta branching was determined to be about 0.005% for the 103–KeV isomeric transition, and the associated log *ft* value was computed to be 8.9. Such large values of log *ft* in allowed transitions between the high spin states have often appeared in this mass range. For example, in the case of transition from the 7/2+ to the 9/2+ state in $Ge^{77} \rightarrow As^{77}$, the log *ft* value has been known to be 8.0[14].

Since the other beta rays have comparatively low values of log *ft* and the Se^{81} ground state has been known as a 1/2− state, the various leves of Br^{81} appearing in the decay of Se^{81} are expected to be low spin and odd parity states; 1/2−, 3/2−. In this mass range it is characteristic that many levels are seen having low spins and odd parities.

The author is deeply indebted to Prof. H. Morigana for interesting discussions in this study.

^{8}Li Emission from Nuclear Disintegrations Produced by 4.3 GeV Negative π-Mesons

By Masaomi (Takahata) OHTA
Department of Physics, Osaka City University

(Received July 14, 1960)

Fifty-five ^{8}Li fragments from heavy element disintegrations produced by 4.3 GeV negative π-mesons were found. The frequency, the energy and angular distributions of these ^{8}Li fragments were compared with those of the fragments produced by 5.7 GeV proton beam reported by Goldsack et al. No appreciable difference has been found between the two cases. Of light element disintegrations, the frequency of ^{8}Li fragments was found to be about 0.006.

§1. Introduction

In 1957, Goldsack et al.[1] studied ^{8}Li emission from heavy element disintegrations produced by 5.7 GeV protons and reported energy and angular distributions and frequency of those fragments. The present work involves an investigation of ^{8}Li fragments from nuclear disintegrations produced by 4.3 GeV negative π-mesons.

It has been found in this laboratory that both the mean number of black prongs in the stars ($N_h \geqq 7$) produced by 6.2 GeV proton beam and that produced by 4.3 GeV negative pion beam are nearly equal to 10. Thus, it may be plausible to assume that the average excitation energies of both stars are nearly equal (~380 MeV), and, in consequence, the frequencies of emission of ^{8}Li fragments may also be equal. A similar consideration may be allowed in the case for 4.3 GeV pion and 5.7 GeV proton. On the other hand, since there is a certain difference between the two incident energies, if the frequency of emission of heavier particles is assumed to depend on the incident energy, the frequency in the present case may be expected to decrease with decreasing energy. Hence, an attempt has been made to compare the frequency, the energy and angular distribution of the two cases.

^{8}Li fragments from light element disintegrations are also studied.

§ 2. Experimental Procedure and Results

A stack of Ilford G5 emulsions 600 μ thick and of size 3″×4″, exposed to 4.3 GeV negative pion beam from the Berkeley Bevatron was used.

Each star with a minimum track in the direction of negative π-mesons was examined under a ×60 oil objective, and all black prongs were followed up either to their ends in the emulsion or to the points at which they left the plates. All the "hammer tracks" found were assumed to be due to ^{8}Li nuclei, it has been known that a small proportion of the hammer tracks may be due to ^{8}B or ^{9}Li nuclei[2].

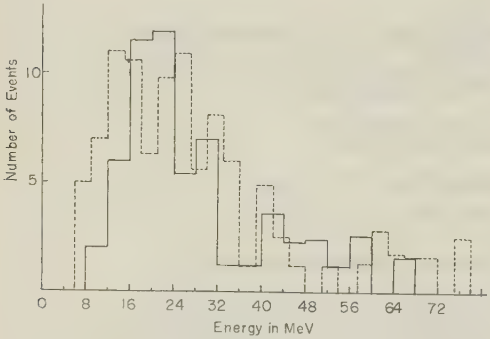

Fig. 1. Energy distribution of the ^{8}Li fragments. The solid histogram represents that of 4.3 GeV negative π-mesons. The dotted histogram represents that of 5.7 GeV protons obtained by Goldsack et al.

In total 6700 stars examined, 65 examples of ^{8}Li emission were observed. One star with two hammer tracks was also found. Of the parent stars, 54 had 7 or more heavily ionizing prongs, and hence correspond to heavy element disintegrations; of the remainder only 6 which had no short recoils were considered to be due to light element disintegrations.

Using the range-energy relation, the energy of each fragment was estimated. The energy distribution of ^{8}Li fragment from the heavy element disintegrations is shown in Fig. 1. The distribution has been corrected for the loss of fragments leaving the emulsion before coming to rest.

The angular distribution of the fragments is plotted with an interval of equal solid angle with respect to the direction of incident beam in Fig. 2, in which the forward to backward ratio was found to be nearly unity.

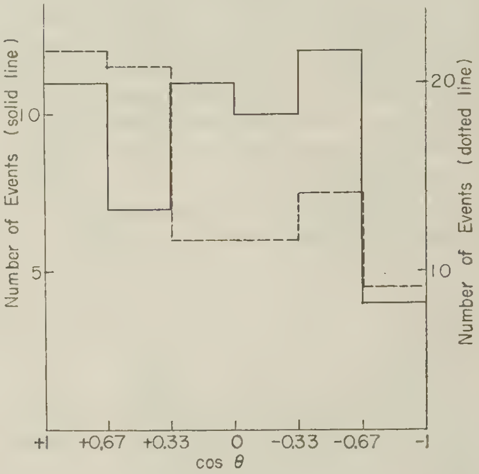

Fig. 2. Angular distribution of the ^{8}Li fragments, plotted in equal intervals of solid angles, and measured with respect to the direction of the incident negative π-mesons or protons. The solid histogram represents that of 4.3 GeV negative π-mesons. The dotted histogram represents that of 5.7 GeV protons obtained by Goldsack et al.

The stars having ^{8}Li fragments have been divided into some groups with respect to their different number of heavy prongs, as shown in Table I, in the same manner as had been done in the case of 5.7 GeV proton reported by Goldsack et al. The frequency of emission of ^{8}Li fragments for each group was estimated and is listed in Table I together with the data of 5.7 GeV proton. The mean value of the frequency was found to be 0.014 ±0.001.

The stars ($N_h \geqq 3$) with less than five black prongs were tentatively classified as light element disintegrations, if they had no short recoil. Although some uncertainty is inevitably included in this classification, the frequency of the ^{8}Li emission has been evaluated to be about 0.006.

Table I.

No. of Black Prongs	No. of Stars	No. of Fragments		Frequency (4.3 GeV π^-) Present author	Frequency (5.7 GeV proton) Goldsack et al.
		Observed	Corrected		
5- 8	2134	11	12.2	0.0057±0.0018	0.0059±0.0012

12–14	672	18	20.2	0.030 ±0.007	0.0186±0.004
15–20	378	19	20.8	0.055 ±0.013	0.0275±0.007
≧21	45	1	1.1	0.03	0.05
Mean value	4301	55	61.1	0.014 ±0.001	0.013 ±0.001

§ 3. Discussion

The energy distribution in Fig. 1 shows that most of the fragments have energies between 8 and 40 MeV but that there is a considerable high energy tail. It is readily seen that this distribution is similar to the case of 5.7 GeV proton obtained by Goldsack et al. which is indicated by dotted line in the same Figure. However, the nearly isotropic angular distribution in Fig. 2 indicates that most of the fragments may be emitted as part of the evaporation process. This seems to differ from the results of 5.7 GeV proton.

In order to interpret the above fact, it may be of use to follow energy and angular distributions more in detail. Hence, the data are divided into two groups depending on the number of black prongs in the parent stars. The fragments from stars with less than 12 black prongs (' small ' stars) and those with 12 or more black prongs (' large ' stars) were compared with corresponding data of proton, respectively. There are 17 observed events in the first group and 38 in the second.

The energy and angular distributions of the fragments from small stars and large stars except the angular distribution of small stars are all similar to those of 5.7 GeV proton. According to Goldsack et al.[1] the fragments from the large stars are ejected as the part of evaporation process, since their angular distribution was essentially isotropic, as it should be for an evaporation process. This does not differ from the present case. On he contrary, the angular distribution of the small stars obtained by them was markedly anisotropic, which differs from the present distribution as shown in Fig. 3.

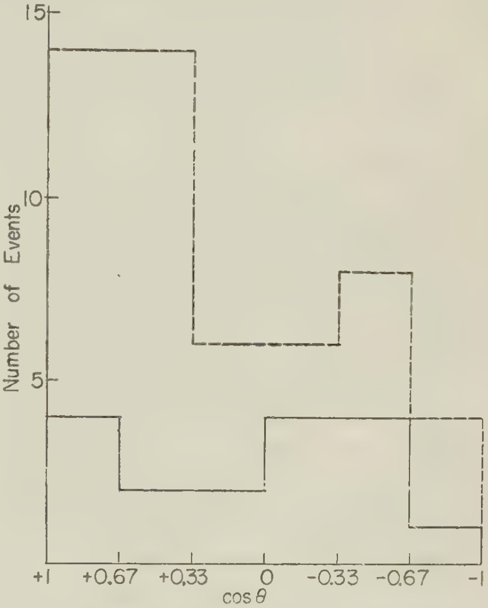

Fig. 3. Angular distribution of the ^{8}Li fragments ejected from stars with less than 12 black prongs. The solid histogram represents that of 4.3 GeV negative π-mesons. The dotted histogram represents that of 5.7 GeV protons obtained by Goldsack et al.

In the present experiment, the ratio of the fragments from the small stars to that from the large one is about one half, while in the case studied by Goldsack et al. the ratio is about 4/3. Further, as seen in Table I the frequency of such small stars is smaller than that of the large stars. Hence, it may be said that the present result is not essentially inconsistent with that obtained by Goldsack et al. as most of the fragments are due to the evaporation process. Namely, the proportion of the fragments which have relatively high energies and may be ejected in the forward direction seen in the case of the small stars is small in the present case, and consequently the contribution of these fragments to the total angular distribution may be inappreciable. However, the isotropic distribution in Fig. 3 may be partly considered to be due to its poor statistics. Since Imaeda et al.[2] have studied the angular distribution of the fragments under the same beam exposure as in the present investigation, the data may be more reliable in statistics if the present result is combined with theirs. The combined result is shown in Fig. 4, in which the difference from the case of proton is hardly recognized.

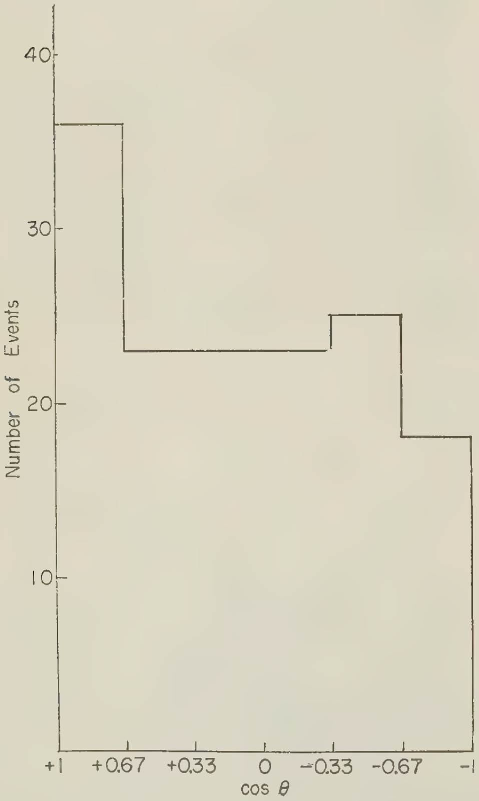

Fig. 4. Angular distribution of the ^{8}Li fragments, the data of Imaeda et al. were combined with ours.

The mean value of the frequency agrees quite well with that of 5.7 GeV proton, though a certain difference is seen for each group. This indicates that, on the average, the frequency of emission of ^{8}Li fragments rather depends on the excitation energy of stars than on the incident energy.

For the ^{8}Li fragments from light element distributions, only a paper by Munir has been reported[3]. He studied the frequency of the fragments from nuclear disintegrations induced by 950 MeV protons. From 3400 light element disintegrations with four or more prongs he obtained the number of ^{8}Li nuclei to be 22.5 from which the frequency can be obtained to be about 0.007 which is very close to the present result of 0.006. The coincidence of the frequencies of the above two cases, in spite of the difference in their energies, may be interpreted, if it is assumed that ^{8}Li fragments are due to nuclei after a light element breakup.

Acknowledgements

The author wishes to express his sincere thanks to Prof. Y. Watase and Dr. S. Kaneko for their encouragement throughout this work. The author is also indebted to Mr. O. Kusumoto and Mr. S. Matsumoto for their helpful advices and discussions. Thanks are also due to Prof. E. J. Lofgren, Dr. W. W. Chupp and Dr. T. Kotani who made the present work possible by exposing the emulsion stack in the negative π-meson beam of Bevatron Berkeley.

A Model Theory of Liquid

By Akiya OOKAWA

Department of Physics and Chemistry, Gakushuin University,
Mejiro, Tokyo

(Received March 1, 1960)

As a structural model of liquid, a crystal threaded by fine network of dislocations is proposed. The main prepositions characterizing the model system are the elastic distortion of the mesh material in bulk rather than the local distortion at the core of the constituent dislocations, the frequency modulation for the transversal shear waves due to the anharmonicity of the potential, and the introduction of degenerated non-harmonic shearing translations. With the prepositions, the model system is shown to display a kind of first order phase transition between an imperfect crystal as representative for the liquid phase and a perfect crystal as representative for the solid phase. The order of magnitude of the frequency modulating coefficient, the only adjustable parameter, is estimated under comparison with the experimental data of noble metals.

§1. Introduction

Any model theory of liquid, regarding the liquid state near the melting point as a kind of imperfect crystal, makes use of lattice imperfections known in the field of crystalline solid, such as the vacant site[1], the dislocation[2], and the grain boundary[3]. In these theories, as to the excess entropy stabilizing the liquid phase compared to the solid phase, the interest is rather directed to the configurational entropy such as those due to the randomness in distributing the said imperfections.

The concentration of lattice imperfections representing the liquid state, however, is expected very large and the interactions between the constituent imperfections is expected accordingly very strong to the order unusually experienced in the field of crystalline solid. Under the circumstances, the individuality of the constituent lattice imperfections could not necessarily be preserved, in the sense that the distortion of the lattice might not be restricted locally near the core of each imperfections.

In the field of the theory of liquid, the importance of the modulation of lattice vibrations due to the anharmonicity of potential is well recognized. Mott[4] has succeeded in early days in relating the change at melting of electric resistivity to the modulation of eigen frequency, although the theory did not stand on any structural background. In the field of crystalline solid, the modulation of lattice vibrational spectrum due to anharmonic potential is discussed by several authors[5],[6],[7],[8], for cases of point lattice defects such as the vacant site and the interstitial atom.

Under the circumstances, in the representative model of liqid crowded with lattice imperfections, the elastic distortion of the lattice in bulk is expected large enough to contribute much to the entropy gain of the system due to anharmonic modulation of eigen frequency[9]. Here we present, standing on these characteristics, a model theory of liquid constituted of aggregate of crystallities in state of self-strain stabilized thermodynamically.

§2. Model Proposed

We consider a crystalline solid threaded by fine network of dislocations. When the dislocation segments are far apart from each other as it is usually in the field of crystal plasticity, the lattice distortion is localized near the core of dislocations. But, as the dislocation segments constituting the present model of liquid are expected neighbouring at a distance of the order of several atom spacings, we assume, instead of the localized distortion at the core of dislocations, rather the distortion in bulk of each lattice material at the mesh of the dislocation network. For a given density of lattice imperfections, the excess energy as well as the excess entropy of the system over those of the perfect crystal are functions of the degree of *diffuseness* of the said imperfections. We ought in general to evaluate the degree of diffuseness by variation principle to minimize the free energy. For system of scarce density of lattice imperfections at low temperature, as it is usually in the solid state, the excess energy favours the lattice distortion well localized at the core of imperfections. For system of large density of imperfections at high temperature, however, the predominance of the excess entropy is expected to favour the lattice distortion rather diffused out in bulk material[9]. The present model assumes the extreme case of the latter as to the diffuseness of lattice distortion in liquid state.

The model is shown schematically in Fig. 1 for the case of two-dimensional simple cubic lattice, where the lattice points at the mesh are disposed in state of self-strain in bulk so as to relax the local strain at the core of dislocations. It can be seen that almost all the material is under shearing strain to the order of $a/\alpha a$, where a is the atom spacing and $2\alpha a$ is the average spacing between the like dislocations. The excess energy of the model system in three dimension over that of a perfect crystal without dislocations can be approximated by

$$U_0=\frac{3}{2}N\mu(a/\alpha a)^2 v_0 \,, \tag{1}$$

where N, μ and v_0 are the number of atoms, the rigidity, and the atomic volume, respectively, The factor 3 is due to the three independent components of shear strain.

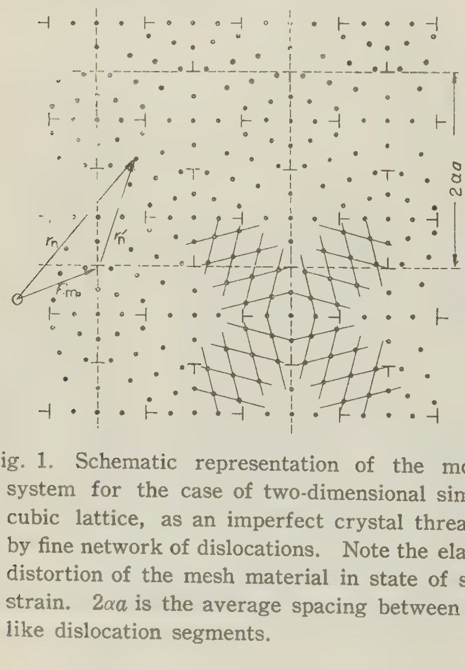

Fig. 1. Schematic representation of the model system for the case of two-dimensional simple cubic lattice, as an imperfect crystal threaded by fine network of dislocations. Note the elastic distortion of the mesh material in state of self-strain. $2\alpha a$ is the average spacing between the like dislocation segments.

The dislocation is the lattice imperfection originally introduced in the field of crystal plasticity. Its prominent feature discriminating it from other lattice imperfections is that the elastic shearing strain energy can be dissipated by the movement of dislocations introduced[10]. Now, in the present model of liquid threaded by dislocation network, the constituent dislocation segments are forced, under the influence of the thermal shear waves, to move in such a manner as to result a kind of plastic flow of the material to annihilate the elastic shear strain energy associated with the thermal shear waves. Taking account of such a dynamical character of the constituent dislocations of the present model, the transversal shear waves with the wave length longer than the average spacing $2\alpha a$ of the constituent dislocation segments are expected to be attenuated by the appropriate movement of the dislocation segments. For sake of simple treatment, we assume, defining a critical wave length $\lambda^*=2\alpha a$ or a corresponding critical wave number

$$k^*=2\pi/\lambda^*=\pi/\alpha a \,, \tag{2}$$

that in the model lattice the thermal shear waves with wave number $k>k^*(\lambda<\lambda^*)$ shall survive as vibrational modes but that the thermal shear waves with wave number $k<k^*$ $(\lambda>\lambda^*)$ shall degenerate into translational modes. This means that we expand the solenoidal displacement $\boldsymbol{u}(\boldsymbol{r}_n, t)$ of atom at coordinate $\boldsymbol{r}_n$ in the form

$$\boldsymbol{u}(\boldsymbol{r}_n,t)=\frac{1}{\sqrt{N}}\sum_{(k>k^*)}\sum_i \boldsymbol{B}_{ki}\exp(i\boldsymbol{k}\boldsymbol{r}_n) +\frac{1}{\sqrt{M}}\sum_{(k<k^*)}\sum_i \boldsymbol{B}'_{ki}\exp(i\boldsymbol{k}\boldsymbol{R}_m) \tag{3}$$

with $\boldsymbol{B}_{ki}\perp\boldsymbol{r}_n$ and $\boldsymbol{B}'_{ki}\perp\boldsymbol{R}_m$, $i=1$, 2 specifying the polarization. The coordinate $\boldsymbol{R}_m$ is defined as such a representative coordinate for each mesh material that the same $\boldsymbol{R}_m$ stands for every $\boldsymbol{r}_n$ belonging to all lattice points of the m-th crystallite (see Fig. 1). $M=N/\alpha^3$ is the total number of the crystallites. These translational thermal modes correspond to the relative shearing translation between the mesh material, each material or the crystallite behaving as a kinetic unit, so to speak. It is to be noted, however, that the translational freedom is introduced as to the solenoidal displacement but not as to the irrotational displacement, and so the total number of degenerated translational modes is equal to twice the number of crystallites.

Thus the Hamiltonian of the model system, of atomic mass m, is assumed in the form

$$\mathscr{H}=U_0+\sum_k \frac{1}{2m}(C_k^2+m^2\omega_{1k}^2 A_k^2)$$
$$+\sum_{(k>k^*)}\sum_i \frac{1}{2m}(D_{ki}^2+m^2\omega_{2ki}'^2 B_{ki}^2)$$
$$+\sum_{(k<k^*)}\sum_i \frac{1}{2m\alpha^3} D_{ki}'^2 \,. \tag{4}$$

The first term U_0 in the right hand side is the configurational excess energy given by Eq. (1), the second term represents the longitudinal vibrational modes each of eigen frequency ω_{1k}, the third term represents the surviving transversal vibrational modes, each of modified eigen frequency ω_{2ki}', and the fourth term represents the transversal translational modes. A_k and B_{ki} are the normal coordinates, and C_k, D_{ki} and D_{ki}' are the momenta, respectively.

As to the modulation of eigen frequency for the transversal shear waves, the main cause of modulation is the shear strain of the material in state of self-strain, $x=a/\alpha a$. To evaluate this anharmonic modulation of the eigen frequency $\omega_{2ki}'(x)$ for strained material, we tentatively assume, by symmetry consideration, a functional relation

$$\omega_{2ki}'(x)/\omega_{2ki}=\exp\left(-\tfrac{1}{2}\gamma x^2\right) \tag{5}$$

with constant coefficient γ, where ω_{2ki} is the natural eigen frequency for unstrained crystal. It can not be denied that, as it is with the Grüneisen's constant in the classical treatment of lattice expansion, this assumption is open to much debate, such as the different modulation for waves of different wave vector, the dependence of the coefficient on the strain, and also the *a posteriori* variation of the constant with temperature. Eq. (5) is assumed for the present provisionally to develope the treatment of the model.

§ 3. Partition Function

As the classical liquid is under consideration in the present treatment, the partition function of the system is gived by

$$Z=h^{-3N}\int\cdots\int \exp\left(-\mathscr{H}/kT\right)d\tau \,,$$

where the integration extends over all the configurations available for N atoms. In the present crystallite model theory, all the configurations of the system can be grouped into subgroups, the members of each subgroup representing the configurations with a specified average mesh size αa. So we may wright in the form

$$Z=\sum_\alpha Z_\alpha \,. \tag{6}$$

The specific partition function for each subgroup is

$$Z_\alpha=h^{-3N}\int\cdots\int^{1} \exp\left(-\mathscr{H}/kT\right)d\tau \,,$$

where the integration extends over configurations available for each specified average mesh size αa. With the Hamiltonian (4), the specific partition function is calculated through

$$Z_\alpha=h^{-3N}\,e^{-U_0/kT}\prod_k\iint \exp\left\{-\frac{1}{2mkT}C_k^2-\frac{m\omega_{1k}^2}{2kT}A_k^2\right\}dA_k dC_k$$
$$\times\prod_{(k>k^*)}\prod_i\iint \exp\left\{-\frac{1}{2mkT}D_{ki}^2-\frac{m\omega_{2ki}'^2}{2kT}B_{ki}^2\right\}dB_{ki}dD_{ki}$$
$$\times\prod_{(k<k^*)}\prod_i\iint \exp\left\{-\frac{1}{2m\alpha^3 kT}D_{ki}'\right\}dB_{ki}'dD_{ki}' \,. \tag{7}$$

The integration range for the harmonic coordinates, A_k and B_{ki}, can be extended from $-\infty$ to $+\infty$, due to neglegible contribution from the extreme configurations. The integration range $\Delta B_{ki}'$ for the translational coordinates, B_{ki}', is estimated to of the order of

$$\Delta B_{ki}'=\frac{k^*}{k}\Delta B_{k^*i}'=\frac{k^*}{k}a \qquad (k<k^*) \tag{8}$$

as follows. As to the critical mode characterized by the wave vector k^*, the transversal translational motion between two neighbouring layers of crystallites, the one in positive and the other in negative direction, is realized by means of one intervening layer of constituent dislocations (see Fig. 1). Because of the quasi-periodic distribution of the constituent dislocation segments, the identical arrangement of dislocations is resumed each after one layer of dislocations moves by the period $2\alpha a$, accompanying relative displacement between two halves of the crystal seperated by the dislocation layer amounting to the lattice constant a. Thus we expect an integration range of amount a for the critical mode. As to the other modes with smaller wave number ($k<k^*$), we have $\lambda/\lambda^*(=k^*/k)$ times as many intervening layers of dislocations, each contributing by the amount a to the relative displacement between two layers of crystallite at maximum displacement. With the integration ranges thus specified, we obtain

$$\ln Z_\alpha=-\frac{U_0}{kT}+\sum_k \ln\left(\frac{kT}{\hbar\omega_{1k}}\right)+2\sum_{(k>k^*)}\ln\left(\frac{kT}{\hbar\omega'_{2k}}\right)+2\sum_{(k<k^*)}\ln\left\{\frac{\sqrt{2\pi m\alpha^3 kT}}{h}\frac{k^*}{k}a\right\}. \tag{9}$$

By use of the spectra, g_l and g_t, each for the longitudinal and for the transversal modes, we have, refering Eq. (1),

$$\begin{aligned}\ln Z_\alpha=&-\frac{3N\mu v_0}{2kT}\alpha^{-2}+\int_0^{k_c}\ln\left(\frac{kT}{\hbar\omega_{1k}}\right)g_l dk+2\int_{k^*}^{k_c}\ln\left(\frac{kT}{\hbar\omega'_{2k}}\right)g_t dk\\&+2\int_0^{k^*}\ln\left\{\frac{\sqrt{2\pi mkT}a}{h}\alpha^{3/2}\frac{k^*}{k}\right\}g_t dk\,.\end{aligned} \tag{10}$$

Now we want to introduce the Debye approximation for the spectra

$$g_l=g_t=3Nk^2/k_c^3\,, \tag{11}$$

normalized to $\int_0^{k_c} g dk=N$, independently of the introduction of network of dislocations. This approximation is not inconsistent with the introduction of the translational shearing modes by Eq. (3), as the total number of these degenerated translational modes

$$2\int_0^{k^*} g_t dk=2N\left(\frac{k^*}{k_c}\right)^3=2N\left(\frac{\pi/\alpha a}{\pi/a}\right)^3=2N/\alpha^3 \tag{12}$$

is equal to twice the number of crystallites.

The partition function Z_0 for an ideally perfect crystal is obtained as the limiting case of infinite mesh size, $\alpha\to\infty$ and $k^*\to 0$;

$$\ln Z_0=\int_0^{k_c}\ln\left(\frac{kT}{\hbar\omega_{1k}}\right)g_l dk+2\int_0^{k_c}\ln\left(\frac{kT}{\hbar\omega_{2k}}\right)g_t dk\,. \tag{13}$$

From Eqs. (10) and (13), it follows

$$\ln\left(\frac{Z_\alpha}{Z_0}\right)=-\frac{3N\mu v_0}{2kT}\alpha^{-2}+2\int_{k^*}^{k_c}\ln\left(\frac{\omega_{2k}}{\omega'_{2k}}\right)g_t dk+2\int_0^{k^*}\ln\left\{\frac{\sqrt{2\pi mkT}a}{h}\frac{k^*}{k}\alpha^{3/2}\Big/\frac{kT}{\hbar\omega_{2k}}\right\}g_t dk\,,$$

which can be transcribed, with the natural frequency $\omega_{2k}=\sqrt{\mu v_0/m}\,k$ and refering Eqs. (5) and (11), to

$$\begin{aligned}\ln\left(\frac{Z_\alpha}{Z_0}\right)&=-\frac{3N\mu v_0}{2kT}\alpha^{-2}+2\ln\left(\frac{\omega_{2k}}{\omega'_{2k}}\right)\int_{k^*}^{k_c}g_t dk+2\ln\left\{\sqrt{\frac{\mu v_0}{2\pi kT}}ak^*\alpha^{3/2}\right\}\int_0^{k^*}g_t dk\\&=-\frac{3N\mu v_0}{2kT}\alpha^{-2}+\gamma\alpha^{-2}\cdot N(1-\alpha^{-3})+2\ln\left\{\sqrt{\frac{\mu v_0}{2kT}}\alpha^{1/2}\right\}\cdot N\alpha^{-3}\,.\end{aligned} \tag{14}$$

Defining the atomic quantities z_α and z_0 by $Z_\alpha=z_\alpha^N$ and $Z_0=z_0^N$, we have

$$\ln\left(\frac{z_\alpha}{z_0}\right)=\left(\gamma-\frac{\Theta}{T}\right)\alpha^{-2}+\ln\left(\frac{\pi}{3}\frac{\Theta}{T}\alpha\right)\alpha^{-3}-\gamma\alpha^{-5}\,, \tag{15}$$

where the reference temperature Θ is defined by

$$k\Theta=\frac{3}{2}\mu v_0\,. \tag{16}$$

§ 4. Thermodynamical Characters

The specific partition sunction $Z_\alpha=z_\alpha{}^N$ represents the relative thermodynamical probability of each subgroup specified by the average mesh size αa. As the relevent number of atoms N is sufficiently large, the total partition function Z is substantially approximated by the specific one Z_{α^*} for most probable subgroup. The mesh size $\alpha^*(T)$ for such a stable configuration is determined, by maximizing expression (15) as function of α for each temperature, by

$$\ln\frac{\pi}{3}-\frac{1}{3}+\ln\alpha^*-\frac{5}{3}\gamma\alpha^{*-2}$$
$$=-\ln\frac{\Theta}{T}+\frac{2}{3}\left(\frac{\Theta}{T}-\gamma\right)\alpha^*\,. \tag{17}$$

In the followings, the stable size α^* will be abbreviated merely by α.

As to the thermodynamical stability of the present system relative to the solid, we may presume that the solid can be represented by the limiting case of infinite mesh size, that is the ideal crystal without any imperfections. It might be argued that the real solid is not perfect but contains many lattice imperfections, which give rise to the well-known structure sensitive properties of the solid. In respect to the thermodynamical quantities, however, we may assume these quantities characteristic to the solid rather insensitive to existing lattice imperfections. Under the circumstances, the melting temperature T_m can be determined by the equilibrium condition between the two phases, $z_\alpha=z_0$. So we have, from Eq. (15) with the stable mesh size α^* of Eq. (17), at the melting point

$$\left(\gamma-\frac{\Theta}{T_m}\right)\alpha_m+\ln\left(\frac{\pi}{3}\,\frac{\Theta}{T_m}\,\alpha_m\right)=\gamma\alpha_m^{-2}\,. \tag{18}$$

For each specified value of the frequency modulating coefficient γ, Eqs. (18) and (17) determine the ratio Θ/T_m between the melting temperature T_m and the reference temperature Θ as well as the stable mesh size α_m at the melting point.

The excess free energy Δf per atom in liquid state over that in the solid state is given by

$$\Delta f=-kT\ln(z_\alpha/z_0)$$

with the stable α^* given by Eq. (17). The excess energy $\Delta e=\partial(\Delta f/T)/\partial(1/T)$ is calculated, noting that $\partial z_\alpha/\partial\alpha=0$ for α^*, to be

$$\Delta e=kT\left(\frac{\Theta}{T}\alpha^{-2}-\alpha^{-3}\right)=\frac{3\mu v_0}{2}\alpha^{-2}-kT\alpha^{-3}\,, \tag{19}$$

the first term in the right hand side being the configurational excess energy and the second term being the energy deficit due to degeneration of $2M(=2N/\alpha^3)$ degrees of freedom from vibrational to translational. The melting entropy $\Delta s(T_m)=\Delta e(T_m)/T_m$ is, accordingly, given by

$$\Delta s(T_m)=k\left(\frac{\Theta}{T_m}\alpha_m^{-2}-\alpha_m^{-3}\right), \tag{20}$$

where α_m is the stable mesh size at the melting point satisfying simultaneously Eqs. (17) and (18).

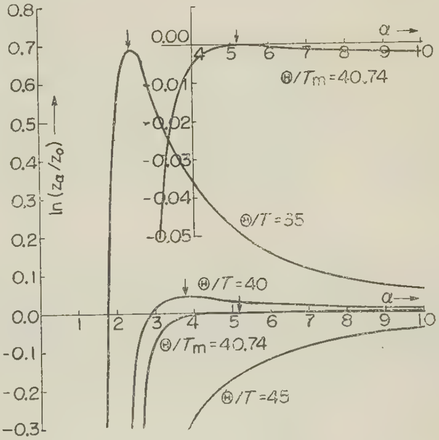

Fig. 2. Relative thermodynamical probability of subgroup at each constant temperature, for a specified value of $\gamma=40$. In the inset, the ordinate is magnified ten times.

§ 5. Discussions

The general trend of the relative thermodynamical probability z_α/z_0 is plotted, according to Eq. (15), in Fig. 2 as function of the mesh size α at each constant temperature, assuming a tentative value $\gamma=40$ for the frequency modulating coefficient. It can be seen that at low enough temperature, $\Theta/T=45$, z_α increases with increasing α monotonously to z_0, thus stabilizing the perfect crystal as representative for the solid phase, while at a high enough temperature, $\Theta/T=35$, z_α takes, at the stable mesh size α^* satisfying Eq. (17), a maximum value exceeding z_0, thus stabilizing the imperfect crystal as representative for the liquid phase. At an intermediate temperature T_m satisfying Eq. (18) as well as Eq. (17) for each specified γ, $\Theta/T_m=40.74$ for $\gamma=40$, the most probable imperfect crystal represented by the average mesh size α_m that maximizes z_α is in equilibrium with the perfect crystal of infinite mesh size, being seperated from each other by an intervening minimum of z_α, which is shown in the inset of Fig. 2. We have accordingly at the temperature T_m a kind of first order transition. The numerical value $\Theta/T_m=40.74$ is estimated graphically from ln $(z_\alpha{}^*/z_0)$ *versus* Θ/T plot for the case $\gamma=40$. The melting entropy $\varDelta s(T_m)$ for the transition is estimated by Eq. (20) to $1.51k$ in this case. Similar results obtained for each specified value of γ are summarized in Table I.

Table I. Predicted values at the melting point.

γ	30	40	50
α_m	4.71	5.18	5.30
Θ/T_m	30.78	40.74	50.67
$\varDelta s(T_m)/k$	1.37	1.51	1.79

The present model theory has, as can be seen in the above procedure, just one adjustable parameter, the frequency modulating coefficient γ. The reference temperature Θ, defined by Eq. (16), is determined by the rigidity μ and the atomic volume v_0 or by the atomic mass m and the propagation velocity v_t of the transversal wave through

$$k\Theta=\frac{3}{2}\mu v_0=\frac{3}{2}\rho v_t{}^2\cdot v_0=\frac{3}{2}mv_t{}^2\ . \tag{21}$$

As the coefficient γ is introduced in the present treatment rather tentatively, we want to estimate the probable value of this coefficient *a posteriori* in comparison with the experimental data. It seems legitimate to choose metals as the material for comparison, because the dislocation characterizing the present model is the lattice imperfection well established in the field of crystal plasticity of metals among others. The experimental data for noble metals is shown in Table II.

As to the ratio Θ/T_m, the experimental value for these metals is very close to 40, which suggests, refering Table I, a value nearly equal to 40 for the frequency modulating coefficient γ. For other face-centred cubic metals, the experimental value of the ratio ranges between 30 and 50. For body-centred cubic metals, iron and tungsten, the ratio is of order of 60. In the poor state of the present theory inherent from many approximations, we are reluctant from discussing specifically solely on the coefficient γ, but it seems that the order of magnitude of the coefficient can be evaluated empirically on these lines.

Table II.

Metal	T_m (°K)	Q_m (kcal/mol)	$\varDelta s/k$	v_t (m/sec)	atomic weight	Θ (°K)	Θ/T_m
copper	1,356	3.1	1.15	2,260	63.54	59,000	43.5
silver	1,233	2.69	1.10	1,590	107.88	49,200	39.9
gold	1,336	3.05	1.15	1,200	197.0	51,100	38.3

As to the melting entropy $\varDelta s(T_m)$, the estimated value exceeds the experimental one, and the discrepancy does not seem remediable by mere adjustment of value for γ. Now, in reviewing the prepositions introduced in § 2, the expression (1) for the configurational excess energy of the model system seems to be criticized. We see in Table I that the stable mesh size α^*a for the model system is less than several atom spacings. The average shear strain, $a/\alpha a$, is accordingly larger than 1/10 and so, because of the anharmonic nature of the strain energy, the expression (1) is expected to overestimate the configurational excess energy. This overestimation in the configurational energy may be the cause resulting in the said discrepancy of the melting entropy.

The author wishes to express his cordial thanks to Prof. M. Kotani and Prof. T. Muto for criticizing discussions throughout.

Surface Free Energy of a Dilute Gas

By Takuji TSUZUKI

Yokohama Municipal University Kanazawa-ku, Yokohama

(Received August 6, 1960)

The effect of boundary wall on a dilute gas of hard spheres is discussed. The free energy of the system is given as a function, not only of the volume, but also of the surface area of the container. The formula for the excess free energy due to the surface (surface tension) is given both for classical as well as for quantum mechanics. The quantum correction substitutes the effective diameter σ_{eff} for the classical diameter σ of a molecule.

§1. Introduction

In the current theories of statistical mechanics, systems are usually treated in the limit of infinite volume keeping the density constant. The physical quantities thus evaluated are therefore independent of the shape and the size of the vessel containing the system. These treatments are however inconvenient when the size of the system is small, or when the thickness of container becomes very small. For example, the spin wave theory for thin ferromagnetic materials has been developed by M. J. Klein and R. S. Smith[1]. They have shown theoretically that the spontaneous magnetization decreases with decreasing thickness. Their results are qualitatively in good agreement with experimental data of E. C. Crittendon and R. W. Hoffman[2]. Besides magnetic properties, we may cite many anomalous properties of thin substances, e. g., lowering of melting point[3], increasing of electric resistance[4], and decreasing of specific heat[5].

Another typical example of a small system is an atomic nucleus. Even for the heaviest atom, the number of nucleons at the surface of a nucleus is by no means negligible compared with the total number of nucleons. The surface tension and the surface energy play undoubtedly very important roles in determining the properties of nuclei. However statistical mechanics of nuclei, taking the effect of nuclear surface into account, is not yet fully developed.

In these problems we are more or less concerned with the surface free energy, that is, the surface tension. This is defined as the excess free energy per unit surface area. In general the structure near the surface of any system is obviously different from that in bulk. Particularly, the surface tension of liquid has been investigated by many authors[6] from the theoretical view-point. In the quantum treatment, A. Harasima et al.[7] has introduced the zero-point energy into the evaluation of surface energy, and M. Toda[8] has derived the general expression of surface tension in terms of density matrix.

Since, in general, the quantum treatment of the surface effect on a system of many particles with mutual interaction is of great difficulty, only the case of a dilute gas is investigated in this paper. Section 2, is devoted to classical dilute gas composed of hard spheres. Molecules interacting with square well potential is also treated in Appendix III. In Section 3, it is shown that by the quantum correction, the effective diameter of a particle must be larger than the diameter of a classical molecule.

§ 2. Classial Gas

We shall begin with the case of a gas of very low density. The constituent molecules are assumed to be hard spheres of diameter σ. If we increase area of the surface by the amount A, the volume which is accessible to the molecules diminishes by the amount $A\sigma/2$, since any molecule can not come closer to the surface than its radius $\sigma/2$. For a very dilute gas the part of the free energy which depend on the volume V is given by $-NkT\log V$, where N is the number of gas molecules. Therefore the increment of the free energy due to the new surface is given, for unit area, by

$$\gamma=-\frac{1}{A}NkT\log\{(V-A\sigma/2)/V\}\cong\frac{N}{V}kT\frac{\sigma}{2}\,. \tag{2.1}$$

This is the first approximation for the excess free energy γ per unit area of the surface. We may also apply Eq. (2.1) to the change in surface tension of liquid caused by solute molecules (Appendix I).

When the density of the gas is higher, collision between molecules is to be taken into consideration. For the equation of state this corresponds to the calculation of the second virial coefficient. If, in general, the interaction energy between molecules is given in the form

$$U=\sum_{i>j=1}^{N}u(i,j)\,,$$

the configurational partition function is given by the integral of

$$e^{-\beta U}=1+\sum_{i>j=1}^{N}(e^{-\beta u(i,j)}-1)+\cdots\,. \tag{2.2}$$

The first term on the right-hand side of Eq. (2.2) gives Eq. (2.1) for the surface free energy. For hard sphere molecules under consideration, each of the second term is -1 when $r_{ij}<\sigma$ and vanishes when $r_{ij}>\sigma$.

When we integrate Eq. (2.2), especially each of the second term, with respect to a molecule, we are to subtract that part of the volume which is not accessible to that molecule. If the area of the vessel is A and if any molecule can not come closer to the wall than the distance a, the region with volume Aa near the surface and the interaction sphere with volume $4\pi\sigma^3/3$ around any other molecule are not accessible. The region common to these is not to be counted twice. For a molecule which is at x from the wall, this part of the interaction sphere is

$$v(x)=\int_{x-a}^{\sigma}d\xi\,\pi(\sigma^2-\xi^2)=\frac{\pi}{3}(x-\sigma-a)^2(x+2\sigma-a)\,. \tag{2.3}$$

We find thus the free energy F expressed by the formula

$$\begin{aligned}\lambda^{3N}N!\exp(-\beta F)&=\int\cdots\int dx_1\cdots dx_N e^{-\beta U}\\&=(V-Aa)^N+N(N-1)/2\cdot(V-Aa)^{N-2}\\&\quad\times\left\{\left(-\frac{4}{3}\pi\sigma^3-Aa\right)(V-Aa)+A\int_a^{a+\sigma}v(x)dx\right\}+\cdots\\&=(V-Aa)^N\left\{1-\frac{N(N-1)}{2(V-Aa)}\left(\frac{4}{3}\pi\sigma^3-\frac{\pi}{4}\sigma^4\frac{A}{V-Aa}\right)\right\}+\cdots\,.\end{aligned} \tag{2.4}$$

Or, expanding the logarithm, we obtain the result configurational part of the free energy F_0

$$F_c=-NkT\left(\log V-\frac{2\pi}{3}\sigma^3\frac{N}{V}\right)+\gamma A\,, \tag{2.5}$$

where

$$\gamma=\frac{NkT}{V}\left\{a+\frac{\pi}{24}(16a-3\sigma)\sigma^3\frac{N}{V}\right\}\,. \tag{2.6}$$

If we define the effective volume $V_{\rm eff}$ as follows

$$\lambda^{3N} N! \exp(-\beta F) = V_{\rm eff}^{N}\,, \tag{2.7}$$

then it becomes from Eq. (2.4)

$$V_{\rm eff} = V - Aa - N\left(\frac{2}{3}\pi\sigma^3 - \frac{\pi}{8}\sigma^4\frac{A}{V}\right). \tag{2.8}$$

W. A. Steele and G. D. Halsey, Jr.[9] have calculated the effective volume assuming the attractive force of Lennard-Jones type, and obtained

$$V_{\rm eff} = V - Aa + Aa\sum_{\tau=1}^{\infty}\{1/\tau!(3\tau-1)\}(\mathcal{E}/kT)^{\tau}\,. \tag{2.9}$$

The third term in the right-hand side of Eq. (2.9) is derived from the attractive forces between the gas molecules and the wall. In the present paper, however, the effect of the attractive force caused by the square-well potential will be expanded in Appendix III.

Putting $a=\sigma/2$, we get the second approximation for the surface free energy:

$$\gamma = \frac{NkT\sigma}{2V}\left(1+\frac{5\pi}{12}\sigma^3\frac{N}{V}\right). \tag{2.10}$$

The equation of state is, from Eq. (2.5),

$$p = \frac{NkT}{V}\left(1+\frac{2\pi}{3}\sigma^3\frac{N}{V}\right). \tag{2.11}$$

We may interprete Eq. (2.1) the other way: the most convenient way of estimating surface effect is to introduce a very thin wall at the middle of the system and thus divide it into two parts keeping the total volume unaltered. As is shown in Fig. 1, if we want to introduce a wall amidst the vessel, we have to push aside those molecules which lies on that plane. To do this we first introduce two hypothetical membranes side by side. These membranes are such that through which the center of any molecule can not pass. Introduction of these membranes does not affect the free energy of the total system. Then we push one of the membrane to the right and the other to the left by the same amount $\sigma/2$ (see Fig. 1). At this stage we can introduce, without any work, a wall of infinitesimal thickness amidst the membranes to divide the system into two parts. Increase in the free energy is equal to the work done by moving the membranes. Since the gaseous pressure exerting on each membrane is, in the first approximation, equal to the pressure p of the gas, the work per unit area of each membrane is $p\sigma/2$ which is the excess free energy given by Eq. (2.1) because $p=NkT/V$ is satisfied in this approximation.

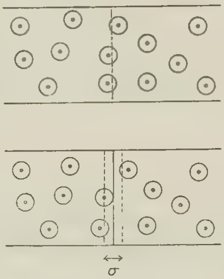

Fig. 1.

A similar interpretation for Eq. (2.10) is not difficult. After some calculations given in Appendix II, we see that the pressure on the membranes when separated mutually by the distance s is

$$p(s) = \frac{NkT}{V}\left\{1+\frac{\pi}{3}(3\sigma^2 s - s^3)\frac{N}{V}\right\}.$$

Therefore the work done by unit surface of the membranes is

$$\frac{1}{2}\int_0^{\sigma} p(s)ds = \frac{NkT\sigma}{2V}\left(1+\frac{5\pi}{12}\sigma^3\frac{N}{V}\right),$$

which is identical to the surface free energy given by Eq. (2.10).

It is straight-forward to extend the calculation to more general case in which attractive force is present (Appendix III).

§ 3. Quantum Corrections

When the gas is very dilute we can treat the molecules as free particles. Then we have exact density matrix

$$\rho^{(1)}(\boldsymbol{x}, \boldsymbol{x}')=\sum_{k=1}^{\infty} \varphi_k{}^*(\boldsymbol{x}') \exp(-h^2k^2/8\pi^2mkT)\varphi_k(\boldsymbol{x}) , \tag{3.1}$$

where

$$\varphi(\boldsymbol{x})= \prod_{x,y,z}\sqrt{\frac{2}{L_x}} \sin\frac{\pi n_x}{L_x}x , \qquad n_x=1, 2, \cdots \tag{3.2}$$

and L_x etc. mean the widths of the container.

From Eq. (3.1) we get the well-known expression for the density $\rho(x)$ at distance $x(\ll L_x)$ from the surface wall. When $\rho(x)$ is normalized so that $\rho\rightarrow 1$ as x becomes large, we have

$$\rho(x)=1-\exp(-4\pi x^2/\lambda^2) , \tag{3.3}$$

with

$$\lambda^2=h^2/2\pi mkT , \tag{3.4}$$

where h stands for the Planck's constant, k the Boltzmann constant and T the temperature.

The surface free energy in this case has been given by Toda[8]. The result is

$$\gamma=\frac{N}{V}\frac{\lambda}{4}kT . \tag{3.5}$$

This formula affords following interpretation. If there is no wall $\rho(x)$ stays 1 up to $x=0$. Introduction of the wall at $x=0$ causes a decrease in the density. The amount of this decrease can be expressed by the length δ:

$$\delta=\int_0^\infty \exp(-4\pi x^2/\lambda^2)dx=\lambda/4 . \tag{3.6}$$

In other words, the volume accessible to a molecule is diminished by $A\delta$, where A denoted the area of the surface as before. The surface free energy is therefore obtained by substituting δ for $\sigma/2$ in Eq. (2.1). This gives immediately Eq. (3.5).

When the diameter of molecules is finite and is σ, we have to substitute $\sigma/2+\delta$ for $\sigma/2$ in Eq. (2.1). We obtain thus the first approximation for a very dilute gas at low temperatures:

$$\gamma=\frac{N}{V}kT\left(\frac{\sigma}{2}+\frac{\lambda}{4}\right) . \tag{3.7}$$

We see that $\gamma/\gamma_{\text{class}}$ increases with decreasing temperature.

The second approximation, which takes molecular collision into account, can be obtained if the counter-part of Eq. (2.2) in quantum mechanics is evaluated. This is given as[10]

$$\begin{aligned}\exp(-\beta H^{(N)})&=\exp(-\beta H_0{}^{(N)})\\ &\quad+\sum_{i>j} \exp(-\beta H_0{}^{(N-2)}(\{i, j\})[\exp(-\beta H^{(2)}(i, j)-\exp(-\beta H^{(2)}(i, j))]+\cdots ,\end{aligned} \tag{3.8}$$

where $H^{(N)}$ denotes the hamiltonian of N particles and $H_0{}^{(N)}$ that without interaction. The bracket $\{i, j\}$ means that the i-th and the j-th molecules are excluded.

The first term on the right-hand side of Eq. (3.8) gives Eq. (3.7). Up to the second term we have

$$e^{-\beta F}=\frac{\lambda^{-3N}}{N!}\left\{V-A\left(\frac{\sigma}{2}+\frac{\lambda}{4}\right)\right\}^{N}$$
$$\times\left\{1+\frac{N(N-1)}{2}\left[V-A\left(\frac{\sigma}{2}+\frac{\lambda}{4}\right)\right]^{-2}\iint d\boldsymbol{x}_1 d\boldsymbol{x}_1(S-1)+\cdots\right\}, \tag{3.9}$$

where S is defined by

$$\langle \boldsymbol{x}_1, \boldsymbol{x}_2| \exp[-\beta H^{(2)}(1,2)]|\boldsymbol{x}_1, \boldsymbol{x}_2\rangle=\lambda^{-6}S(\boldsymbol{x}_1, \boldsymbol{x}_2) . \tag{3.10}$$

The integral appearing in Eq. (3.9) is difficult to evaluate.

If we neglect the effect of the boundary, however, S is obtained and gives the second virial coefficient, which is given by

$$B(T)=2\pi N\int_0^\infty r^2 dr(1-S(r)) , \tag{3.11}$$

where

$$S(r)=S(|\boldsymbol{x}_1-\boldsymbol{x}_2|) . \tag{3.12}$$

Noting that $\rho^{(2)}=\exp(-\beta H^{(2)})$ satisfies the Bloch equation we can calculate its diagonal element. The result is (cf. reference 11)

$$S(r)=\frac{\sqrt{2}\,\lambda^3}{\pi^2 r^2}\sum_l (2l+1)\int_0^\infty dk \exp(-\lambda^2k^2/2\pi)v_l^2(k, r) , \tag{3.13}$$

where

$$v_l(k, r)=\sqrt{\frac{\pi kr}{2}}\,\frac{J_{-l-(1/2)}(k\sigma)J_{l+(1/2)}(kr)-J_{l+(1/2)}(k\sigma)J_{-l-(1/2)}(kr)}{\{J^2_{l+(1/2)}(k\sigma)+J^2_{-l-(1/2)}(k\sigma)\}^{1/2}} , \tag{3.14}$$

in which σ means the diameter of a molecule.

Making use of the definition of Bessel functions we can show, for large value of kr, that

$$v_l^2(kr)\sim\begin{cases}\dfrac{1}{\sqrt{1-(l/kr)^2}}\sin^2\{k(r-\sigma)\sqrt{1-(l/kr)^2}\} , & (l<kr)\\ 0 , \quad (l>kr) . & \end{cases} \tag{3.15}$$

For high temperatures we get finally

$$\begin{aligned}S(r)&=\frac{\sqrt{2}\,\lambda^3}{\pi^2 r^2}\int_0^\infty dk\int_0^{kr}\frac{2l dl}{\sqrt{1-(l/kr)^2}}\sin^2\{k(r-\sigma)\sqrt{1-(l/kr)^2}\}\exp(-\lambda^2k^2/2\pi)\\&=\frac{\sqrt{2}\,\lambda^3}{\pi^2 r^2}\int_0^\infty dk(kr)^2\left\{1-\frac{\sin 2k(r-\sigma)}{2k(r-\sigma)}\right\}\exp(-\lambda^2k^2/2\pi)\\&=1-\exp\{-2\pi(r-\sigma)^2/\lambda^2\} .\end{aligned} \tag{3.16}$$

The second virial coefficient can be calculated easily with the use of (3.16), namely

$$B(T)=\frac{2}{3}\pi N\sigma^3+\frac{\pi}{\sqrt{2}}N\sigma^2\lambda+N\sigma\lambda^2+\frac{1}{4\sqrt{2}}N\lambda^3 , \tag{3.17}$$

which agrees with calculation by other authors except for the last term. Quantum effect appears in our theory, in the deviation of $S(r)$ from unity in the range $\sigma\leq r$. The same argument used in deriving Eq. (3.6) applies to Eq. (3.16). Thus the effective diameter σ_{eff} defined by

$$\sigma_{\text{eff}}=\sigma+\frac{\lambda}{2\sqrt{2}} \tag{3.18}$$

must be substituted for the classical diameter σ. The meaning of the density matrix in quantum theory is illustrated in Appendix IV.

A temporal second appoximation for the surface free energy is given, in quantum mechanics, by replacing σ by σ_{eff} and a by $\sigma/2+\lambda/4$ in Eq. (2.6). That is

$$\gamma=\frac{NkT}{V}\left[\left(\frac{\sigma}{2}+\frac{\lambda}{4}\right)+\left\{\frac{2}{3}\pi\left(\frac{\sigma}{2}+\frac{\lambda}{4}\right)-\frac{\pi}{8}\left(\sigma+\frac{\lambda}{2\sqrt{2}}\right)\right\}\left(\sigma+\frac{\lambda}{2\sqrt{2}}\right)^3\frac{N}{V}\right]. \tag{3.19}$$

§ 4. Concluding Remarks

When statistical effect is introduced, we have to consider exchange of particles. Exchanging $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ in Eq. (3.13), the same formula is given for even l, and sign changes for odd l. namely

$$S(r)=1-\exp\{-2\pi(r-\sigma)^2/\lambda^2\}\pm\frac{\sqrt{2}\,\lambda^3}{\pi^2 r^2}\sum_l(-)^l\int_0^\infty dk\exp(-\lambda^2k^2/2\pi)v_l^2(kr)\,, \tag{3.20}$$

in which the upper sign corresponds to Bose-Einstein statistics and the lower to Fermi-Dirac statistics. However in the approximation for high temperature, the third term in the right hand side of Eq. (3.20) nearly vanishes. The Slater sum of pair particles is scarcely influenced by the statistical effect in high temperature region.

The evaluation of the surface tension of a dilute gas has a certain relation to the calculation of the third virial coefficient in the sense that the wall can be introduced by making the diameter of the third molecule infinite. Recently A. Pais and G. E. Uhlenbeck[12] have investigated the third virial coefficient in quantum treatment. However, application of this theory to the problem of the surface tension does not seem to be possible.

Acknowledgement

In conclusion the author wishes to express his hearty thanks to Professor M. Toda of Tokyo University of Education for his helpful discussions and encouragement.

Appendix I.

There is intimate similarity between the behaviors of a dilute gas and of a dilute solution. The pressure p of a gas corresponds to the osmotic pressure π of a solution, and the surface tension γ of a gas corresponds to the increase in the surface tension of the solution $\Delta\gamma=\gamma-\gamma_0$, in which γ is the surface tension of the solutions and γ_0 is that of pure solvent.

If we assume that the solute molecules are hard spheres which do not make their appearance the free surface of the solution we can apply the above results to this case and obtain

$$\Delta\gamma=\frac{1}{2}\pi\sigma\,. \tag{A.1}$$

For example, for aqueous solution of saccharose with one molal concentration, $\Delta\gamma=1.2$ dyne/cm and $\pi=27$ atm., thus we obtain from Eq. (A.1) $\sigma\approx9$ Å. This value seems reasonable qualitatively, though the molecule ($C_{12}H_{22}O_{11}$) is not a hard sphere.

Appendix II.

The membranes considered in § 2 are separated by the distance s in Fig. 2. At any instant, there are molecules whose interaction spheres cut the membranes. A and B in Fig. 2 are those areas of one of the membranes cut by the molecules in the right and in the left halves of the vessel respectively. Let S_A and S_B be the total area of these per unit area of the membrane. Then we have

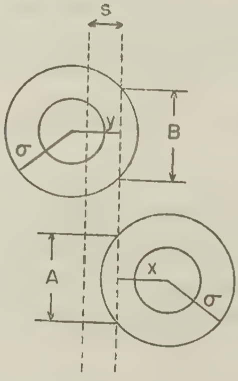

Fig. 2.

$$S_A=\frac{N}{V}\int_0^{\sigma}\pi(\sigma^2-x^2)\,dx=\frac{2\pi}{3}\sigma^3N/V$$

$$S_B=\begin{cases}\dfrac{N}{V}\displaystyle\int_s^{\sigma}\pi(\sigma^2-y^2)\,dy=\left(\dfrac{2\pi}{3}\sigma^3+\dfrac{\pi s^3}{3}-\pi\sigma^2 s\right)\dfrac{N}{V}\,, & (s<\sigma)\\ 0\,, \quad (s>\sigma)\,. \end{cases} \tag{A.2}$$

In the calculation of the impact on the membrane due to a molecule the areas S_A and S_B covered by other molecules are to be excluded. Since the probability density for a molecule is $1/(V-4\pi N\sigma^3/3)$, the pressure on the membrane is

$$p(s)=\frac{NkT}{V-4\pi N\sigma^3/3}(1-S_A-S_B)\cong\frac{NkT}{V}\left\{1+\frac{\pi}{3}(3\sigma^2 s-s^3)\frac{N}{V}\right\}\,,\qquad (s<\sigma) \tag{A.3}$$

$p(s)$ increases with increasing s, and reaches at $s=\sigma$ the actual pressure of the gas given by Eq. (2.11).

Appendix III.

M. P. Freeman and G. D. Halsey, Jr.[13] have investigated the adsorption phenomena of gases to solids. They assumed the hard sphere repulsion and the cube law attraction between each molecule and the surface, and only the hard sphere repulsion between the gas molecules. We shall here treat the gas molecules with attraction. Besides the interaction between molucules $u(r)$, we shall introduce the potential energy between a molecule and the boundary wall $u_w(x)$, which is a function of the shortest distance x from the center of a molecule to the surface of the wall. Both $u(r)$ and $u_w(x)$ may be very large where r and x become smaller compared with molecular dimension, and may have negative values at appropriate values of r and x, and vanish in the limit $r\to\infty$ and $x\to\infty$. Tendency of cohesion and adhesion can be expected from the negative values of $u(r)$ and $u_w(x)$ respectively. It may be allowed to approximate the function $u(r)$ by a square-well potential of the form

$$u(r)=\begin{cases}\infty & \text{for} \quad 0\leq r\leq\sigma\\ -\varepsilon & \text{for} \quad \sigma<r\leq g\sigma\\ 0 & \text{for} \quad g\sigma<r\,,\end{cases} \tag{A.4}$$

where σ denotes the diameter of a molecule, g is a dimensionless constant. It has been shown by T. Kihara[14] that Eq. (A.4), with $g=2$, gives the second virial coefficient in good agreements with experimental results for rare gases.

For $u_w(x)$ we assume the analogous form

$$u_w(x)=\begin{cases}\infty & \text{for} \quad 0\leq x\leq a\\ -\Delta & \text{for} \quad a<x\leq b\\ 0 & \text{for} \quad b<x\end{cases} \tag{A.5}$$

where a means the collision radius between a molecule and the wall and is nearly equal to or slightly larger than the molecular radius $\sigma/2$. $c\equiv b-a$ means the width of the well. For brevity's sake, we introduce dimensionless quantities

$$F\equiv e^{\beta\varepsilon}-1\,,\qquad G\equiv e^{\beta\Delta}-1\,. \tag{A.6}$$

The total potential energy U is written

$$U(\boldsymbol{x}_1,\boldsymbol{x}_2,\cdots,\boldsymbol{x}_N)=\sum_{i>j}^{N}u(|\boldsymbol{x}_i-\boldsymbol{x}_j|)+\sum_{i=1}^{N}u_w(\boldsymbol{x}_i) \tag{A.7}$$

and the formula $\exp(-\beta U)$ can be expanded when the density of the gas is dilute. After some calculations, the free energy F is given by

$$\lambda^{3N}N!\exp(-\beta F)=(V-aA+cGA)^N + \frac{N(N-1)}{2}(V-aA+cGA)^{N-2}\left\{(V-aA)\frac{4}{3}\pi\sigma^3[-1+(g^3-1)F]+IA\right\}, \quad \text{(A.8)}$$

in which

$$I=FG^2\pi\left(g^2\sigma^2c^2-\frac{4}{3}\sigma^3c+\frac{1}{2}\sigma^4-\frac{1}{6}c^4\right)+G^2\pi\left(\frac{1}{2}\sigma^4-\frac{4}{3}\sigma^3c\right) +FG\pi\left(\frac{4}{3}g^3\sigma^3c+g^2\sigma^2c^2-\frac{8}{3}\sigma^3c+\frac{1}{2}\sigma^4-\frac{1}{6}c^4\right) +G\pi\left(\frac{1}{2}\sigma^4-\frac{8}{3}\sigma^3c\right)+F\pi\left(-\frac{1}{4}g^4\sigma^4+\frac{1}{4}\sigma^4\right)+\pi\frac{1}{4}\sigma^4. \quad \text{(A.9)}$$

The pressure p becomes

$$\frac{p}{kT}=-\frac{1}{kT}\left(\frac{\partial F}{\partial V}\right)_T=\frac{N}{V}-\frac{N^2}{V^2}\frac{2}{3}\pi\sigma^3[-1+(g^3-1)F]. \quad \text{(A.10)}$$

The second term in the right-hand side of Eq. (A. 10) is identical with the second virial coefficient in the limit of infinite volume.

The surface tension γ is derived as follows

$$\frac{\gamma}{kT}=\frac{N}{V}(a-cG)-\frac{N^2}{V^2}\left\{\frac{2}{3}\pi\sigma^3[-1+(g^3-1)F](a-2cG)+\frac{1}{2}I\right\}, \quad \text{(A.11)}$$

where I was defined in Eq. (A.9). When the hard sphere model is adopted, Eq. (A.11) reduces to Eq. (2.6).

The surface energy U_A, which is defined as the derivative of the energy with respect of the surface area, becomes

$$U_A=-\frac{N}{V}cG'-\frac{N^2}{V^2}\left\{\frac{2}{3}\pi\sigma^3[-a(g^3-1)F'-2(-1+(g^3-1)F)cG']+\frac{1}{2}I'\right\}, \quad \text{(A.12)}$$

where prime denotes the derivative with respect to β, namely

$$I'=\frac{\partial}{\partial\beta}I, \qquad F'=\frac{\partial F}{\partial\beta}=\mathcal{E}e^{\beta\varepsilon} \qquad \text{and} \qquad G'=\frac{\partial G}{\partial\beta}=\varDelta e^{\beta\Delta}.$$

Appendix IV.

The diagonal element of the density matrix can be written, in terms of the path-integral, as

$$\rho^{(N)}(\boldsymbol{x}_1,\cdots,\boldsymbol{x}_N;\ \boldsymbol{x}_1,\cdots\boldsymbol{x}_N) =\int\exp\left[-\int_0^\beta\left\{\frac{2\pi^2m}{h^2}\left|\frac{d\boldsymbol{x}(u)}{du}\right|^2+U[\boldsymbol{x}(u)]\right\}du\right]\mathscr{D}\boldsymbol{x}(u), \quad \text{(A.13)}$$

where the paths are such that

$$\boldsymbol{x}_1(0)=\boldsymbol{x}_1(\beta)=\boldsymbol{x}_1,\ \boldsymbol{x}_2(0)=\boldsymbol{x}_2(\beta)=\boldsymbol{x}_2,\cdots,\ \boldsymbol{x}_N(0)=\boldsymbol{x}_N(\beta)=\boldsymbol{x}_N.$$

For small β (high temperatures) the paths which contribute to the integral are nearly straight. In this case, we get the classical expression. For large β (low temperatures) the paths may wiggle and the molecules may collide even if they are separated in the initial or final state. This is the quantum effect that the effective diameter of molecules increases with decreas ing temperature.

Ferrimagnetic Reasonance in Europium-Iron Garnet

Tomonao MIYADAI

Electrical Communication Laboratory Nippon Telegraph and Telephone Public Corporation Tokyo Japan

(Received June 13, 1960)

Ferrimagnetic reasonance experiment in a single crystal and polycrystalline samples has been carried out by a usual microwave technique. It has been found, for the single crystal, that the temperature variations of the g-factor and the line width are similar to those of erbium-iron garnet (ErIG) except for the existence of a broad maximum in line width at about 200°K. These behaviors agree well with Kittel's theory proposed recently. At room temperature, $g_{\rm eff}=1.32$, $\Delta H=600$ œ (anisotropy in line width having been hardly observed) and $K_1/M_s=-400$ œ (which is an order of magnitude larger than that of YIG). For polycrystalline samples, $g_{\rm eff}$ is essentially the same as for the single crystal sample. In the absorption curve, a secondary peak appears, below 200°K, in the lower magnetic field side of the main absorption peak. Electronic state of Eu^{3+} in the garnet crystal is briefly discussed.

§1. Introduction

Yttrium-iron garnet (YIG)[1),2)] and lutethium-iron garnet (LuIG)[3)] show a very narrow ferrimagnetic resonance line width, while all the other garnets reported so far[4)] show very broad one. Furthermore, both line widths and g-factors differ considerably among them. It is, therefore, obvious that rare earth ions in the garnet considerably affect the behavior of ferrimagnetic resonance. This is contrasted to the role of rare earth ions in optical properties[5)] to which they make little contribution. Now we are interested in the role of rare earth ions in ferrimagnetic resonance in rare earth-iron garnets.

Recently, Kittel et al.[6),7)] proposed a theory of ferrimagnetic resonance in rare earth-iron garnets. The temperature dependences of line widths and g-factors for erbium-iron garnet (ErIG) and holumium-iron garnet (HoIG)[4)] are explained very well by the theory. For samarium-iron garnet (SmIG) and ytterbium-iron garnet (YbIG), however, it appears that the theory should be modified to some extent.[4)] For gadolinium-iron garnet (GdIG)[4)], Tsuya-Wangsness' model[8),9)] is found to hold.[4),10)] For the other grants, there are little data.

We have, here, chosen europium-iron garnet (EuIG), Eu$_3$Fe$_5$O$_{12}$. One of the reasons for the choice is that no data have been reported so far and another reason is as follows: the multiplet terms of Eu^{3+} in free ion state are so closely located near the lowest state (the ground state has $J=0$, $^7F_0$) that magnetic properties of Eu^{3+} in crystals cannot be explained without taking into account the mixing of excited states having $J\neq 0$.[11] For example, Eu^{3+} in garnet crystal (EuIG) has a magnetic moment of about 0.8 μ_B per ion,[12] even at 4.2°K. Accordingly it may be expected that these special situations for Eu^{3+} affect the character of ferrimagnetic resonance in EuIG. In this paper, it is shown that the behavior of ferrimagnetic resonance in EuIG can be explained very well by kittel's theory and that the ground state for Eu^{3+} in EuIG may be mixed with higher states having $J\neq 0$ in some way.

§ 2. Samples and Experimental Procedures

The single crystal sample was prepared by flux method.[13] The starting proportion of the oxides, Eu_2O_3 (99.9%)*), Fe_2O_3 and PbO was somewhat different from that**) proposed by Nielsen[13]; a little less in contents of Eu_2O_3 and PbO than that of Nielsen. It was found that our proportion was preferable in order to get large single crystals under the conditions used here. Our treatment was as follows: the mixed powder was maintained to melt for 5 hours and then cooled very slowly down to about 900°C at various rates of 1 to 5°C/hr according to temperature ranges and finally drawn out of the furnance into air. The temperature control system[14] used in the heat treatments had a detecting unit which was operated by magnetic modulation system and could detect the difference between the temperature inside the furnance and a reference one given by a precision potentiometer. The polycrystalline sample was prepared by coprecipitation method[15]; the mixed powder obtained was prefired at 1000°C for about 2 hours and then sintered at 1330°C for 5.3 hours, both in air. The apparent density of the sample was equal to 5.36, corresponding to relative density of 90%, and the Curie temperature measured by a magnetic balance[16] was equal to 292°C, which agreed with the value obtained by Pauthenet.[12] The shape of the single crystal- and polycrystalline samples used for resonance absorption measurement were sphers of 0.59 mm and 0.54 mm in diameters, respectively. For polycrystalline samples, several spheres with different diameters were also measured at room temperature. Since no difference between them was observed for g-factor and line width within the experimental errors, a sphere of 0.54 mm in diameter alone was used for measurement at various temperatures.

The resonance absorption measurement were made in the temperature range between liquid nitrogen and Curie point at 18320 Mc/sec, the power of which was obtained by frequency doubling of microwave power of 9160 Mc/sec from a 2K25 klystron. The experimental procedures were a usual microwave technique. A frequency-modulation method was used***) (its modulation amplitude being so as to cover the Q-curve for the cavity), and the static magnetic field was slowly sweeped manually through the resonance field and the absorption curve was recorded automatically on an X-Y recorder.

§ 3. Experimental Results

Single crystal sample At room temperature, the measurement was made by rotating the sample around a ⟨110⟩ direction at every 10 degrees. At other temperatures, it was made for three principal axes; with magnetic fields parallel to ⟨100⟩, ⟨110⟩ and ⟨111⟩ directions. At low temperatures, no absorption could be observed for ⟨100⟩ direction, because the resonant field required at those temperatures is beyond the available field (~16000 œ). The g-factor and the first order cubic anisotropy field K_1/M_s at room temperature was obtained from the relation[18] for a (110) plane in which the saturation magnetization M_s lies;

$$\left.\begin{aligned}\omega^2=\gamma^2&\left\{H_0+(2-\sin^2\theta-3\sin^2 2\theta)\frac{K_1}{M_s}\right\}\\&\times\left\{H_0+2\left(1-2\sin^2\theta-\frac{3}{8}\sin^2 2\theta\right)\frac{K_1}{M_s}\right\}\\\gamma&=g_{\mathrm{eff}}\frac{e}{2mc}\end{aligned}\right\} \qquad (1)$$

---

*) Product of Davison Chem. Co., USA. It contains $Sm_2O_3+Gd_2O_3$ of 0.1% as impurities according to chemical analysis by the company.

**) $Y_2O_3:Fe_2O_3:PbO=3.5:44:52.5$ (mol %).

***) The details of the equipment are described elsewhere[17].

where H_0 stands for the resonant field, θ for the angle between M_s (or H_0) and a ⟨100⟩ direction which lies in the (110) plane. The observed resonant fields are plotted as a function of θ in Fig. 1 in which is also shown the curve calculated from Eq. (1) with $g=1.32$ and $K_1/M_s=-410$ œ.

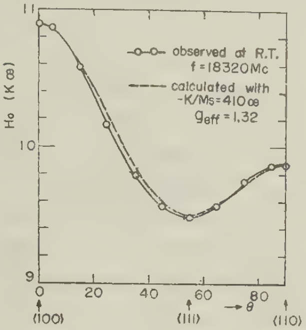

Fig. 1. Reasonant fields *vs* θ in a (110) plane at room temperature. θ is the angle between M_s and <100>.
Dashed curve represents the calculated one by Eq. (1).

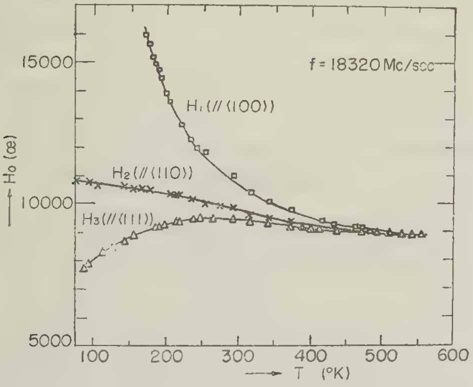

Fig. 2. Temperature variations of resonant fields for three principal axes.

The resonant fields for three principle axes ⟨100⟩, ⟨110⟩ and ⟨111⟩ are plotted as a function of temperature in Fig. 2. The g-faotcr and cubic anisotropy fields K_1/N_s and K_2/M_s are calculated from the relations[19]:

$$\left.\begin{aligned}&\omega^2=\gamma^2(H_1+2K_1/M_s)^2\ ,\\&\omega^2=\gamma^2(H_2-2K_1/M_s)(H_2+K_1/M_s+K_2/2M_s)\ ,\\&\omega^2=\gamma^2(H_3-4K_1/3M_s-4K_2/9M_s)^2\ ,\end{aligned}\right\}\tag{2}$$

where H_1, H_2 and H_3 refer to resonant fields parallel to ⟨100⟩, ⟨110⟩ and ⟨111⟩, respectively. In the calculation, the values for H_1, H_2 and H_3 were read on the smoothed out curves in Fig. 2. The errors of K_1/M_s and K_2/M_s were 100 and several hundreds, oersteds, respectively.

K_2/M_s vanishes at room temperature, but it becomes comparable with K_1/M_s at about 200°K, although it involves rather large uncertainty, namely the observed value is comparable with that of experimental error. Values of K_2/M_s at low temperatures are tabulated in Table I.

Table I.

T (K°)	K_1/M_s (œ)	K_2/M_s (œ)	g_{eff}
230	− 870	0	1.24
210	−1180	+ 300	1.22
190	−1670	+ 500	1.20
170	−2170	+1000	1.15

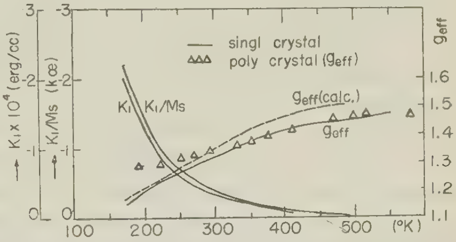

Fig. 3. K_1/M_s, K_1 and g_{eff} for single crystal sample are shown as functions of temperature. Dashed curve represents the calculated one by Eq. (3). g_{eff} for polycrystalline sample is also plotted.

There are temperature dependences of g-factor as well as K_1/M_s. They are shown in Fig. 3. Similar temperature dependences of g-factor were also found in other garnets.[4]

$-K_1/M_s$ seems to increase rapidly with decreasing temperature in the temperature range where K_2/M_s is also appreciable. K_1/M_s is equal to about −400 œ at room temperature. Such a value is an order of magnitude larger than that of YIG. K_1/M_s reaches about −2000 œ at 180°K. In Fig. 3 is also shown the anisotropy constant K_1 calculated by using Pauthenet's data[12] for saturation magnetization. The full line width varies with temperature as shown in Fig. 4.

Anisotropy in line width was hardly detected within the experimental errors (~10%), although the line width for ⟨100⟩ $(H_{\langle 100\rangle})$ seemed to be the narrowest. A broad maximum occurs near 200°K; such a peak has not been observed so far in other garnets except for YIG containing terbium (Tb) as an impurity.[20] Such a behavior that the line width decreases with increasing temperature and increases rapidly just below Curie temperature, is common to other garnets.[21]

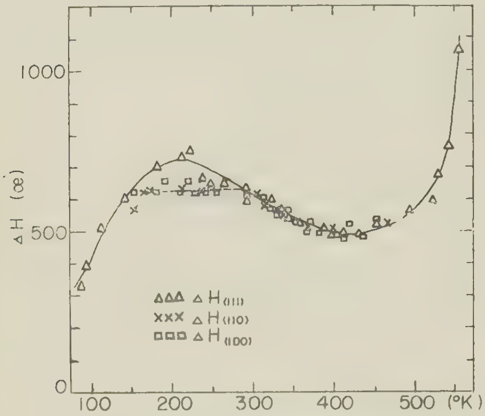

Fig. 4. Line width for single crystal *vs* temperature. There is little anisotropy in line width except near 200°K.

Polycrystalline sample The *g*-factor and line width were measured under the same conditions as above. The *g*-factor of polycrystalline sample has almost the same values as that of single crystal above room temperature, whereas below room temperature the former has values slightly larger than the latter and are less temperature-dependent (Fig. 3). The line width at room temperature is about 1200 œ, which is about two times larger than that for single crystal. Below about 200°K, a secondary peak appears on the lower magnetic field side of the main peak, and it becomes more intense and shifts further away from the main peak as the temperature decreases.[22] It is interesting that the temperature at which the secondary peak appears, coincides with that at which the maximum in line width for single crystal occurs. The line width involving the secondary peak increases rapidly at low temperature and reaches 5000 œ at 80°K.

§ 4. Discussion

g-factor Recently Kittel et al[6),7)] proposed a theory of ferromagnetic resonance in rare earth garnets. The theory assumes that a) rare earth garnet can be treated as a ferrimagnetics with two sublattices (one consisting of Fe^{3+} on 16–a sites and Fe^{3+} on 24–d sites, the other consisting of M^{3+} on 24–c sites); b) rare earth ions (except for ions having $L=0$ or $J=0$) are highly damped, while ferric ions are not damped except through ferric-rare earth exchange coupling. On these assumptions, the theory predicts that the effective *g*-factor g_{eff} of the granet is given by

$$g_{\text{eff}}=g(Y)\frac{M_s(M)}{M_s(Y)} \qquad (3)$$

where M_s denotes saturation magnetization, M refers to MIG and Y to YIG. Eq. (3) holds in the intermediate temperature region i.e. below Curie point down to such a temperature that relaxation frequency τ^{-1} of rare earth ions becomes comparable to ferric-rare earth exchange frequency ω_{AB}. At lower temperatures, where $\tau^{-1}<\omega_{AB}$,

$$g_{\text{eff}}=M_s(\mathrm{M})/\{M_s(\mathrm{Y})/g(\mathrm{Y})+M_s(\mathrm{M}^{3+})/g(\mathrm{M}^{3+})\} \qquad (4)$$

in which M^{3+} refers to rare earth sublattice. Eq. (4) is identical with Tsuya-Wangsness formula[8),9)] for a two-sublattice ferrimagnet.

The calculated curve by Eq. (3) is shown in Fig. 3. In the calculation, *g*(Y) was assumed to be equal to 2.0 independent of temperature. For M_s(Eu) and M_s(Y), the data of Pauthenet[12)] were adopted. If Eu^{3+} is in a state having $J=0$, as Kittel noted, it could not work on the movement of Fe^{3+} as a damper since it does not interact with lattice. In such a case, the Kittel's theory will not apply. The calculated g_{eff} of EuIG is actually in good agreement with the observed one. This is an indication that Eu^{3+} does interact with lattice, in other words, that it is in a state of which J does not completely vanish.

The *g*-factor for the polycrystal is, below room temperature, slightly larger and less temperature dependent than that for the single crystal. This can be explained according to Schlömann[23)] who calculated ferromagnetic resonance condition in polycrystalline ferrites. He showed that there exists in a polycrystalline sample having cubic anisotropy, an additive internal field H_i, which is given by

$$H_i=\frac{|K_1|}{M_s}+1.5(4\pi M_s)\frac{\Delta v}{V} \qquad (5)$$

where $\Delta v/V$ is the ratio of the total pore-volume to the sample volume. As the reults, $g_{\rm eff}$ for polycrystal can show an apparent temperature dependence and have a larger value than true $g_{\rm eff}$. Since both $|K_1|/M_s$ and M_s are decreasing functions of temperature $g_{\rm eff}$ for polycrystalline sample would decrease with increasing temperature or would suppress tendency of increase. For example, at about 200°K, $H_i \approx 1000$ œ. This is about 10% of the resonant field (~ 10000 œ) and a reasonable value in order to explain the g-value for polycrystal which is about 10% larger than for single crystal.

Line width The theory of Kittel et al[7)] predicts that the line width varies schematically with temperature as shown in Fig. 5.

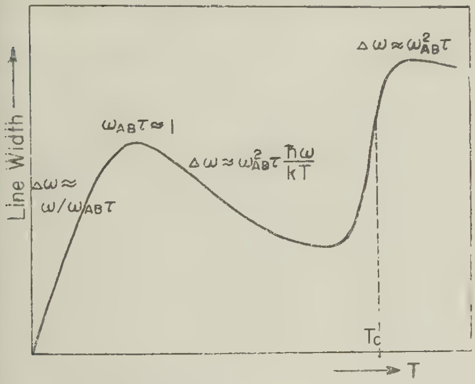

Fig. 5. Schematic temperature dependence of line width by Kittel's theory.

For the sincle crystal, the temperature dependence of line width has just the same form as Fig. 5. A secondary peak, which appears in the polycrystalline sample at low temperatures, may be explained by Schlöman's mechanism.[24)] According to it, in polycrystalline samples having cubic anisotropy and $M_s \ll H_a$ ($H_a = 2|K_1|/M_s$), a secondary peak appears in the lower magnetic field side of the main resonance peak when k ($\equiv H_a/\omega$)>0.5 is satisfied. In our case in which the condition $M_s \ll H_a$ is well satisfied below room temperature,[12)] since a secondary peak appears at about 200°K, k is thought to have reached about 0.5 at the temperature. In other words $|K_1|/M_s$ is to be equal to ≈ 2500 œ at 200°K. But the measured value is only 1500 œ. It is possible that this discrepancy is due to the fact that K_2/M_s becomes significant there.

Anisotropy The first order cubic anisotropy constant K_1 or anisotropy field K_1/M_s for EuIG is about an order of magnitude larger than that for YIG.[1)] If Eu^{3+} were in a state with $J=0$ in the garnet crystal, the anisotropy for EuIG would be comparable with that for YIG.

Electronic state for Eu^{3+} in the garnet crystal As described in preceding paragraphs, we are led to conclude that Eu^{3+} in EuIG is in a state mixed with higher states having $J \neq 0$ in some way, say, with the aid of crystal fields and polarization effect pointed out by van Vleck and Frank,[25)] because of the following reasons; a) g-factor for Eu^{3+} does not contribute to the effective g-factor for EuIG as the result of having been damped out of rare earth spins; b) above 200°K, line width decreases montonically with increasing temperature up to below Curie point (this may be interpreted as motional narrowing by high relaxation frequency τ^{-1} of rare earth spins); c) Eu^{3+} makes a large contribution to anisotropy for EuIG; d) Eu^{3+} has a magnetic moment of 0.8 μ_B per ion in EuIG.[12)]

Above conclusion and our experimental results are somewhat contradictory with the experiment of Dillon et al[20)] in which there has not been observed, below room temperature, any maximum in line width for YIG single crystal containing Eu-impurity of 1%. According to our results and Kittel's theory which predicts linear dependence of line width upon impurity concentration, the sample of Dillon et al would have a maximum in line width of about 7 œ near 200°K since the temperature, at which a maximum occurs, does not depend on resonance frequency.

§ 5. Conclusion

The temperature dependence of $g_{\rm eff}$ for EuIG is in good quantitative agreement with the prediction of Kittel's theory[6),7)] and the temperature dependence of line width shows a qualitative agreement with it. From this fact and others, it is concluded that the state for Eu^{3+} in the garnet crystal is considered to be mixed with higher states having $J \neq 0$. The difference between the g-factor of single- and polycrystals, and also the occurance of a secondary peak in the polycrystal can be explained by Schlömann's mechanism.[23),24)]

Acknowledgement

The author wishes to express his sincere appreciation to Dr. N. Tsuya of Tohoku

University and Mr. Y. Shichijo, Chief of the magnetic materials research section of our laboratory for their general guidance and continued encouragement. He is much indebted to Mr. H. Takata of our laboratory for his very able assistance. It is also a pleasure to acknowledge the assistance of Mr. T. Ito in measurements.

Note added in proof:

As for the electronic state of Eu^{3+}, there exists a possibility that local uniaxial crystalline fields at each 24–C site cause level mixing of $J=0$ state (ground state for free Eu^{3+}) and $J\neq0$ states.

Thermal Conduction in Ferroelectric Ceramics

By Ikushi Yoshida

The Institute for Solid State Physics, University of Tokyo,
and Tokyo Institute of Technology, Tokyo

(Received June 28, 1960)

Apparatuses were constructed and measurements were made on the thermal conductivity of insulating crystals over the temperature ranges from −200°C to 600°C. For the lower temperature range, the absolute measurement was used, while for the higher one, the comparative method was adopted. The thermal conductivities of ferroelectric $PbTiO_3$ and anti-ferroelectric $PbZrO_3$ showed a rather large step-wise increase, in contrast to the case of $BaTiO_3$, as they passed into the paraelectric state. Discussions are given of the relation between the magnitude of thermal conductivity and the crystal structure. It is pointed out that the anharmonic potential for the smaller ions should be responsible for the scattering of phonons in these substances.

1. Introduction

Phase transitions of crystals are in general accompanied by anomalies in many physical properties. In dielectric substances, anomalies are often found in the specific heat, the coefficient of thermal expansion (change of volume), the dielectric constant and other quantities, and they supply us with a useful clue to discovering and confirming a new transition, and in further investigations of it. On the other hand, the main carriers of heat are thought to be the lattice waves in dielectric substances, and so it is expected that the thermal conductivity of them would show some peculiar features when phase changes take place.

Eucken and Schöder found no appreciable change of thermal conductivity of solid hydrogen bromide on passing through the two transitions at 117°K and 113°K, but found a steep increase with decreasing temperature for the transition at 89°K.[1] This increase began somewhat above 89°K and continued down to 78°K. They attributed the heat conduction to the waves of the torsional motion of individual HBr molecules and explained the sudden decrease of thermal conductivity as due to the onset of random molecular orientation. Gerritsen and van der Star found a peak of thermal conductivity of solid methane around the phase transition at 20°K[2] and explained it by a simple formula based on a consideration of rotations of CH_4 groups. According to them, CH_4 molecules are rotating above the transition and their rotational kinetic energy is propagated by resonance, resulting in a peak of thermal conductivity which corresponds to that of specific heat and is proportional to the latter. According to v. Simson, the thermal conductivity of ammonium chloride shows a steep increase with decreasing temperature around the transition at −30°C[3], but no positive explanation is given.

Crystallographically, ferroelectrics belong to the crystal classes having pyroelectricity but are characterized by the fact that their polar structures are caused by a slight distorsion of nonpolar ones. It is well expected that such a distorsion of ion arrangement would affect the behaviour of the vibration of ions, and hence the mutual couplings of phonons. The phase change from polar to non-polar states, or *vice versa*, may, therefore, cause some anomaly in the thermal conductivity.

It was reported that the thermal conductivity of barium titanate ceramic actually shows a small anomaly around the transition at 120°C[4], where the phase change from the ferroelectric to paraelectric state takes place. The anomaly is, however, fairly small and it was difficult to make a sufficient discussion.

We have now measured the thermal conductivity of lead titanate ceramic with a hope that its large tetragonality ratio c/a compared with of barium titanate might result in a larger anomaly in the thermal conductivity, supplying us with a clearer knowledge on a relation between phase transition and thermal conductivity.

A mersurment has also been made on the antiferroelectric lead zirconate for the purpose of comparing the effect of antiferroelectric lattice deformation on the thermal conductivity with that of ferroelectric one. Temperature ranges of the measurement have been extended to lower side for both barium titanate and strontium titanate ceramics.

§ 2. Apparatus and Measurement

Absolute measurement was used for the measurement of thermal conductivity at temperatures lower than room temperature. However, heat leak due to radiation, which is almost inevitable in calorimetric measurements, rapidly increases with temperature, so that we were obliged to give up the plan of measuring the thermal conductivity of a substance from liquid nitrogen temperature up to about 600°C using the same apparatus. At temperatures higher than room temperature, we therefore decided to resort to the comparative method. Details of apparatuses for these two methods will be described in the following.

2. 1. *Low-Temperature Apparatus*

In Fig. 1 is shown the main part of the apparatus. A heater H_1 attached to one end of the specimen S with a cross-sectional area A supplies heat of constant rate Q. It consists of a zigzag strip of silver metal formed on the basal face of the ceramic specimens by air-drying silver paste and has a resistance of several ohms. This structure was adopted in order to reduce the heat leak from the surface and to eliminate excess heat capacity which would lower the accuracy of measurement. T_1 and T_2 are Cu-constantan thermocouples with 0.1 mm diameter, and were used to measure the temperature difference ΔT between the two points separated l longitudinally in the specimen. T_3 was used to measure the temperature difference between the specimen and the radiation shield which was necessary to evaluate the side-wise heat leak.

C is a radiation shield of stainless steel and is provided with a copper basal cap D and a heater H_2. E serves as a sink of the heat flow through the specimen and has a heater H_3. Using H_2 and H_3, it is in principle possible to make measurements at temperatures higher than the coolant, but difficulty arises in maintaining the whole of the inner part of the apparatus at a temperature higher than the outer vessel for a long time without any appreciable fluctuation, and necessarily lowers the accuracy of measurement, so that our measurements were restricted to discrete temperatures determined by the temperature of the coolant, with the exceptions of a few cases.

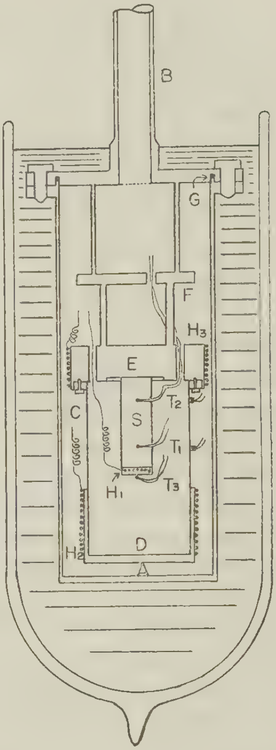

Fig. 1. Main part of the low-temperature apparatus.

The heat sink is connected to the thermal damper F and the latter to the outer vessel A. G is a lead gasket. All leads of heaters and thermocouples go through the stainless steel pipe B, which is long enough to decrease the consumption of the coolant due to heat conduction, and come out of the vessel through vacuum seals. The degree of vacuum was better than 10^{-4} mm Hg. Under the vacuum of this degree the heat leak due to convection was practically negligible, but when the vacuum was only of the order of $1\sim0.1$ mm Hg. at room temperature the leak was from a few to ten percent of Q.

Liquid nitrogen, dry ice with alcohol or ice flakes with or without salt was used as coolant.

Thermal conductivity of the specimen κ is obtained by the formula

$$\kappa = Q \frac{l}{A \cdot \Delta T}. \qquad (1)$$

The validity of this formula rests on the assumption that there is no heat leak from the surface of the heater by radiation or any other mechanism. If this heat leak is Q_{loss}, (1) must be modified to

$$\kappa = (Q - Q_{loss}) \frac{l}{A \cdot \Delta T}, \qquad (2)$$

Q_{loss} due to convection or conduction through heater leads and thermocouples was found to be negligible compared to Q, but that due to radiation, which strongly depends on the temperature and increases as the cube of absolute temperature, becomes appreciable at higher temperatures. At room temperature Q_{loss} due to radiation was about 20% of Q or so, and we adopted the corrected formula (2) for the determination of κ. The following two reasons seem to secure the plausibility of the correction;

(i) κ's obtained by correcting for Q_{rad}'s for different Q's are in good accordance.

(ii) κ's so corrected agree with those obtained by the comparative method.

2. 2. *High-Temperature Apparatus*

At high temperatures the radiation loss becomes exceedingly large, and so the comparative method had to be adopted. In Fig. 2, A and B are two rods with known thermal conductivities and S is a disc specimen. In the stationary state, the following equation holds provided that there is no side-wise heat leak:

$$\kappa_A \left(\frac{dT}{dx}\right)_A = \kappa_S \left(\frac{dT}{dx}\right)_S = \kappa_B \left(\frac{dT}{dx}\right)_B. \qquad (3)$$

By measuring the temperature gradients in A, S and B one can obtain the thermal conductivity of the specimen κ_S.

Difficulty in boring holes into the specimen to insert thermocouples made us adopt a method in which the temperature gradient in the specimen was not directly measured, but calculated from the difference between the temperatures at both sides of the specimen obtained by extrapolation. Temperature drops at the surfaces of specimen in contact with the reference substances were eliminated by pasting the surfaces of contact with air-drying silver paste and by giving a large mechanical pressure.

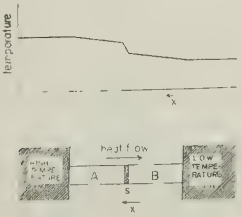

Fig. 2. Principle of the comparative method.

The main part of the apparatus is shown in Fig. 3. The specimen S is placed between two rods A and B, both of which are made of pure iron. Two pairs of reference rods were prepared, the diameters of which were 2 cm (rod 1) and 3 cm (rod 2), respectively. Thermal conductivity for these reference substances were taken from the "*American Institute of Physics Hand-book, 2nd ed.* (1957)".

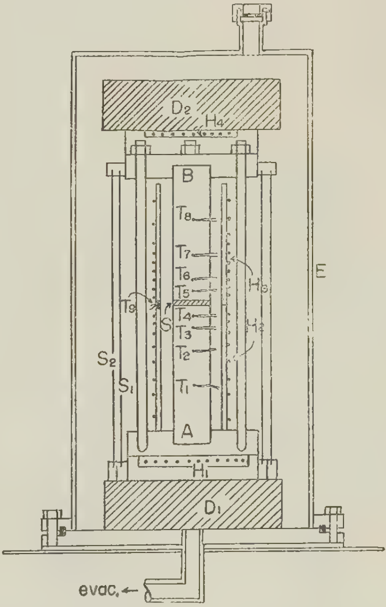

Fig. 3. Main part of the high-temperature apparatus.

The temperature gradients established in the rods A and B, generated by two main heaters H_1 and H_4, were measured by eight alumel-chromel thermocouples $T_1 \sim T_8$ with 0.3 mm diameter. T_9 is a subsidiary thermocouple to measure the temperature of side heaters which also serve as thermal shields. Two subsidiary heaters H_2 and H_3 serve to give a suitable temperature distribution to the thermal shields lest the side-wise heat leak from the rods and specimen should cause a non-linear temperature distribution. S_1 and S_2 are copper radiation shields, and D_1 and D_2

are insulating bricks. E is a vacuum vessel which was evacuated by a rotary pump.

An example of the temperature distribution along the rods and the specimen is shown in Fig. 4. The thermal conductivity of rutile was measured as a calibration of the apparatus, and the result is shown in Fig. 5 along with that due to Kingery et al[5]., the correction for the porosity being made for both of them. Agreement is quite satisfactory.

§ 3. Preparation of Specimens.

For the preparation of lead titanate ceramic, powdered raw materials of PbO and TiO_2 were mixed together with water, pressed into a disc and fired in a Siliconit furnace. The product was crashed, well pulverized and meshed, then pressed into the desired form and sintered. Other specimens were prepared by a similar procedure. Sizes and conditions of fabrication are listed in Table I.

ductivity about the phase transition at 490°C, where the ferroelectricity disappears. In Fig. 6 is shown the temperature dependence of the thermal conductivity of lead titanate. The thermal conductivity decreases with increasing temperature up to about 350°C, then begins to increase until a maximum is reached at about 500°C, and then decreases again.

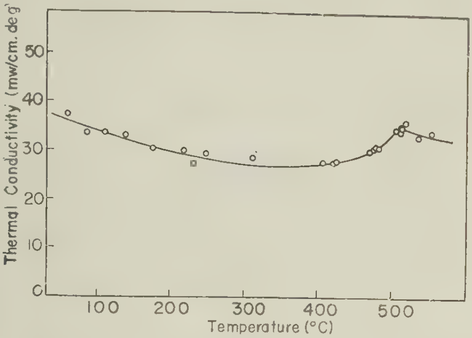

Fig. 6. Thermal conductivity of $PbTiO_3$.

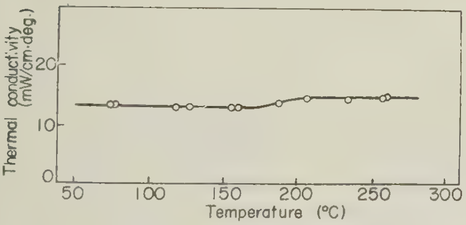

Fig. 7. Thermal conductivity of $PbZrO_3$.

4. 2. *Lead Zirconate*

In Fig. 7 is shown the temperature dependence of the thermal conductivity of lead zirconate ceramic. The phase transition is known to occur at about 230°C, and above this temperature the antiferroelectricity disappears. The change of thermal conductivity observed somewhat below this temperature may correspond to the transition.

Reproducibility of measurement was good below the transition temperature, but at higher temperatures the thermal conductivity was somewhat increased with the repetition of measurements. It seems possible that some changes in the state of aggregation of grains took place by repeated heating and cooling under a large mechanical pressure.

4. 3. *Barium Titanate*

Temperature dependence of thermal conductivity of barium titanate ceramic above room temperature (specimen No. 1) has already been published,[4] and that below room temperature (specimen No. 2) is shown in Fig. 8. The temperature coefficient is slightly positive, and the magnitude of thermal conductivity at room temperature is compatible with that given in the previous paper which was measured by a different method.

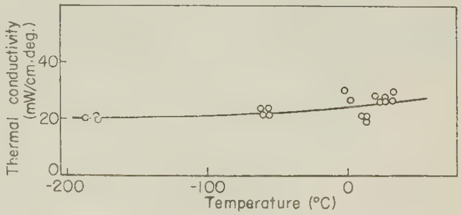

Fig. 8. Thermal conductivity of $BaTiO_3$

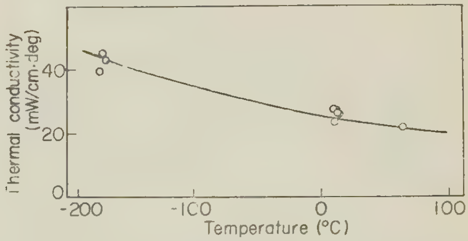

Fig. 9. Thermal conductivity of $SrTiO_3$.

4. 4. *Strontium Titanate*

Fig. 9 shows the temperature dependence of thermal conductivity at low temperatures (specimen No. 2), and that at higher temperatures (specimen No. 1) will be found in the previous paper.[4] Thermal conductivity of strontium titanate increases fairly steeply with decreasing temperature.

§ 5. Discussions

5. 1. *Magnitude of Thermal Conductivity*

In discussing the absolute value of the thermal conductivity of ceramic substances, appropriate considerations must be taken of the porosity effect. Through pores embedded in a continuum heat may be transmitted by convection and radiation, when a temperature gradient is set up in the medium. An apparent thermal conductivity of a pore κ_P may be defined so that the pore can be replaced by a medium with thermal conductivity equal to κ_P .

Several theoretical formula have been proposed to express the dependence of the thermal conductivity of a porous substance κ upon its porosity P[6][7], using thermal conductivities of the dense material κ_0 and of the pore κ_P. When pores are sufficiently small and the temperature is not so extremely high, κ_P/κ_0 becomes negligibly small and all formulae approximately reduce to

$$\kappa=(1-P)\kappa_0 . \tag{4}$$

Table II gives some typical values for the perovskite type substances with correction for the porosity by using the formula (4). The result on rutile is also given for comparison. Corrected values of specimens with different porosities agree well with each other for barium titanate and lead titanate, and as has already been stated, our corrected value of rutile agrees well with that obtained by Kingery et al. The specimen of strontium titanate used for low temperature measurement had a crack perpendicular to the length, which might have increased its thermal resistance.

Table II. Corrected values of thermal conductivities of some ceramics.

Substance	Thermal conductivity (mW/cm.deg.)	Temperature (°C)	Porosity (%)	Corrected for porosity (mW/cm.deg.)	Apparatus
$BaTiO_3$	30.2	55	10.6	33.4	High
	27.0	27	16.0	32.2	Low
$SrTiO_3$	59.0	60	12.8	67.8	High
	43.0	64	19.5	53.5	Low
$PbTiO_3$	33.6	110	14.6	39.4	High
	31.6	64	15.7	37.6	High
$PbZrO_3$	13.3	75	25.5	17.9	High
TiO_2	57.2	100	13.4	66.0	High

Although purely theoretical evaluation of the thermal conductivity of insulators seems rather difficult and no satisfactory theory has yet been proposed, the formula by Dugdale and MacDonald[8] giving the mean free path l of phonons

$$l=A_0/3\beta\gamma T \tag{5}$$

seems to give a tolerable accordance with experiments for alkali halide crystals, where A_0, β and γ mean the nearest neighbour distance, linear coefficient of thermal expansion and Grüneisen constant. γ is expressed as

$$\gamma=3\beta/\chi c , \tag{6}$$

where χ is the compressibility and c the specific heat per unit volume.

We shall now apply (5) to the case of barium titanate as an example. Using $\beta=0.9\times10^{-5}$ deg.$^{-1}$, $A_0=2\times10^{-8}$ cm, $\chi=0.617\times10^{-12}$ cm^2/dyn., and $c=0.78$ cal/deg. cm^3, we have $\gamma=1.34$ and $l=180$ Å (at 300°K). On the other hand, the experimental value of l is defined by

$$\kappa=\frac{1}{3}cvl , \tag{7}$$

where v is the mean group velocity of phonons. Using $\kappa=32.2$ mW/cm. deg. (at 300°K) and $v=3.73\times10^5$ cm/sec, we have $l=7.95$ Å. This is much shorter than the calculated value.

Some ambiguity is always involved in the interpretation of experimental data on the specific heat of crystal with a complex lattice, when a comparison is to be made with theories which are usually based on a simple lattice.

A unit cell of barium titanate contains one molecule, or five ions with fifteen degrees of freedom, which can be classified into three degrees of freedom associated with lattice translations, three associated with torsional motions of the unit cell, and nine associated with vibrational motions of a TiO_6 octahedron. Each of these vibrational modes will be approximated by an Einstein model, and the characteristic temperatures of them were determined by Last[9], from the infrared absorption, as 720°K for three modes and 490°K for other six modes respectively. These modes are considered to contribute scarecely to the thermal conduction because of their low group velocities. If these modes of vibrations were omitted in the discussions of thermal conduction, barium titanate crystal can be regarded as a diatomic lattice having the CsCl structure and may be compared with alkali halides, many of which, however, have the NaCl structure. The specific heat of barium titanate to be inserted into (6) and (7) is thus estimated as

0.3 cal/deg. cm^3, which changes γ and the theoretical and the experimental l's as follows;

$\gamma=3.50$

$l=71.0$ Å, theoretical

$l=20.7$ Å experimental.

A large discrepancy between theoretical and experimental value is still seen, and it would be far more serious at lower temperatures for (5) predicts that the theoretical mean free path length increases with decreasing temperature while the experiment does not show any such tendency. Similar discrepancy between the theoretical mean free path and that calculated from the thermal conductivity is also found in other crystals measured in our experiment. A tentative explanation of this contradiction, though qualitative, is as following.

Taking an ionic model of barium titanate we may regard its lattice to be composed of larger ions Ba^{--} (r=1.43 Å) and O^{--} (r=1.32 Å), together forming a face-centered, approximately cubic lattice, and of smaller ions Ti^{4+} (r=0.64 Å) occupying one kind of interstitial positions — the body center, but not the edge centers. This interstitial position assigned to Ti^{4+} is spacious enough for the ion to move about*, and it can really be shifted to a position near one of six neighbouring O^{--}, thus causing the ferroelectricity. Ti^{4+} ion is therefore considered to be bound with a highly anharmonic restoring force, and according to Devonshire[11] and to Slater[12] this anharmonicity is the origin of a linear increase of polarizability with decreasing tempearture, which causes the $4\pi/3$ catastrophe in barium titanate. This anharmonicity associated with the relative displacement of Ti ions against O ions is now not directly connected to the thermal expantion of the whole crystal, for the latter is mainly determined by anharmonicities in potentials between larger ions constituting the framework of the crystal. It seems probable that the translational waves propagating heat may be coupled with the motion of Ti ion, and the anharmonic potential energy of the latter comes into the Hamiltonian describing the system of phonons as a perturbation, resulting in an increase of collision probability of phonons and therefore of thermal resistivity. A similar argument will be made also for other crystals.

It is noteworthy and moreover suggestive that the thermal conductivities of barium titanate, lead titanate and strontium titanate increase in this order, while the infrared absorption frequencies change also in the same order[9], (545 cm^{-1}, 590 cm^{-1} and 610 cm^{-1}), which are thought to show the character of the potentials for the Ti ion in these substances.

5. 2. *Temperature Dependence of Thermal Conductivity*

According to Peierls[13] the thermal conductivities of simple crystals decrease nearly proportionally to 1/T with increasing temperature at higher temperatures ($T \gtrsim \theta_D$), and this temperature dependence was experimentally confirmed[14]. The thermal conductivity of glassy substance, on the other hand, generally increases with increasing temperature and is said to be proportional to the specific heat[14]. There are many substances of which the thermal conductivity has the temperature dependence between 1/T and that of specific heat. In this connection the ratio of the thermal conductivity at 83°K to that at 273°K, obtained by Eucken and Kuhn for many substances[15], is interesting. A few of the values of this ratio are cited in Table III, together with those of barium titanate and strontium titanate ceramics.

An examination of the Table III shows a general tendency that the complexity of structure lowers the ratio and the aggregation of crystallites still more. Though the scantiness of measurements does not permit us to say much about the temperature dependence of thermal conductivity of strontium titanate, the fact that there exists no phase transition would secure a discussion of general tendency. The ratio 1.80 is considerably smaller than 3.29, the inverse ratio of 83°K, to 273°K, and this would suggest that a considerable portion of thermal resistance has come from other sources than the U-process of three phonons, i. e., couplings of translational waves with vibrations of Ti ions or many other modes of vibrations, grain boundary scattering of phonons, etc.

---

* In this estimation Goldschmidt's ionic radii were used. Kittel insists[10] that the Ti-O contact determines, using Zachariazen's ionic radii, the lattice constant as 4.12 Å, which is larger than the actual value 4.004 Å, suggesting a mixture of covalency into the bonding.

Some complication may be involved in the case of barium titanate because of the existence of three phase transitions at 120°C, 5°C and −90°C, respectively, but the deviation from 1/T law has probably, or even more certainly, the same reason as in strontium titanate.

The thermal resistivity of lead titanate ceramic versus temperature is shown in Fig. 10, and the following empirical formula was found to hold in a rather wide temperature range.

$$1/\kappa = 14.0 + 0.042\ T\ \text{(cm.deg./W)}, \tag{8}$$

or

$$\kappa = 23.9/(T+334)\ \text{(W/cm.deg.)}. \tag{9}$$

Table III. Ratios of low- to high-temperature thermal conductivity

Substance	K_{83}/K_{273}
marble	1.21
calcite (crystal, ⊥)	4.09
sylvine	2.09
KCl (crystal)	4.27
NaCl (crystal)	3.78
KNO_3 (crystal aggregation)	0.89
$K_2Cr_2O_7$ (crystal, ⊥)	0.851
$K_2Cr_2O_7$ (crystal, //)	0.922
$BaTiO_3$ (ceramic)	0.80
$SrTiO_3$ (ceramic)	1.80

5. 3. *Thermal Conductivity Anomalies*

The anomaly of thermal conductivity observed in barium titanate at about 120°C is small and it seems difficult to decide whether this anomaly is truly of the peak type, as was found in solid methane by Gerritsen and van der Star, or of the step type, as in lead titanate and lead zirconate.

Anyhow, the simple explanation that the anomaly in the thermal conductivity would be merely a direct reflection of that in the specific heat, supposing that v and l in the expression (7) do not appreciably change with temperature, seems incorrect, for the anomalous specific heat does not come from the vibrational energy of propagating waves but from the potential energy of Ti ions, which, in the first approximation, are considered to be oscillating independently. There seem to be two competing factors; the increase of symmetry which would operate to increase the thermal conductivity, and the augmentation in amplitude of Ti ions, detected by Känzig[16], in going into the paraelectric state which may operate to lower the thermal conductivity.

The increase of thermal conductivity is far more clearly manifested in lead titanate and lead zirconate. The additional part of the thermal conductivity of lead titanate, obtained by subtracting the " normal " part of thermal conductivity (experimental formula (9)) from the observed one, is shown in Fig. 11. It is reasonable to attribute the increase of thermal conductivity to the increase of symmetry, due to the restoring back of Pb and Ti ions to their positions of symmetry from the much shifted positions in the ferroelectric state. It is interesting to compare the behaviours of ion-shifting in barium titanate and lead titanate in this connection. In the former, Ti ion is responsible for the main part of the crystal deformation and the relative shift of Ba ion against O ion is considered small, while in lead titanate, the shift of Pb ion is larger than that of Ti ion and so the face-centered cubic lattice composed of Pb and O is much deformed. This latter affair seems to explain why the thermal conductivity of the cubic structure is much larger than that of the tetragonal structure in lead titanate.

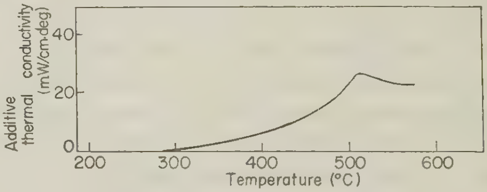

Fig. 11. Additional thermal conductivity of $PbTiO_3$.

The situation would be nearly the same for lead zirconate, and no essential difference between the ferroelectric and antiferroelectric substances was observed in this point.

§ 6. Summary

Two apparatuses for the measurement of thermal conductivity were described.

The thermal conductivities of barium titanate, strontium titanate, lead titanate and lead zirconate were measured on ceramic specimens, and suitably corrected for the porosity. The low value of thermal conductivity of barium titanate cannot be explained by the application of the formula due to Dugdale and MacDonald, and similar discrepancies between the experiment and the theory were observed for the other substances. A possibility was pointed out that Ti ions loosely bound in the O octahedron scatter the phonon waves and lower the thermal conductivity.

The temperature dependences of thermal conductivities of them were far from the 1/T law, and the grain boundary resistance and couplings of translational waves with vibrations of Ti ions were proposed as possible causes of the discrepancy. The thermal resistance of the well sintered lead titanate specimen was analyzed as the sum of the two components, one being proportional to the absolute temperature and the other one constant.

Little was discussed on the small anomaly of thermal conductivity of barium titanate, but the large step-wise increase of thermal conductivity of lead titanate was considered to have originated from the increase of symmetry, i. e., from the restoring-back of the shifted ions Ti and Pb to the positions of symmetry. The general affair was considered not much different in anti-ferroelectric lead zirconate.

§ 7. Acknowledgement

The author should like to express his sincere thanks to Prof. S. Sawada for his kind guidance, whose incessant advices and criticisms were indispensable for the accomplishment of the work. Hearty thanks are also due to Prof Y. Kakiuchi for showing interest and for many valuable suggestions, who was very generous in affording every facilities for the investigation. The author wishes to thank Prof. S. Nomura for many useful discussions.

Paramagnetic Susceptibility of an Electron Gas in Alkali Metals

By Masao Shimizu

Department of Physics, Tokyo Metropolitan University

(Received July 4, 1960)

The paramagnetic susceptibilily of an electron gas is calculated by making use of the Bohm-Pines description of electron interactions. The contribution from the long-range correlation to the susceptibility calculated by Pines is modified by using the larger cutoff wave vector of plasma oscillations and including the new contribution from the zero-point energy of plasma oscillations. The contribution from the second-order perturbation-theoretic calculation of the screened Coulomb interactions is obtained by a proper approximation. The contribution from the third-order perturbation-theoretic calculation of the interactions is obtained by a rather crude approximation. The comparisons of paramagnetic susceptibility with experimental values for alkali metals are made and the agreements for Li and Na are satisfactory. The volume dependences of paramagnetic susceptibility for alkali metals are examined by comparing the experimental results on the pressure dependence of the Knight shift with the Brooks calculations of the Fermi interaction.

§ 1. Introduction

The paramagnetic susceptibility of conduction electrons was first calculated by Pauli[1]. Sampson and Seitz[2] took into account the effect of the exchange interaction between electrons and the correlation in the calculation of paramagnetic susceptibility of conduction electrons. Pines[3,4] calculated the paramagnetic susceptibility of conduction electrons using the Bohm-Pines collective description of electron interactions[5], and obtained satisfactory agreements with the experimental values for alkali metals. In this paper, however, we shall extend Pines' calculation by making use of the better approximation.

In the first place, as seen from the calculation of susceptibility for an electron gas at high density by Brueckner and Sawada[6], the contribution from the short-range correlation to the susceptibility obtained by Pines[5] is smaller than the value at high density limit and must be corrected.

In the second place, we must use a larger maximum wave vector k_c of plasma oscillations than that used by Pines. Ferrell[7] and Sawada et al.[8] obtained the relation,

$$\beta=k_c/k_0=0.47r_s^{1/2}\ , \tag{1.1}$$

in the case of the non-magnetic state, where k_0 is the wave vector at the Fermi surface and r_s is the radius, measured in atomic units, of a sphere having the same volume with the volume per electron. We use this relation in determining the screening of the Coulomb interaction.

In the paramagnetic state of an electron gas, β would be dependent on its magnetization. Since, however, the total energy of an electron gas in the non-magnetic state should be independent of β, we may also use in the paramagnetic state the constant β given by (1.1) as long as the magnetization is very small.

In the third place, the dispersion relation of plasma oscillations depends on the distribution of electrons, that is, their magnetization. Then we must take into account the change of the zero-point energy of plasma oscillations due to the magnetization and the contribution to paramagnetic susceptibility.

In the fourth place, as seen from the Pines calculation[3),4)] the effect of the short-range correlation energy, that is, the second-order perturbation energy of the screened Coulomb interaction, on the susceptibility is considerable in comparison with the effect of the exchange interaction. Accordingly it will be expected that the contribution from the third-order perturbation calculation of the screened Coulomb interaction may also be considerable.

The energy of the first-order perturbation calculation of the screened Coulomb interaction, that is, the exchange energy, decreases if the number of parallel spins of electrons increases. On the contrary the energy of the second-order perturbation calculation increases as a correction to the first-order energy if the number of parallel spins increases. Then the energy of the third-order perturbation calculation is expected to behave like the energy of the first-order perturbation calculation.

Taking into consideration the four points mentioned above, we shall calculate the paramagnetic susceptibility of an electron gas by means of the B–P collective description of interaction. The results on the first and third points have been already reported[9].

At 0°K we consider an aggregate of N electrons embedded in a background of a uniform positive charge, whose density is equal to that of the electrons. We assume that the spin directions of N_+ electrons are left-hand (positive) and that of N_- electrons are right-hand (negative). The state of electrons is specified by wave vectors. The maximum wave vector occupied by electrons of positive and negative spin directions are k_+ and k_- respectively. Then we have

$$(V/6\pi^2)k_+{}^3=N_+\ ,\quad (V/6\pi^2)k_-{}^3=N_-\ . \tag{1.2}$$

Let the difference between N_+ and N_- be n, and we define ξ as follows:

$$n/N=\xi\ ,\quad N_+-N_-=n\ ,\quad N_++N_-=N\ . \tag{1.3}$$

When $\xi \ll 1$, the total kinetic energy of an electron gas and its total exchange energy of the ordinary long-range Coulomb interactions are expanded by ξ, a well-known fact, as follows:

$$E_F=E_F^0+\gamma_F\xi^2\ ,\quad E_{\text{ex.}}=E_{\text{ex.}}^0+\gamma_{\text{ex.}}\xi^2\ . \tag{1.4}$$

respectively, where

$$\gamma_F=1.228r_s^{-2}(m/m^*)\ , \tag{1.5}$$

$$\gamma_{\text{ex.}}=-0.2036/r_s\ . \tag{1.6}$$

m^* is an effective mass of electrons and we assume that the effective mass reduces only the thermal kinetic energy as Pines pointed out[4]. Energies are measured by Rydberg unit per electron.

In §2, the contribution of the long-range cerrelation is calculated. The second-order perturbation calculation of the screened Coulomb interaction is worked out in §3. In §4 the third-order perturbation calculation is worked out.

In §5 we obtain the values of paramagnetic susceptibility for alkali metals and compare them with the experimental results.

In §6 the volume dependences of susceptibility are compared with the experimental results of the pressure dependence of the Knight shifts by making use of the Brooks calculation on the effective masses and the hyperfine interactions for alkali metals.

§2. Contribution from the Long-Range Correlation

When $n\neq 0$, the following four terms of the long-range correlation energies which depend on n are considered.

The first term is the zero-point energy of plasma oscillations, and has been given in (I) as follows:

$$\varDelta E_P=\gamma_P\xi^2\ ,\quad \gamma_P=0.008981\ . \tag{2.1}$$

The second term is the correction of (1.6) when the Coulomb interaction is screened by plasma oscillations and has been calculated by Pines[4]. This is (see (3.16) in (I))

$$E'_{\text{ex.}}=\gamma'_{\text{ex.}}\xi^2\ ,\quad \gamma'_{\text{ex.}}=0.01125\ . \tag{2.2}$$

The third term is the exchange energy of the weak velocity dependent interactions which are deduced from the second-order perturbation calculation of the electron-plasma interaction. The exchange integral of this interaction between electrons with wave vectors $\boldsymbol{k}$ and $\boldsymbol{k}'$ is approximately given by

$$\left.\begin{aligned} J^{r.p.}_{\boldsymbol{kk}'} &= -\frac{\pi e^2\hbar^2}{Vm^2}\,\frac{(k^2-k'^2)}{\{\omega^2-\hbar^2(k^2-k'^2)^2/4m^2\}(\boldsymbol{k}-\boldsymbol{k}')^2}\ , && \text{if}\quad |\boldsymbol{k}-\boldsymbol{k}'|<k_c;\\ &=0\ , && \text{if}\quad |\boldsymbol{k}-\boldsymbol{k}'|>k_c\ . \end{aligned}\right\} \tag{2.3}$$

where ω is the plasma angular frequency.

When $n\neq 0$, the total exchange energy of $J^{r.p.}_{\boldsymbol{kk}'}$ in (2.3) is

$$E^{r.p.}(n)=-\frac{1}{2}\sum_{k<k_+,}\ \sum_{k'<k_+} J^{r.p.}_{\boldsymbol{kk}'}-\frac{1}{2}\sum_{k<k_-,}\ \sum_{k'<k_-} J^{r.p.}_{\boldsymbol{kk}'}\ . \tag{2.4}$$

This is approximately calculated as follows:

$$E^{r.p.}(n)=\frac{e^2\hbar^2 V}{4\pi^3 m^2\omega_p^2}\left\{\frac{2}{45}(k_+{}^5+k_-{}^5)k_c{}^3-\frac{1}{16}\frac{0.98}{0.517}(k_+{}^4+k_-{}^4)k_c{}^4\right.$$
$$\left.+\frac{1}{30}(k_+{}^3+k_-{}^3)k_c{}^5-\frac{1}{144}(k_+{}^2+k_-{}^2)k_c{}^6\right\}, \qquad (2.5)^*$$

by taking into account the results when $n=0$, that is,

$$E^{r.p.}=-\sum_{k<k_0,\, k'<k_0}\sum J^{r.p.}_{kk'}=\frac{e^2\hbar^2 V k_0{}^8}{2\pi^3 m^2\omega_p{}^2}\left(\frac{2\beta^3}{45}-\frac{0.98}{0.517}\frac{\beta^4}{16}+\frac{\beta^5}{30}-\frac{\beta^6}{144}\right), \qquad (2.6)^*$$

where $\omega_p{}^2=(4\pi e^2N/mV)$. The terms proportional to $k_c{}^4$ or β^4 in (2.5) and (2.6) are correctec by the factor (0.98/0.517) which is expected from the higher-order perturbation calculation[10]

If $\xi\ll 1$, (2.5) is expanded from (1.1), (1.2) and (1.3) as follows**:

$$\left.\begin{aligned}&E^{r.p.}(n)/N=E^{r.p.}/N+\gamma_{r.p.}\xi^2\,,\\&\gamma_{r.p.}=-0.01065+0.02124r_s{}^{-1/2}+0.00006893r_s\,.\end{aligned}\right\} \qquad (2.7$$

The fourth term is the energy of the reaction to the self-energy of electrons coming from the interaction between electrons and plasma oscillations. This is given by the following expression.

$$\left.\begin{aligned}&E'_F(n)=-\frac{\beta^3}{6N}\frac{\hbar^2}{2m}\left(\sum_{k<k_+}k^2+\sum_{k<k_-}k^2\right)=E'_F+\gamma'_F\xi^2\,,\\&\gamma'_F=-0.02124r_s{}^{-1/2}\,,\end{aligned}\right\} \qquad (2.8$$

where E'_F is the energy of the reaction when $n=0$.

The part of the long-range correlation energy which depends on n is given, from (2.1), (2.2), (2.7) and (2.8), by

$$\left.\begin{aligned}&\Delta E_{l.r.}=\gamma_{l.r.}\xi^2\,,\\&\gamma_{l.r.}=\gamma_P+\gamma'_{\mathrm{ex.}}+\gamma_{r.p.}+\gamma'_F=0.009580+0.00006893r_s\,.\end{aligned}\right\} \qquad (2.9)$$

$4\gamma_{l.r.}$ corresponds to $\alpha_{l.r.}$ given by Pines[4)], but there is a considerable difference between them. The difference may be attributable to the different approximations which are made use of in the calculation of energy of the electron gas as an expansion of r_s.

§ 3. Effect of the Short-Range Correlation

The short-range correlation energy is obtained from the second-order perturbation calculation of the screened Coulomb interaction. This energy when $n\neq 0$ is given by[4)]

$$\left.\begin{aligned}&E^{s.r.}_{\mathrm{corr.}}(n)=E^{s.r.}_{+-}+\tfrac{1}{2}(E^{s.r.}_{++}+E^{s.r.}_{\mathrm{ex.}++})+\tfrac{1}{2}(E^{s.r.}_{--}+E^{s.r.}_{\mathrm{ex.}--})\,,\\&E^{s.r.}_{xy}=-\frac{m}{\hbar^2}\left(\frac{4\pi e^2}{V}\right)^2\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2}\sum_{\boldsymbol{p}}\frac{1}{p^4\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)}\,,\\&E^{s.r.}_{\mathrm{ex.}xy}=\frac{m}{\hbar^2}\left(\frac{4\pi e^2}{V}\right)^2\sum_{\boldsymbol{k}_1}\sum_{2}\sum\frac{1}{p^2(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)^2\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)}\,,\end{aligned}\right\} \qquad (3.1)$$

where the regions of the sums are given by $k_1<k_x$, $|\boldsymbol{k}_1+\boldsymbol{p}|>k_x$, $k_2<k_y$, $|\boldsymbol{k}_2+\boldsymbol{p}|>k_y$, $p>k_c$, and $E^{s.r.}_{\mathrm{ex.}xy}$ is subject to an additional restriction, $|\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2|>k_c$. $E^{s.r.}_{+-}$ is the correlation energy between electrons with antiparallel spins. $\frac{1}{2}(E^{s.r.}_{\pm\pm}+E^{s.r.}_{\mathrm{ex.}\pm\pm})$ are the correlation energies between electrons with parallel spins.

---

* In (2.5) and (2.6) the ordinary unit of energy is used.

** In the previous paper, (I), the formula for $\gamma_{r.p.}$, (4.20), was misprinted. $\gamma_{r.p.}$ in (2.7) is the correct result. Moreover, the coefficient of r_s in (5.7) of (I), 0.2272, should be replaced by 0.2744.

For the calculation of $E^{s.r.}_{\pm\pm}$ we make use of the results calculated by Pines[4] and Fletcher and Larson[11] when $n=0$. For the calculation of $E^{s.r.}_{\mathrm{ex.}\pm\pm}$ we make use of the results obtained by Gell-Mann and Brueckner[12] and Nozières and Pines[10].

When $n=0$ and $\beta<2$[4,11],

$$E^{s.r.}_{+-}(0)=E^{s.r.}_{\pm\pm}(0)\equiv E^{s.r.}(0)=-\frac{m}{\hbar^2}\left(\frac{4\pi e^2}{V}\right)^2\sum_{\substack{k_1<k_0,\\|\boldsymbol{k}_1+\boldsymbol{P}|>k_0,}}\sum_{\substack{k_2<k_0,\\|\boldsymbol{k}_2+\boldsymbol{P}|>k_0,}}\sum_{p>k_c}\frac{1}{p^4\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)}$$

$$=\frac{e^2}{2a_0}\frac{Vk_0{}^3}{3\pi^4}\left\{-\frac{11}{6}+\frac{\pi^2}{4}-\frac{8}{3}\ln 2+2(\ln 2)^2+2(1-\ln 2)\ln\beta-\frac{\beta^2}{16}+\frac{\beta^4}{960}\right\}. \tag{3.2}$$

If $n=0$, $E^{s.r.}_{\mathrm{ex.}++}+E^{s.r.}_{\mathrm{ex.}--}$ becomes[12,10]

$$\tfrac{1}{2}E^{s.r.}_{\mathrm{ex.}++}(0)+\tfrac{1}{2}E^{s.r.}_{\mathrm{ex.}--}(0)\equiv E^{s.r.}_{\mathrm{ex.}}(0)$$

$$=\frac{m}{\hbar^2}\left(\frac{4\pi e^2}{V}\right)^2\sum_{\substack{k_3<k_0,\\|\boldsymbol{k}_1+\boldsymbol{P}|>k_0,}}\sum_{\substack{k_2<k_0,\\|\boldsymbol{k}_2+\boldsymbol{P}|>k_0,}}\sum_{\substack{p>k_c\\|\boldsymbol{P}+\boldsymbol{k}_1+\boldsymbol{k}_2|>k_c}}\frac{1}{p^2(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)^2\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)}$$

$$=\frac{e^2}{2a_0}\frac{Vk_0{}^3}{3\pi^2}(0.046-0.015\beta^2\pm0.002). \tag{3.3}$$

In $n\neq0$, $E^{s.r.}_{++}$ and $E^{s.r.}_{--}$ are written from (3.2) as

$$E^{s.r.}_{\pm\pm}=\frac{e^2}{2a_0}\frac{Vk_\pm{}^3}{3\pi^4}\left\{-\frac{11}{6}+\frac{\pi^2}{4}-\frac{8}{3}\ln 2+2(\ln 2)^2+2(1-\ln 2)\beta_\pm-\frac{\beta_\pm{}^2}{16}+\frac{\beta_\pm{}^4}{960}\right\}, \tag{3.4}$$

where $\beta_\pm=k_c/k_\pm$. Similarly $E^{s.r.}_{\mathrm{ex.}++}+E^{s.r.}_{\mathrm{ex.}--}$, when $n\neq0$, is written from (3.3) as

$$\tfrac{1}{2}E^{s.r.}_{\mathrm{ex.}++}+\tfrac{1}{2}E^{s.r.}_{\mathrm{ex.}--}=\frac{e^2}{2a_0}\frac{V}{6\pi^2}\{k_+{}^3(0.046-0.015\beta_+{}^2)+k_-{}^3(0.046-0.015\beta_-{}^2)\}. \tag{3.5}$$

$E^{s.r.}_{+-}$, when $n\neq0$, is analytically calculated by replacing the sums in (2.1) by integrations, and is written as a function of k_+, k_- and k_c in the case of $k_+>k_-$ and $2k_->k_c$ as follows:

$$\begin{aligned}E^{s.r.}_{+-}=&-(e^2/2a_0)(V/3\pi^4)\Big[\{13/40-(\ln 2)^2+(\ln 2)(\ln k_c)\}(k_+{}^3+k_-{}^3)\\&+(4/15+\ln 2-\ln k_c)k_+k_-(k_++k_-)+k_c{}^2(k_++k_-)/120-(k_-{}^3\ln 2+k_+{}^3/3-k_+{}^2k_-)\ln k_+\\&-(k_+{}^3\ln 2+k_-{}^3/3-k_-{}^2k_+)\ln k_-+(1/24)(-7k_+{}^3+15k_+{}^2k_-+15k_+k_-{}^2-7k_-{}^3)\ln(k_++k_-)\\&+(5/8)(k_+{}^3-k_+{}^2k_--k_+k_-{}^2+k_-{}^3)\ln(k_+-k_-)+\{k_c{}^3/120-k_c(k_+{}^2+k_-{}^2)/4\\&+3(k_+{}^2-k_-{}^2)^2/8k_c+(k_+{}^5-5k_+{}^3k_-{}^2-5k_+{}^2k_-{}^3+k_-{}^5)/20k_c{}^2\}\ln\{(k_++k_--k_c)/(k_++k_-+k_c)\}\\&-(1/12)(k_+{}^3-6k_+{}^2k_--6k_+k_-{}^2+k_-{}^3)\ln\{1-k_c{}^2(k_++k_-)^{-2}\}+\{(k_c{}^3/384)-(3k_+{}^2k_c/16)\\&+(3k_+{}^4/8k_c)\}\ln\{(2k_-+k_c)/(2k_--k_c)\}-(k_-{}^3/6)\ln\{1-(k_c{}^2/4k_-{}^2)\}\\&-\frac{1}{2}(k_+{}^3+k_-{}^3)\int_{2k_+}^{\infty}\frac{dp}{p}\ln\frac{p+k_++k_-}{p-(k_++k_-)}+\frac{1}{2}(k_+{}^3-k_-{}^3)\int_{2k_+}^{\infty}\frac{dp}{p}\ln\frac{p+k_+-k_-}{p-k_++k_-}\\&-\frac{1}{2}(k_+{}^3+k_-{}^3)\int_{2k_-}^{2k_+}\frac{dp}{p}\ln(p+k_++k_-)+\frac{1}{2}(k_+{}^3-k_-{}^3)\int_{2k_-}^{2k_+}\frac{dp}{p}\ln(p+k_+-k_-)\\&+\frac{1}{2}k_-{}^3\int_{2k_-}^{2k_+}\frac{dp}{p}\ln(p^2+4k_-{}^2)+\frac{1}{2}k_-{}^3\int_{k_c}^{2k_-}\frac{dp}{p}\ln(4k_-{}^2-p^2)\\&-\frac{1}{2}(k_+{}^3+k_-{}^3)\int_{k_c}^{2k_-}\frac{dp}{p}\{(k_++k_-)^2-p^2\}+\frac{1}{2}k_+{}^3\int_{k_c}^{2k_-}\frac{dp}{p}\ln(4k_+{}^2-p^2)\Big].\end{aligned} \tag{3.6}$$

If $n=0$, that is, $k_+=k_-=k_0$, this formula completely coincides with the formula for $E^{s.r.}(0)$ obtained by Fletcher and Larson[11].

In the case where $\xi=n/N\ll1$, using (1.2) and (1.3) we obtain from (3.2) and (3.6)

$$\left.\begin{aligned} E^{s.r.}_{+-} &= E^{s.r.}(0)+\frac{e^2N}{2a_0}\gamma^{+-}_{s.r.}\xi^2\,, \\ \gamma^{+-}_{s.r.} &= \frac{1}{\pi^2}\left(\frac{1}{2}-\frac{1}{9}\ln 2-\frac{1}{3}\ln\beta-\frac{\beta^2}{720}-\frac{\beta^4}{8640}\right). \end{aligned}\right\} \tag{3.7}$$

and from (3.2), (3.3), (3.4) and (3.5) we obtain

$$\left.\begin{aligned} \frac{1}{2}(E^{s.r.}_{++}+E^{s.r.}_{\text{ex.}\,++})+\frac{1}{2}(E^{s.r.}_{--}+E^{s.r.}_{\text{ex.}\,--}) &= E^{s.r.}(0)+E^{s.r.}_{\text{ex.}}(0)+\frac{e^2N}{2a_0}(\gamma^{++}_{s.r.}+\gamma^{--}_{s.r.})\xi^2\,, \\ (\gamma^{++}_{s.r.}+\gamma^{--}_{s.r.}) &= \frac{1}{\pi^2}\left\{-\frac{1}{3}(1-\ln 2)+\frac{\beta^2}{144}+\frac{\beta^4}{4320}\right\}+\frac{0.015\beta^2}{9}\,. \end{aligned}\right\} \tag{3.8}$$

Then, the total short-range correlation energy, $E^{s.r.}_{\text{corr.}}(n)$ in (3.1), is expanded in powers of ξ as follows:

$$\left.\begin{aligned} E^{s.r.}_{\text{corr.}}(n) &= 2E^{s.r.}(0)+E^{s.r.}_{\text{ex.}}(0)+\frac{e^2N}{2a_0}\gamma_{s.r.}\xi^2\,, \\ \gamma_{s.r.} &= \gamma^{+-}_{s.r.}+\gamma^{++}_{s.r.}+\gamma^{--}_{s.r.}=\frac{1}{\pi^2}\left(\frac{1}{6}+\frac{2}{9}\ln 2-\frac{1}{3}\ln\beta+\frac{\beta^2}{180}+\frac{\beta^4}{8640}\right)+\frac{0.015\beta^2}{9}\,. \end{aligned}\right\} \tag{3.9}$$

From (1.1), $\gamma_{s.r.}$ is rewritten as

$$\gamma_{s.r.}=0.05799-0.01689\ln r_s+0.0004925r_s+0.0000005722r_s{}^2\,. \tag{3.10}$$

The coefficient of $\ln r_s$ in $\gamma_{s.r.}$ is $-(1/6\pi^2)$ and coincides with the result for the electron gas at high density obtained by Brueckner and Sawada, and the constant term in $\gamma_{s.r.}$ is nearly equal to their result[6].

§4. Third-Order Perturbation Calculation of the Screened Coulomb Interaction

In an unperturbed ground state, electrons are assumed to compactly occupy up to the levels with k_+ and k_- for positive and negative spins respectively. We consider only the excited states in which two electrons are excited over the Fermi surface by the screened Coulomb interaction. Using the vector model we calculate the third-order perturbation energy of the screened Coulomb interaction. The details of the calculation are given in Appendix I. The results are as follows:

$$E^{(3)}=E_1{}^{(3)}+E_2{}^{(3)}+E_3{}^{(3)}\,, \tag{4.1}$$

$$\begin{aligned} E_1{}^{(3)} &= \frac{1}{2}\left(\frac{4\pi e^2}{V}\right)^3\frac{m^2}{\hbar^4}\sum_{\mathbf{k}_i,}\sum_{\mathbf{k}_j,}\sum_{\mathbf{p},}\sum_{\mathbf{p}'}\Bigg[\frac{1}{p^2p'^2\mathbf{p}\cdot(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)\mathbf{p}'\cdot(\mathbf{p}'+\mathbf{k}_i+\mathbf{k}_j)} \\ &\quad\times\{(\mathbf{p}-\mathbf{p}')^{-2}-(\mathbf{p}+\mathbf{p}'+\mathbf{k}_i+\mathbf{k}_j)^{-2}P_{ij}{}^{\sigma}\}\Bigg]\,, \end{aligned} \tag{4.2}$$

$$\begin{aligned} E_2{}^{3)} &= \frac{1}{2}\left(\frac{4\pi e^2}{V}\right)^3\frac{m^2}{\hbar^4}\sum_{\mathbf{k}_i,}\sum_{\mathbf{k}_j,}\sum_{\substack{\mathbf{k}_l\neq\mathbf{k}_i,\\ \neq\mathbf{k}_j,}}\sum_{\mathbf{p}}\Bigg[\Bigg[\frac{1}{\mathbf{p}\cdot(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)\mathbf{p}\cdot(\mathbf{p}+\mathbf{k}_l+\mathbf{k}_j)} \\ &\quad\times\Bigg\{\frac{1}{p^6}-\frac{P_{ij}{}^{\sigma}}{p^4(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)^2}-\frac{P_{jl}{}^{\sigma}}{p^4(\mathbf{p}+\mathbf{k}_j+\mathbf{k}_l)^2}-\frac{P_{il}{}^{\sigma}}{p^4(\mathbf{k}_i-\mathbf{k}_l)^2}+\frac{P_{ij}{}^{\sigma}P_{il}{}^{\sigma}}{p^2(\mathbf{k}_i-\mathbf{k}_l)^2(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)^2} \\ &\quad+\frac{P_{ij}{}^{\sigma}P_{il}{}^{\sigma}}{p^2(\mathbf{k}_i-\mathbf{k}_l)^2(\mathbf{p}+\mathbf{k}_j+\mathbf{k}_l)^2}+\frac{P_{ij}{}^{\sigma}P_{jl}{}^{\sigma}}{p^2(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)^2(\mathbf{p}+\mathbf{k}_j+\mathbf{k}_l)^2} \\ &\quad-\frac{P_{il}{}^{\sigma}}{(\mathbf{k}_i-\mathbf{k}_l)^2(\mathbf{p}+\mathbf{k}_i+\mathbf{k}_j)^2(\mathbf{p}+\mathbf{k}_j+\mathbf{k}_l)^2}\Bigg\}\Bigg] \\ &\quad+\text{[Here insert the above term with } i \text{ and } j \text{ interchange]}\Bigg]\,, \end{aligned} \tag{4.3}$$

$$E_3{}^{(3)}=\frac{1}{2}\left(\frac{4\pi e^2}{V}\right)^3\frac{m^2}{\hbar^4}\sum_{\boldsymbol{k}_i,}\sum_{\boldsymbol{k}_j,}\sum_{\substack{\boldsymbol{k}_l\neq\boldsymbol{k}_i,\\ \neq\boldsymbol{k}_j,}}\sum_{\boldsymbol{p}}\left[\frac{1}{\underline{p}^2\{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_i+\boldsymbol{k}_j)\}^2}\left\{-\frac{P_{il}{}^\sigma}{\underline{p}^2}\left(\frac{1}{(\underline{\boldsymbol{p}+\boldsymbol{k}_i+\boldsymbol{k}_l})^2}-\frac{1}{(\underline{\boldsymbol{k}_i-\boldsymbol{k}_l})^2}\right)\right.\right.$$

$$-\frac{P_{jl}{}^\sigma}{p^2}\left(\frac{1}{(\underline{\boldsymbol{p}+\boldsymbol{k}_j+\boldsymbol{k}_l})^2}-\frac{1}{(\underline{\boldsymbol{k}_j-\boldsymbol{k}_l})^2}\right)+\frac{P_{ij}{}^\sigma P_{il}{}^\sigma}{(\boldsymbol{p}+\underline{\boldsymbol{k}_i+\boldsymbol{k}_j})^2}\left(\frac{1}{(\underline{\boldsymbol{p}+\boldsymbol{k}_j+\boldsymbol{k}_l})^2}-\frac{1}{(\underline{\boldsymbol{k}_j-\boldsymbol{k}_l})^2}\right)$$

$$\left.\left.+\frac{P_{ij}{}^\sigma P_{jl}{}^\sigma}{(\underline{\boldsymbol{p}+\boldsymbol{k}_i+\boldsymbol{k}_j})^2}\left(\frac{1}{(\underline{\boldsymbol{p}+\boldsymbol{k}_i+\boldsymbol{k}_l})^2}-\frac{1}{(\underline{\boldsymbol{k}_j-\boldsymbol{k}_l})^2}\right)\right\}\right]. \tag{4.4}$$

$P_{ij}{}^\sigma$ is an operator which exchanges the spin coordinates of i and j electrons and so on. We have $P_{ij}{}^\sigma=\frac{1}{2}(1+4\boldsymbol{S}_i\cdot\boldsymbol{S}_j)$, where $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ are spin operators of i and j electrons respectively. If i and j spins are parallel $P_{ij}{}^\sigma=1$, and if they are antiparallel $P_{ij}{}^\sigma=0$. In (4.2), (4.3) and (4.4) the summations over $\boldsymbol{k}_i$, $\boldsymbol{k}_j$, $\boldsymbol{k}_l$, $\boldsymbol{p}$ and $\boldsymbol{p}'$ are taken such that the absolute values of the vectors underlined are larger than k_c, $|\boldsymbol{k}|<k_+$ and $|\boldsymbol{k}+\boldsymbol{p}|>k_+$ or $|\boldsymbol{k}+\boldsymbol{p}'|>k_+$ when the state with the wave vector $\boldsymbol{k}$ is a positive spin state, and $|\boldsymbol{k}|<k_-$ and $|\boldsymbol{k}+\boldsymbol{p}|>k_-$ or $|\boldsymbol{k}+\boldsymbol{p}'|>k_-$ when the state with the wave vector $\boldsymbol{k}$ is a negative spin state.

As shown in (A15) of Appendix I, each term in $E_1{}^{(3)}$, (4.2), is derived from the processes in which two electrons jump out of the Fermi surface because of the screened Coulomb interaction between them and again jump into other states and finally they go back to the original states. Each term in $E_2{}^{(3)}$, (4.3), as shown in (A16) of Appendix I, is derived from the processes, in which two electrons jump out of the Fermi surface, and then, one of these electrons goes back to one of the original states occupied by them before and another new electron jump out of the Fermi surface simultaneously, and finally two electrons above the Fermi surface go back under the Fermi surface. As shown in (A17) of Appendix I, each term in $E_3{}^{(3)}$, (4.4), corresponds to the processes, in which two electrons jump out of the Fermi surface, and then, one of these electrons and another electron are exchanged because of the exchange interaction between them and finally two electrons go back as before.

In the case of the high-density limit of the electron gas, only the term being proportional to p^{-6} in (4.3) is taken into account.

We can write $E_1{}^{(3)}$, $E_2{}^{(3)}$, $E_3{}^{(3)}$ for the electron configuration, in which electrons with positive and negative spins occupy compactly up to the states with the wave vectors k_+ and k_- respectively, in the following way. Hereafter we replace the sums by integrations and wave vectors are measured in units of k_0. We use $\alpha=(4/9\pi)^{1/3}$ and the Rydberg units per electron as the unit of energy.

When the spins of electrons with $\boldsymbol{k}_i$ and $\boldsymbol{k}_j$ are positive and negative respectively, $E_1{}^{3)}$, (4.2), becomes

$$E_1{}^{(3)}(+-)=\frac{3\alpha r_s}{32\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{p}\int d^3\boldsymbol{p}'\frac{1}{\underline{p}^2\underline{p}'^2(\boldsymbol{p}-\boldsymbol{p}')^2\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}'\cdot(\boldsymbol{p}'+\boldsymbol{k}_1+\boldsymbol{k}_2)}, \tag{4.5}$$

where the regions of integrations are given by $p>\beta$, $p'>\beta$, $|\boldsymbol{p}-\boldsymbol{p}'|>\beta$, $0<k_1<n_+$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_+$, $|\boldsymbol{k}_1+\boldsymbol{p}'|>n_+$, $0<k_2<n_-$, $|\boldsymbol{k}_2+\boldsymbol{p}|>n_-$ and $|\boldsymbol{k}_2+\boldsymbol{p}'|>n_-$. n_+ and n_- are k_+/k_0 and k_-/k_0 respectively.

When both spins of electrons with $\boldsymbol{k}_i$ and $\boldsymbol{k}_j$ are positive or negative, we have from (4.2)

$$E_1{}^{(3)}(\pm\pm)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{p}\int d^3\boldsymbol{p}'\frac{1}{\underline{\boldsymbol{p}}^2\underline{\boldsymbol{p}}'^2\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}'\cdot(\boldsymbol{p}'+\boldsymbol{k}_1+\boldsymbol{k}_2)}$$

$$\times\{(\underline{\boldsymbol{p}-\boldsymbol{p}'})^{-2}-(\underline{\boldsymbol{p}+\boldsymbol{p}'+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}\}. \tag{4.6}$$

The regions of these integrations are given by the ones in which $n_\mp$ is replaced by $n_\pm$ in the regions for $E_1{}^{(3)}(+-)$, (4.5).

Similarly, $E_2{}^{(3)}$, (4.3), and $E_3{}^{(3)}$, (4.4), when the spins of electrons with $\boldsymbol{k}_i$, $\boldsymbol{k}_j$ and $\boldsymbol{k}_l$ are determined as positive or negative, are given as follows:

$$E_2^{(3)}(\pm\pm\mp)=\frac{3\alpha r_s}{32\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3)}$$
$$\times\{\underline{p}^{-6}-\underline{p}^{-4}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}\}\ , \tag{4.7}$$

where the regions of integrations are $p>\beta$, $0<k_1<n_\pm$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_\pm$, $0<k_2<n_\pm$, $|\boldsymbol{k}_2+\boldsymbol{p}|>n_\pm$, $0<k_3<n_\mp$, and $|\boldsymbol{k}_3+\boldsymbol{p}|>n_\mp$;

$$E_2^{(3)}(\pm\mp\mp)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3)}$$
$$\times\{2\underline{p}^{-6}-\underline{p}^{-4}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}-\underline{p}^{-4}(\underline{\boldsymbol{k}_2-\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_2-\boldsymbol{k}_3})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_3})^{-2}\}\ , \tag{4.8}$$

where the regions of integrations are $p>\beta$, $0<k_1<n_\pm$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_\pm$, $0<k_2<n_\mp$; $|\boldsymbol{k}_2+\boldsymbol{p}|>n_\mp$ $0<k_3<n_\mp$, and $|\boldsymbol{k}_3+\boldsymbol{p}|>n_\mp$;

$$E_2^{(3)}(\pm\mp\pm)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3)}$$
$$\times\{2\underline{p}^{-6}-\underline{p}^{-4}(\underline{\boldsymbol{k}_1}-\underline{\boldsymbol{k}_3})^{-2}-\underline{p}^{-4}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_1-\boldsymbol{k}_2})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}\}\ , \tag{4.9}$$

where the regions of integrations are $p>\beta$, $0<k_1<n_\pm$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_\pm$, $0<k_2<n_\mp$, $|\boldsymbol{k}_2+\boldsymbol{p}|>n_\mp$ $0<k_3<n_\pm$, and $|\boldsymbol{k}_3+\boldsymbol{p}|>n_\pm$;

$$E_2^{(3)}(\pm\pm\pm)=\frac{3\alpha r_s}{32\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3)}$$
$$\times\{\underline{p}^{-6}-\underline{p}^{-4}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}-\underline{p}^{-4}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-3}-\underline{p}^{-4}(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}$$
$$+\underline{p}^{-2}(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}+\underline{p}^{-2}(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}$$
$$+\underline{p}^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}\}\ , \tag{4.10}$$

where the regions of integrations are $p>\beta$, $0<k_1<n_\pm$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_\pm$, $0<k_2<n_\pm$, $|\boldsymbol{k}_2+\boldsymbol{p}|>n_\pm$, $0<k_3<n_\pm$, and $|\boldsymbol{k}_3+\boldsymbol{p}|>n_\pm$; and

$$E_3^{(3)}(\pm\pm\pm)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\underline{p}^2\{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\}^2}$$
$$\times[-\underline{p}^{-2}\{(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}\}-\underline{p}^{-2}\{(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_2-\boldsymbol{k}_3})^{-2}\}$$
$$+(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2})^{-2}\{(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_3})^{-2}+(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{k}_2-\boldsymbol{k}_3})^{-2}\}]\ , \tag{4.11}$$

$$E_3^{(3)}(\pm\pm\mp)=0\ , \tag{4.12}$$

$$E_3^{(3)}(\pm\mp\mp)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\underline{p}^4\{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\}^2}$$
$$\times\{(\underline{\boldsymbol{k}_2-\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3})^{-2}\}\ , \tag{4.13}$$

$$E_3^{(3)}(\mp\pm\mp)=\frac{3\alpha r_s}{64\pi^7}\int d^3\boldsymbol{k}_1\int d^3\boldsymbol{k}_2\int d^3\boldsymbol{k}_3\int d^3\boldsymbol{p}\,\frac{1}{\underline{p}^4\{\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\}^2}$$
$$\times\{(\underline{\boldsymbol{k}_1-\boldsymbol{k}_3})^{-2}-(\underline{\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_3})^{-2}\}\ , \tag{4.14}$$

where the regions of integrations are the same with the ones in the respective cases of the spin configurations for $E_2^{(3)}$ given above.

As the necessary integrations in (4.5)–(4.14) have not been carried out analytically, we obtain the coefficients of ξ^2 approximately in the form of the expansions of the order of ξ using four approximations which are expected to hold when β is nearly equal to 1 or $r_s\sim4.5$, as shown in Appendix II. The result is given by (A34) and shown in Fig. 1 by a dotted line.

As shown in Appendix III, from the calculation of $E^{(3)}$ in the case of the high-density imit of the electron gas, we obtain (A39). Then, from the above two calculations we determine $E^{(3)}$ approximately as follows (see Appendix III):

$$E^{(3)}=E_0{}^{(3)}+\gamma^{(3)}_{\text{corr.}}\xi^2\ ,$$

$$\gamma^{(3)}_{\text{corr.}}=-0.0658\exp(-0.278r_s)\ , \qquad (4.15)$$

and this is shown in Fig. 1.

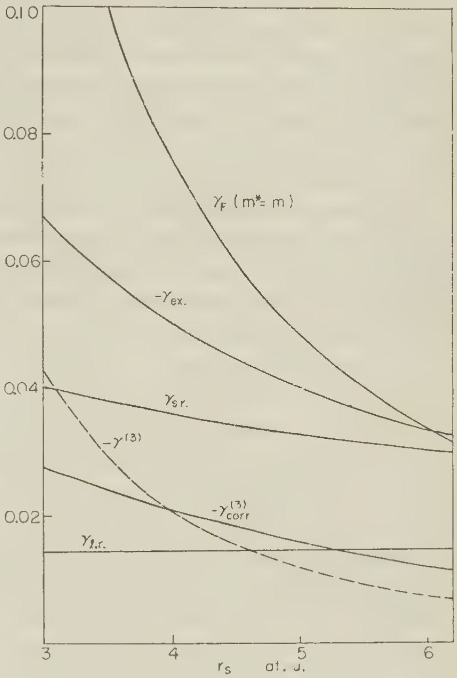

Fig. 1. Various contributions to γ, e.g. γ_F (1.5), $\gamma_{\text{ex.}}$ (1.6), $\gamma_{l.r.}$ (2.9), $\gamma_{s.r.}$ (3.10), $\gamma^{(3)}$ (A34), $\gamma^{(3)}_{\text{corr.}}$ (4.15) are shown as functions of r_s.

§ 5. Comparisons with Paramagnetic Susceptibilities of Alkali Metals

The total energy of the completely degenerate electron gas in the external magnetic field is given by the sum of the Fermi energy, exchange energy, long-range correlation energy, short-range correlation energy, third-order perturbation-theoretic energy of the screened Coulomb interaction and the Zeeman energy as follows:

$$E_{\text{total}}=E_0+\xi^2\gamma-\mu_B(n/N)H/(e^2/2a_0)\ , \qquad (5.1)$$

where E_0 is the total energy of the electron gas when $\xi=0$ and $H=0$, and from (1.5), (1.6), (2.9), (3.10) and (4.15) γ becomes

$$\gamma=\gamma_F+\gamma_{\text{ex.}}+\gamma_{l.r.}+\gamma_{s.r.}+\gamma^{(3)}_{\text{corr.}}\ . \qquad (5.2)$$

By looking for n so as to minimize the total energy (E_{total}), we can obtain the paramagnetic susceptibility in c.g.s. unit as follows:

Table I. Paramagnetic susceptibilities of alkali metals.

Metal	Li	Na	K	Rb	Cs
r_s at. u.	3.24	3.99	4.90	5.31	5.79

a Calculated from the measurements of the Knight shift by G. B. Benedek and T. Kushida: J. Phys. Chem. Solids **5** (1958) 241 and the calculations of the hyperfine interaction by H. Brooks (quoted by G. B. Benedek and T. Kushida).

b Calculated from the measurement of the Knight shift by W. B. Gager and F. J. Milford: Bull. Am. Phys. Soc. **5** (1960) 176 and the calculation of the hyperfine interaction by J. Callaway: *Solid State Physics* vol. 7 (Academic Press Inc., New York, 1958) 144.

c Obtained from the paramagnetic resonance experiments at 77°K by R. T. Schumacher and C. P. Slichter: Phys. Rev. **101** (1956) 58.

d Obtained in the same way as c by R. Hecht and A. G. Redfield: Bull. Am. Phys. Soc. **4** (1959) 240.

e Obtained like c at 4°K by R. T. Schumacher and W. E. Vehse: Bull. Am. Phys. Soc. **5** (1960) 296.

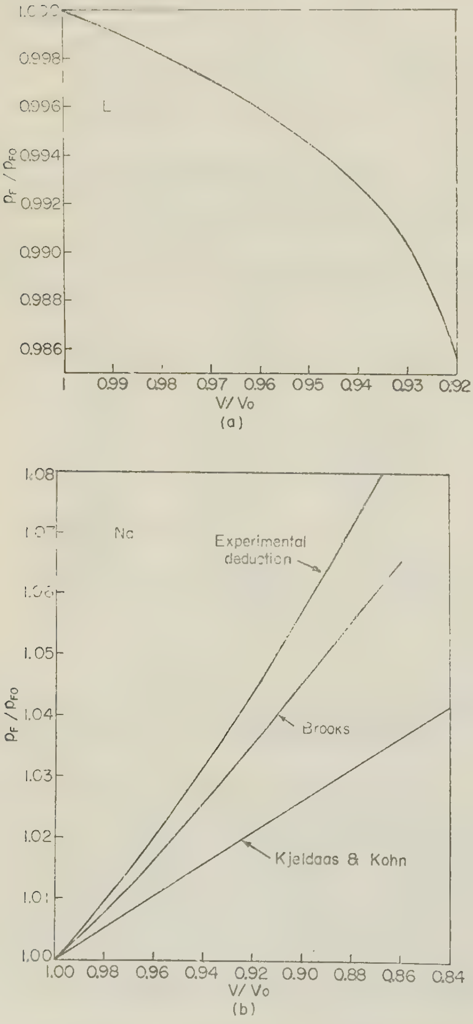
$$\chi=(n\mu_B/HV)=(N\mu_B^2/2\gamma V)=3.18\times10^{-6}r_s^{-3}\gamma^{-1}\ . \tag{5.3}$$

From (5.3) the paramagnetic susceptibilities for alkali metals are calculated and are shown in Table I. In this table, the values of r_s are the values at room temperature (300°K)[13] and we use the values of the effective mass calculated by Brooks[14].

The paramagnetic susceptibilities calculated for alkali metals are compared with the observed values, obtained from the intensity-measurement of the paramagnetic resonance of conduction electrons, for Li[15),16)] and Na[15),17)].

Table II. Volume dependence of $\chi\Omega$.

Metal	Li	Na	Rb	Cs
q	$\simeq -0.03$	$+0.635$	$+0.516$	$+0.601$



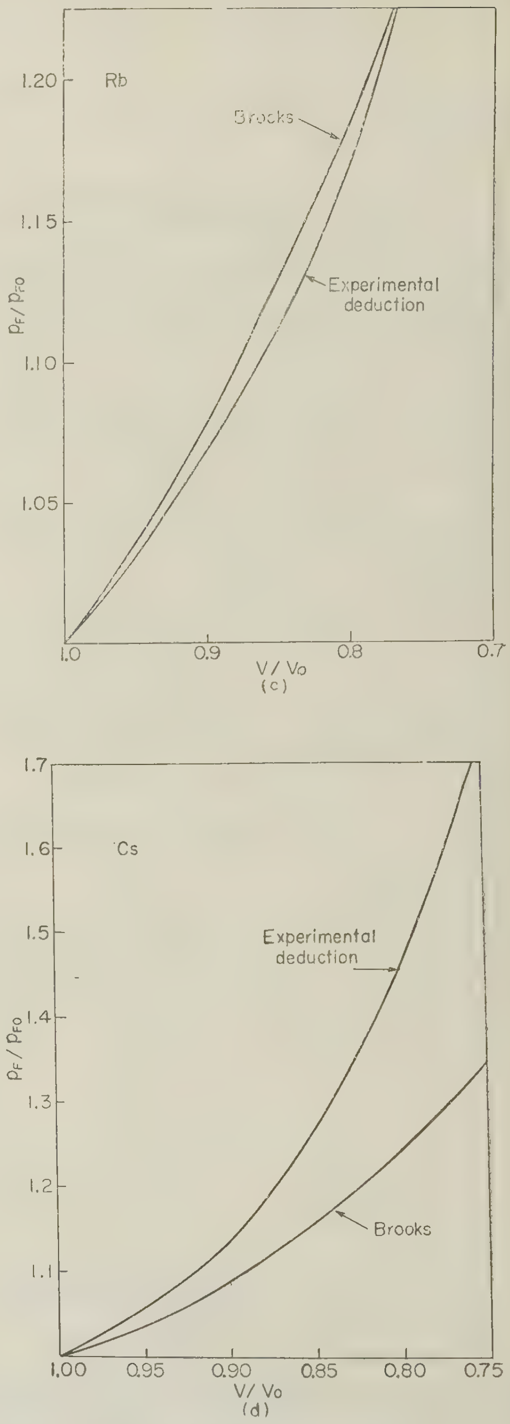


Fig. 2. Volume dependences of P_F for Li, Na, Rb and Cs derived from (5.3) and (5.4) using the Benedek and Kushida data[13)], together with the theoretical results obtained by Kjeldaas and Kohn[24)] for Na and those obtained by Brooks[25)] for Na, Rb and Cs.

On the other hand, the Knight shift K is given by[18)]

$$K=(8\pi/3)\chi\Omega P_F\ , \tag{5.4}$$

where Ω is atomic volume, $P_F=\langle|\Psi_F(0)|^2\rangle$ is the probability density of an electron, whose energy is equal to the Fermi energy, at the nucleus. From the measurements of the Knight shifts for Li, Na, Rb, Cs[13)] and K[19)] and the calculations of P_F for Li, Na, Rb, Cs by Brooks[20)] and for K by Callaway[21)], we can obtain χ using (5.4) and show the results in the eleventh row of Table I.

The agreements between the theoretical values and the experimental values of paramagnetic susceptibility for Li and Na are satisfactory. Generally it will be expected that the theoretical value obtained here is greater than the experimental one because we take into account up to the third-order perturbation calculation which contributes to γ as negative. However, for K, Rb, Cs the latter is greater than the former. This disagreement will be due to the fact that the higher-order terms of r_s in γ which are neglected in our calculation become important for K, Rb, Cs.

§ 6. Comparison with Pressure-Effect of the Knight Shift for Alkali Metals

Benedek and Kushida measured the pressure dependence of the Knight shift for Li, Na, Rb and Cs[13)], and determined the volume dependence of the Knight shift using Bridgman's data[22)] on the $P-V$ isotherms for the alkali metals. Following their analysis we shall discuss the volume dependence (or r_s dependence) of the paramagnetic susceptibility calculated in § 5.

In order to find the volume dependence of χ, (5.3), for alkali metals, we use the values of effective mass and its volume dependence* which were calculated by Brooks[14)] and Brooks and Ham[23)]. Expressing the volume dependence of $\chi\Omega$ as $\chi\Omega/(\chi\Omega)_0=(V/V_0)^q$, where V_0 is the volume at room temperature (300°K), from (5.3) we obtain the values of q as shown in Table II.

From the volume dependence of the Knight shift determined by Benedek and Kushida and that of the $\chi\Omega$ determined above, the volume dependences of P_F for Li, Na, Rb and Cs are obtained by (5.4) and are shown in Fig. 2. In Fig. 2b the comparisons with the calculated values by Kjeldass and Kohn[24)] and Brooks[25)] for Na are made. In Fig. 2c and 2d the comparisons with the calculated values of P_F by Brooks[25)] for Rb and Cs are made respectively. Although we could not make any comparison with the calculated values of P_F for Li, it is interesting to note that the volume dependence of P_F for this metal is very small.

Appendix I

Using the vector model of electron spins we calculate the third-order perturbation-theoretic energy of the screened Coulomb interaction. We consider N electrons in the volume V. The energy of the perturbation is as follows:

$$H'=\sum_{i>j} H_{ij}'\ , \tag{A1}$$

$$H_{ij}'=(4\pi e^2/V)\sum_{|\boldsymbol{p}|>k_c} p^{-2}\exp(i\boldsymbol{p}\cdot(\boldsymbol{r}_i-\boldsymbol{r}_j))\ . \tag{A2}$$

Let the unperturbed states be the states of the completely free electrons. In the ground state we assume that N electrons occupy the states with the wave vectors $\boldsymbol{k}_1, \boldsymbol{k}_2, \cdots, \boldsymbol{k}_N$

---

* For the r_s dependence of effective mass m^* of Cs we use the following data calculated by Brooks (private communication):

r_s	4.2	4.6	5.0	5.4	5.8	6.2
m/m^*	1.7297	1.4858	1.3068	1.2862	1.2370	1.2004

We should like to express our sincere thanks to Professor H. Brooks and Dr. T. Kushida for informing us of these results.

respectively and the spin function is expressed by Θ_0. Then, the total wave function $\Psi_0(\boldsymbol{k}_1, \boldsymbol{k}_2, \cdots, \boldsymbol{k}_N)$ is

$$\Psi_0(\boldsymbol{k}_1, \boldsymbol{k}_2, \cdots, \boldsymbol{k}_N)=(N!)^{-1/2}\sum_P \varepsilon_P P\varphi_{\boldsymbol{k}_1}(1)\varphi_{\boldsymbol{k}_2}(2)\cdots\varphi_{\boldsymbol{k}_N}(N)P^\sigma\Theta_0 \,, \tag{A3}$$

where

$$\varphi_{\boldsymbol{k}_j}(i)=V^{-1/2}\exp(i\boldsymbol{k}_j\cdot\boldsymbol{r}_i) \,. \tag{A4}$$

P and P^σ are permutation operators on electron coordinates and spin coordinates respectively and $\varepsilon_P=+1$ or -1 if P is an even or an odd permutation.

In the state in which i and j electrons jump to other orbits with the wave vectors $\boldsymbol{k}_i'$ and $\boldsymbol{k}_j'$ and the total spin states is described by $\Theta_{m'}$, the total unperturbed wave function is as follows:

$$\begin{aligned}\Psi_{m'}(\boldsymbol{k}_i', \boldsymbol{k}_j')=(N!)^{-1/2}\sum_P \varepsilon_P P\varphi_{\boldsymbol{k}_1}(1)\cdots\varphi_{\boldsymbol{k}_{i-1}}(i-1)\varphi_{\boldsymbol{k}_i'}(i)\varphi_{\boldsymbol{k}_{i+1}}(i+1)\cdots\\ \times\varphi_{\boldsymbol{k}_{j-1}}(j-1)\varphi_{\boldsymbol{k}_j'}(j)\varphi_{\boldsymbol{k}_{j+1}}(j+1)\cdots\varphi_{\boldsymbol{k}_N}(N)P^\sigma\Theta_{m'} \,.\end{aligned} \tag{A5}$$

Using the formula of the third-order perturbation-calculation,

$$E_\lambda{}^{(3)}=\sum_\mu{}'\sum_\gamma{}'\frac{H_{\lambda\mu}'H_{\mu\gamma}'H_{\gamma\lambda}'}{(E_\lambda-E_\mu)(E_\lambda-E_\gamma)}-\sum_\mu{}'\frac{H_{\lambda\mu}'H_{\mu\lambda}'H_{\lambda\lambda}'}{(E_\lambda-E_\mu)^2} \,, \tag{A6}$$

we can obtain the third-order perturbation-theoretic energy of the screened Coulomb interactions as follows:

$$E^{(3)}=E_1{}^{(3)}+E_2{}^{(3)}+E_3{}^{(3)} \,, \tag{A7}$$

$$\begin{aligned}E_1{}^{(3)}=\frac{1}{8}\sum_{\boldsymbol{k}_i,\boldsymbol{k}_j,}\sum_{\boldsymbol{k}_i',\boldsymbol{k}_j',}\sum_{\boldsymbol{k}_i'',\boldsymbol{k}_j'',}\sum_{m',m''}\frac{(0;\,\boldsymbol{k}_i\boldsymbol{k}_j|H_{ij}'|m';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m';\,\boldsymbol{k}_i'\boldsymbol{k}_j'|H_{ij}'|m'';\,\boldsymbol{k}_i''\boldsymbol{k}_j'')}{\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}\{\varepsilon(\boldsymbol{k}_i'', \boldsymbol{k}_j'')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}}\\ \times(m'';\,\boldsymbol{k}_i''\boldsymbol{k}_j''|H_{ij}'|0;\,\boldsymbol{k}_i\boldsymbol{k}_j) \,,\end{aligned} \tag{A8}$$

$$\begin{aligned}E_2{}^{(3)}=\frac{1}{8}\sum_{\boldsymbol{k}_i,\boldsymbol{k}_j,}\sum_{\substack{\boldsymbol{k}_l\neq\boldsymbol{k}_i,\\ \neq\boldsymbol{k}_j,}}\sum_{\boldsymbol{k}_i',\boldsymbol{k}_j',}\sum_{m',m''}\\ \times\Bigg[\sum_{\boldsymbol{k}_i'',\boldsymbol{k}_l'}\frac{(0;\,\boldsymbol{k}_i\boldsymbol{k}_j|H_{ij}'|m';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m';\,\boldsymbol{k}_i\boldsymbol{k}_l|H_{il}'|m'';\,\boldsymbol{k}_i''\boldsymbol{k}_l')(m'';\,\boldsymbol{k}_i''\boldsymbol{k}_j'\boldsymbol{k}_l'|H_{jl}'|0;\,\boldsymbol{k}_i\boldsymbol{k}_j\boldsymbol{k}_l)}{\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}\{\varepsilon(\boldsymbol{k}_i'', \boldsymbol{k}_j', \boldsymbol{k}_l')-\varepsilon|\boldsymbol{k}_i, \boldsymbol{k}_j, \boldsymbol{k}_l)\}}\\ +\sum_{\boldsymbol{k}_j'',\boldsymbol{k}_l'}\frac{(0;\,\boldsymbol{k}_i\boldsymbol{k}_j|H_{ij}'|m';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m';\,\boldsymbol{k}_j'\boldsymbol{k}_l|H_{jl}'|m'';\,\boldsymbol{k}_j''\boldsymbol{k}_l')(m'';\,\boldsymbol{k}_i'\boldsymbol{k}_j''\boldsymbol{k}_l'|H_{il}'|0;\,\boldsymbol{k}_i\boldsymbol{k}_j\boldsymbol{k}_l)}{\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j'', \boldsymbol{k}_l')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j, \boldsymbol{k}_l)\}}\Bigg] \,,\end{aligned} \tag{A9}$$

$$\begin{aligned}E_3{}^{(3)}=\frac{1}{4}\sum_{\boldsymbol{k}_i,\boldsymbol{k}_j,}\sum_{\boldsymbol{k}_i',\boldsymbol{k}_j',}\sum_{m',m''}\\ \times\Bigg[\frac{(0;\,\boldsymbol{k}_i\boldsymbol{k}_j|H_{ij}'|m';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m';\,\boldsymbol{k}_i'\boldsymbol{k}_j'|H'|m'';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m'';\,\boldsymbol{k}_i'\boldsymbol{k}_j'|H_{ij}'|0;\,\boldsymbol{k}_i\boldsymbol{k}_j)}{\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}^2}\\ -\frac{(0;\,\boldsymbol{k}_i\boldsymbol{k}_j|H_{ij}'|m';\,\boldsymbol{k}_i'\boldsymbol{k}_j')(m';\,\boldsymbol{k}_i'\boldsymbol{k}_j'|H_{ij}'|m'';\,\boldsymbol{k}_i\boldsymbol{k}_j)(m'';\,\boldsymbol{k}_i\boldsymbol{k}_j|H'|0;\,\boldsymbol{k}_i\boldsymbol{k}_j)}{\{\varepsilon(\boldsymbol{k}_i', \boldsymbol{k}_j')-\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)\}^2}\Bigg] \,,\end{aligned} \tag{A10}$$

where

$$\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j)=\frac{\hbar^2}{2m}(k_i{}^2+k_j{}^2) \,, \tag{A11}$$

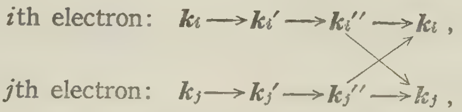
$$\varepsilon(\boldsymbol{k}_i, \boldsymbol{k}_j, \boldsymbol{k}_l)=\frac{\hbar^2}{2m}(k_i{}^2+k_j{}^2+k_l{}^2) \,, \tag{A12}$$

$$(m';\, \boldsymbol{k}_i'\boldsymbol{k}_j'|H_{ij}'|m'';\, \boldsymbol{k}_i''\boldsymbol{k}_j'')=\int \Psi^*_{m'}(\boldsymbol{k}_1\cdots\boldsymbol{k}_i'\cdots\boldsymbol{k}_j'\cdots\boldsymbol{k}_N)H_{ij}'$$
$$\times\Psi_{m''}(\boldsymbol{k}_1\cdots\boldsymbol{k}_i''\cdots\boldsymbol{k}_j''\cdots\boldsymbol{k}_N)d\tau_1\cdots d\tau_N=\frac{4\pi e^2}{V}\sum_{|\boldsymbol{P}|>k} p^{-2}$$
$$\times\{\delta(-\boldsymbol{k}_i'+\boldsymbol{p}+\boldsymbol{k}_i'')\delta(-\boldsymbol{k}_j'-\boldsymbol{p}+\boldsymbol{k}_j'')-\delta(-\boldsymbol{k}_i'+\boldsymbol{p}+\boldsymbol{k}_j'')\delta(-\boldsymbol{k}_j'-\boldsymbol{p}+\boldsymbol{k}_i'')P^{(ij)}_{m'm''}\}\,, \tag{A13}$$

and $P^{(ij)}_{mm'}=\int\Theta^*_m P^{(ij)}\Theta_{m'}d\xi_1\cdots d\xi_N$, where $P^{(ij)}$ is an exchange operator between i and j spin coordinates, and

$$(m;\, \boldsymbol{k}_i\boldsymbol{k}_j\boldsymbol{k}_l|H_{jl}'|m';\, \boldsymbol{k}_i'\boldsymbol{k}_j'\boldsymbol{k}_l')=\int\Psi^*_m(\boldsymbol{k}_1\cdots\boldsymbol{k}_i\cdots\boldsymbol{k}_j\cdots\boldsymbol{k}_l\cdots\boldsymbol{k}_N)H_{jl}'$$
$$\times\Psi_{m'}(\boldsymbol{k}_1\cdots\boldsymbol{k}_i'\cdots\boldsymbol{k}_j'\cdots\boldsymbol{k}_l'\cdots\boldsymbol{k}_N)d\tau_1\cdots d\tau_N$$
$$=\frac{4\pi e^2}{V}\sum_{|\boldsymbol{P}|>k_c} p^{-2}[\delta(\boldsymbol{k}_i-\boldsymbol{k}_i')\{\delta(-\boldsymbol{k}_j+\boldsymbol{p}+\boldsymbol{k}_j')\delta(-\boldsymbol{k}_l-\boldsymbol{p}+\boldsymbol{k}_l')\delta_{mm'}$$
$$-\delta(-\boldsymbol{k}_j+\boldsymbol{p}+\boldsymbol{k}_l')\delta(-\boldsymbol{k}_l-\boldsymbol{p}+\boldsymbol{k}_j')P^{(jl)}_{mm'}\}-\delta(\boldsymbol{k}_i-\boldsymbol{k}_j')\{\delta(-\boldsymbol{k}_j+\boldsymbol{p}+\boldsymbol{k}_i')\delta(-\boldsymbol{k}_l-\boldsymbol{p}+\boldsymbol{k}_l')P^{(ij)}_{mm'}$$
$$-\delta(-\boldsymbol{k}_j+\boldsymbol{p}+\boldsymbol{k}_l')\delta(-\boldsymbol{k}_l-\boldsymbol{p}+\boldsymbol{k}_i')(P^{(ij)}P^{(il)})_{mm'}\}]\,. \tag{A14}$$

(4.2) is obtained from (A8), (A11) and (A13) if we leave the spin permutation operators in the vector model without integrations. The processes of the perturbation in this case are shown as follows:

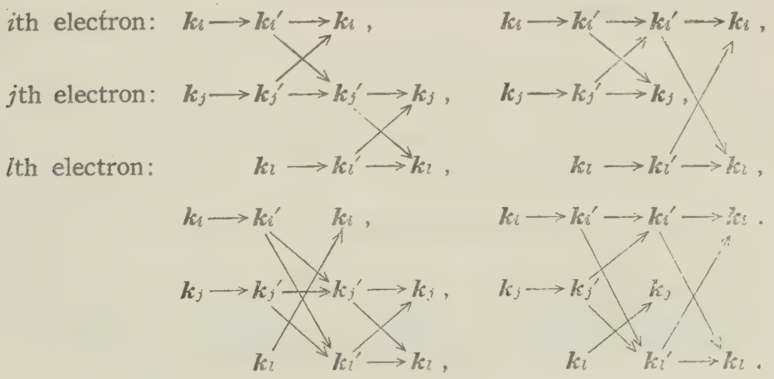


*i*th electron: $\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i'' \longrightarrow \boldsymbol{k}_i$,
*j*th electron: $\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j'' \longrightarrow \boldsymbol{k}_j$,

(A15)

where the crossing of the two arrows means the exchange of the two electrons.

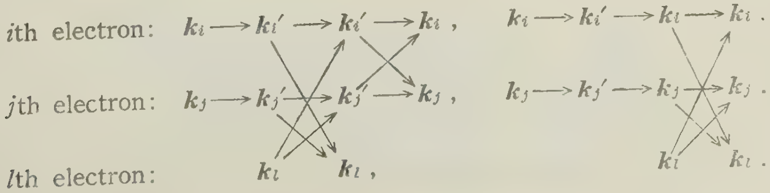
(4.3) is obtained from (A9), (A11), (A12), (A13), and (A14) as before. In this case there are the following 16 processes:



*i*th electron: $\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i$,
*j*th electron: $\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j$,
*l*th electron: $\boldsymbol{k}_l \longrightarrow \boldsymbol{k}_l' \longrightarrow \boldsymbol{k}_l$,
$\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i$,
$\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j$,
$\boldsymbol{k}_l \longrightarrow \boldsymbol{k}_l' \longrightarrow \boldsymbol{k}_l$,
$\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i'$ $\boldsymbol{k}_i$,
$\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j$,
$\boldsymbol{k}_l$ $\boldsymbol{k}_l' \longrightarrow \boldsymbol{k}_l$,
$\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i$.
$\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j'$ $\boldsymbol{k}_j$
$\boldsymbol{k}_l$ $\boldsymbol{k}_l' \longrightarrow \boldsymbol{k}_l$.

(A16)

(4.4) is obtained from (A1), (A10), (A11), and (A13) and there are 8 processes in this case, that is,



*i*th electron: $\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i$,
*j*th electron: $\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j$,
*l*th electron: $\boldsymbol{k}_l$ $\boldsymbol{k}_l$,
$\boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i' \longrightarrow \boldsymbol{k}_i \longrightarrow \boldsymbol{k}_i$.
$\boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j' \longrightarrow \boldsymbol{k}_j \longrightarrow \boldsymbol{k}_j$.
$\boldsymbol{k}_l$ $\boldsymbol{k}_l$.

(A17)

Appendix II

As we have not succeeded in carrying out the necessary integrations in (4.5)–(4.14) analytically, we calculate the integrations using the following four approximations:

(1) The scalar products of two independent vectors are neglected, e.g. $\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\to p^2$, $(\boldsymbol{p}-\boldsymbol{p}')^2\to p^2+p'^2$.

(2) k_1^2, k_2^2 and k_3^2 in the integrands are replaced by the mean values in the Fermi sphere, that is, 3/5.

(3) Taking into account the fact that $p>\beta$, $\beta\sim1$ in alkali metals, and the contribution from the lower value of p is considered to be predominant in the integrations of p, we use the following approximation $(p^2+k_1^2+k_2^2)^{-1}\to p^{-2}-(k_1^2+k_2^2)/(2p^4)$ when $p^2\sim k_1^2+k_2^2$.

(4) By making use of the above three approximations, $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, and $\boldsymbol{k}_3$ in all the integrands disappear. Then, for the integrations over $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, and $\boldsymbol{k}_3$, we use the following approximation. In the equations which define the regions of integrations for $\boldsymbol{k}_1$ in (4.5) and (4.6), $|\boldsymbol{k}_1+\boldsymbol{p}|>n_+$ and $|\boldsymbol{k}_1+\boldsymbol{p}'|>n_+$ are assumed to be independent of each other because $|\boldsymbol{p}-\boldsymbol{p}'|>\beta$. The region of integration for $\boldsymbol{k}_1$ is shown in Fig. 3 as the shaded area, but we neglect the portion where the three spheres O, P, and Q overlap trebly.

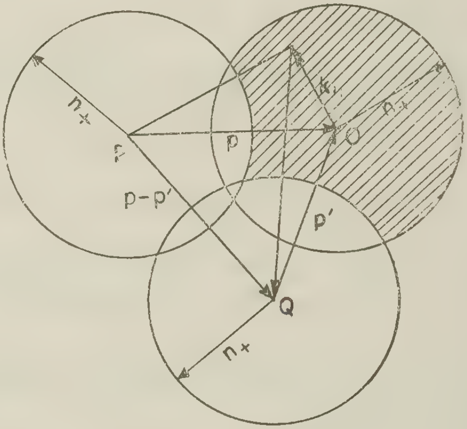


Fig. 3. Allowed regions of integrations for $\boldsymbol{k}_1$, $\boldsymbol{k}_2$ and $\boldsymbol{k}_3$ in (4.5) and (4.6).

Then, when $p<2n_+$, $p'<2n_+$, the integration of $\boldsymbol{k}_1$ over the region $0<k_1<n_+$, $|\boldsymbol{k}_1+\boldsymbol{p}|>n_+$, $|\boldsymbol{k}_1+\boldsymbol{p}'|>n_+$, becomes $\int d^3\boldsymbol{k}_1=\pi\{4n_+^3/3-(4n_+^3/3-n_+^2p+p^3/12)-(4n_+^3/3-n_+^2p'+p'^3/12)\}$, where $\pi((4/3)n_+^3-n_+^2p+(p^3/12))$ is the volume that the spheres O and P in Fig. 3 overlap each other. Similarly the integrations for $\boldsymbol{k}_2$ and the integrations when n_+ is replaced by n_- are carried out.

Furthermore we use the expansions:

$$n_\pm=k_\pm/k_0=1\pm\frac{1}{3}\xi-\frac{1}{9}\xi^2\,, \tag{A18}$$

in the integrations and we calculate the coefficients of ξ^2 only.

Therefore, when $p<2$ and $p'<2$ we have

$$\left.\begin{aligned}K_{+-}&=\int\limits_{\substack{k_1<n_+,\\ |\boldsymbol{k}_1+\boldsymbol{P}|>n_+,\\ |\boldsymbol{k}_1+\boldsymbol{P}'|>n_+.}} d^3\boldsymbol{k}_1\int\limits_{\substack{k_2<n_-,\\ |\boldsymbol{k}_2+\boldsymbol{P}|>n_-,\\ |\boldsymbol{k}_2+\boldsymbol{P}'|>n_-.}} d^3\boldsymbol{k}_2=C_{+-}+\xi^2I_{+-}\,,\\ I_{+-}&=(\pi^2/54)\{-96+112(p+p')-36(p+p')^2+(p+p')(p^3+p'^3)\}\,;\end{aligned}\right\} \tag{A19}$$

when $p<2$ and $p'>2$,

$$K_{+-}=C'_{+-}+\xi^2I'_{+-}\,,\qquad I'_{+-}=-(2\pi^2/3)p^2+(\pi^2/54)p^4\,; \tag{A20}$$

when $p>2$ and $p'<2$,

$$K_{+-}=C''_{+-}+\xi^2I''_{+-}\,,\qquad I''_{+-}=-(2\pi^2/3)p'^2+(\pi^2/54)p'^4\,; \tag{A21}$$

when $p>2$ and $p'>2$,

$$K_{+-}=(16\pi^2/9)(1-\xi^2)\,. \tag{A22}$$

After all, the part of $E_1^{(3)}(+-)$, (4.5), which is proportional to ξ^2 is as follows:

$$E_1^{(3)}(+-)=\frac{3\alpha r_s}{2\pi^5}\xi^2\left[\left\{\int_\beta^2 dp\int_\beta^2 dp' I_{+-}+\int_\beta^2 dp\int_2^\infty dp' I'_{+-}\right.\right.$$
$$\left.\left.+\int_2^\infty dp\int_\beta^2 dp' I''_{+-}-\frac{16\pi^2}{9}\int_2^\infty dp\int_2^\infty dp'\right\}\frac{1}{p^2p'^2(p^2+p'^2)}\right]. \tag{A23}$$

By carrying out the integrations for p and p' and from (1.1), we have

$$E_1^{(3)}(+-)/\xi^2=\gamma_1^{(3)}(+-)=-0.1071r_s^{-1}+0.2042r_s^{-1/2}-0.1331$$
$$+0.01986r_s^{1/2}+0.005284r_s+0.0001167r_s(\ln r_s)^2-0.002108r_s\ln r_s$$
$$-0.0001426r_s^{3/2}+0.00003265r_s^2+1.346\times10^{-6}r_s^{5/2}-1.338\times10^{-8}r_s^{7/2}\,. \tag{A24}$$

The integrations for $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ in (4.6) are worked out as before, and when $p<2$ and $p'<2$ we have

$$\left.\begin{aligned}
K_{\pm\pm}&=\int\limits_{\substack{k_1<n_\pm,\\ |\boldsymbol{k}_1+\boldsymbol{P}|>n_\pm,\\ |\boldsymbol{k}_1+\boldsymbol{P}'|>n_\pm,}} d^3\boldsymbol{k}_1\int\limits_{\substack{k_2<n_\pm,\\ |\boldsymbol{k}_2+\boldsymbol{P}|>n_\pm,\\ |\boldsymbol{k}_2+\boldsymbol{P}'|>n_\pm,}} d^3\boldsymbol{k}_2=C\pm D\xi+\xi^2 I\,,\\
I&=\pi^2\left\{\frac{16}{9}-\frac{40}{27}p+\frac{2}{9}p^2+\frac{p^4}{54}+\left(-\frac{40}{27}+\frac{4}{9}p+\frac{p^3}{54}\right)p'+\frac{2}{9}p'^2+\frac{pp'^3}{54}+\frac{p'^4}{54}\right\};
\end{aligned}\right\} \tag{A25}$$

when $p<2$ and $p'>2$ we have

$$K_{\pm\pm}=C'\pm D'\xi+\xi^2 I'\,,\qquad I'=(\pi^2/54)p^2(12+p^2)\,; \tag{A26}$$

when $p>2$ and $p'<2$ we have

$$K_{\pm\pm}=C''\pm D''\xi+\xi^2 I''\,,\qquad I''=(\pi^2/54)p'^2(12+p'^2)\,; \tag{A27}$$

and when $p>2$ and $p'>2$ we have

$$K_{\pm\pm}=(16\pi^2/9)(1\pm2\xi+\xi^2)\,. \tag{A28}$$

From (A25)-(A28), (4.6) becomes

$$E_1^{(3)}(++)+E_1^{(3)}(--)=\frac{3\alpha r_s}{2\pi^5}\,\frac{6}{5}\xi^2\left[\left\{\int_\beta^2 dp\int_\beta^2 dp' I+\int_\beta^2 dp\int_2^\infty dp' I'\right.\right.$$
$$\left.\left.+\int_2^\infty dp\int_\beta^2 dp' I''+\frac{16\pi^2}{9}\int_2^\infty dp\int_2^\infty dp'\right\}\frac{1}{p^2p'^2(p^2+p'^2)^2}\right]. \tag{A29}$$

By carrying out the integrations for p and p' and from (1.1), we have

$$\{E_1^{(3)}(++)+E_1^{(3)}(--)\}/\xi^2=\gamma_1^{(3)}(++)+\gamma_1^{(3)}(--)$$
$$=0.07060r_s^{-2}-0.07796r_s^{-3/2}+0.01664r_s^{-1}+0.001354-4.171\times10^{-4}r_s^{1/2}$$
$$+2.198\times10^{-5}r_s-4.075\times10^{-6}r_s^{3/2}+1.657\times10^{-6}r_s^2+6.851\times10^{-9}r_s^{5/2}\,. \tag{A30}$$

Then from (A24) and (A30) $E_1^{(3)}$, (4.2), becomes

$$E_1^{(3)}=E_1^{(3)}(+-)+E_1^{(3)}(++)+E_1^{(3)}(--)=\text{const.}+\xi^2\gamma_1^{(3)}\,,$$
$$\gamma_1^{(3)}=\gamma_1^{(3)}(+-)+\gamma_1^{(3)}(++)+\gamma_1^{(3)}(--)$$
$$=0.07060r_s^{-2}-0.07796r_s^{-3/2}-0.09050r_s^{-1}+0.2042r_s^{-1/2}$$
$$-0.1318+0.01945r_s^{1/2}+0.005306r_s-1.467\times10^{-4}r_s^{3/2}$$
$$+3.431\times10^{-5}r_s^2+1.353\times10^{-6}r_s^{5/2}-1.338\times10^{-8}r_s^{7/2}$$
$$+1.167\times10^{-4}r_s(\ln r_s)^2-2.108\times10^{-3}r_s\ln r_s\,. \tag{A31}$$

For the calculations of $E_2^{(3)}$ and $E_3^{(3)}$ the same approximations with the ones used for the calculation of $E_1^{(3)}$ are made use of and the results are as follows:

$$\left.\begin{aligned}E_2^{(3)}=&E_2^{(3)}(+++)+E_2^{(3)}(++-)+E_2^{(3)}(+-+)+E_2^{(3)}(-++)\\&+E_2^{(3)}(---)+E_2^{(3)}(--+)+E_2^{(3)}(-+-)+E_2^{(3)}(+--)=\text{const.}+\xi^2\gamma_2^{(3)}\ ,\\ \gamma_2^{(3)}=&-0.1819r_s^{-2}-0.09327r_s^{-1}+0.04218-0.004582r_s-5.371\times10^{-6}r_s^2+0.001002r_s\ln r_s\ ,\end{aligned}\right\}\tag{A32}$$

and

$$\left.\begin{aligned}E_3^{(3)}=&E_3^{(3)}(+++)+E_3^{(3)}(++-)+E_3^{(3)}(+-+)+E_3^{(3)}(-++)\\&+E_3^{(3)}(---)+E_3^{(3)}(--+)+E_3^{(3)}(-+-)+E_3^{(3)}(+--)=\text{const.}+\xi^2\gamma_3^{(3)}\ ,\\ \gamma_3^{(3)}=&-0.6318r_s^{-5/2}+0.2214r_s^{-3/2}-0.003347r_s^{-1/2}+5.518\times10^{-4}r_s^{1/2}+8.321\times10^{-5}r_s\ .\end{aligned}\right\}\tag{A33}$$

Then, from (A31), (A32) and (A33) $E^{(3)}$, (4.1), becomes

$$\left.\begin{aligned}E^{(3)}=&E_0^{(3)}+\gamma^{(3)}\xi^2\ ,\\ \gamma^{(3)}=&\gamma_1^{(3)}+\gamma_2^{(3)}+\gamma_3^{(3)}=-0.6318r_s^{-5/2}-0.1113r_s^{-2}+0.1435r_s^{-3/2}-0.1838r_s^{-1}\\&+0.1708r_s^{-1/2}-0.08959+0.02000r_s^{1/2}+8.073\times10^{-4}r_s\\&-1.467\times10^{-4}r_s^{3/2}+2.894\times10^{-5}r_s^2+1.353\times10^{-6}r_s^{5/2}\\&-1.338\times10^{-8}r_s^{7/2}-0.001106r_s\ln r_s+1.167\times10^{-4}r_s(\ln r_s)^2\ .\end{aligned}\right\}\tag{A34}$$

In (A34) there are several terms which diverge if r_s tends to zero. This comes from the fact that we use the approximations, in obtaining (A34), which are reasonable at actual metallic densities ($r_s\sim4$) and undoubtedly will be wrong approximations at $r_s=0$, as seen from the dotted curve in Fig. 1.

Appendix III

At the high-density limit of the electron gas, the most important term in the third-order perturbation-calculation energies of the screened Coulomb interactions is the term which is independent on the spin orientations in $E_2^{(3)}$, (4.3). This is given by

$$\begin{aligned}E_h^{(3)}(\xi)=&f(n_+,n_+,n_+)+f(n_+,n_+,n_-)+f(n_+,n_-,n_-)+f(n_+,n_-,n_+)\\&+f(n_-,n_-,n_-)+f(n_-,n_-,n_+)+f(n_-,n_+,n_+)+f(n_-,n_+,n_-)\ ,\end{aligned}\tag{A35}$$

where $f(x_1, x_2, x_3)$ is defined as follows:

$$f(x_1,x_2,x_3)=\frac{3\alpha r_s}{32\pi^7}\int_{\substack{k_1<x_1,\\|\boldsymbol{k}_1+\boldsymbol{P}|>x_1,}}d^3\boldsymbol{k}_1\int_{\substack{k_2<x_2,\\|\boldsymbol{k}_2+\boldsymbol{P}|>x_2,}}d^3\boldsymbol{k}_2\int_{\substack{k_3<x_3,\\|\boldsymbol{k}_3+\boldsymbol{p}|>x_3.}}d^3\boldsymbol{k}_3\int_{p>\beta,}d^3\boldsymbol{p}\,\frac{1}{p^6\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_1+\boldsymbol{k}_2)\boldsymbol{p}\cdot(\boldsymbol{p}+\boldsymbol{k}_2+\boldsymbol{k}_3)}\ .\tag{A36}$$

From $n_\pm=1\pm(1/3)\xi-(1/9)\xi^2$, $E_h^{(3)}(\xi)$ is expanded in powers of ξ^2 as follows:

$$E_h^{(3)}(\xi)-E_h^{(3)}(0)=\frac{4}{3}\xi^2\left\{-2\frac{\partial f(x,1,1)}{\partial x}+\frac{\partial^2 f(x,1,1)}{\partial x^2}\right\}_{x=1}.\tag{A37}$$

We calculate $f(x_1, x_2, x_3)$ at the limit $\beta\to0$ in the following way. Let the direction cosines between $\boldsymbol{p}$ and $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, $\boldsymbol{k}_3$, be λ_1, λ_2, λ_3 respectively. When $p\to0$, the regions of the integrations for $\boldsymbol{k}_i$ become $0\leq\lambda_i\leq1$, $k_i>x_i>k_i-p\lambda_i$ ($i=1, 2, 3$). Then we have

$$f(x_1,x_2,x_3)=\frac{3\alpha r_s}{\pi^3}\int_\beta^\infty\frac{dp}{p^3}\int_0^1d\lambda_1\int_0^1d\lambda_2\int_0^1d\lambda_3\,\frac{\lambda_1\lambda_2\lambda_3x_1^2x_2^2x_3^2}{(x_1\lambda_1+x_2\lambda_2)(x_2\lambda_2+x_3\lambda_3)}\ .\tag{A38}$$

From (A38) and $\beta=0.47r_s^{1/2}$, (A37) becomes

$$E_h^{(3)}(\xi)-E_h^{(3)}(0)=\xi^2\gamma_h^{(3)}\ ,\qquad\gamma_h^{(3)}=-0.0658\ ,\tag{A39}$$

When $r_s \rightarrow 0$, $\gamma^{(3)}$, given by (A34), of course does not coincide with $\gamma_h{}^{(3)}$, then we correct $\gamma^{(3)}$ as follows: assuming that at $r_s=0$ $\gamma^{(3)}$ becomes $\gamma_h{}^{(3)}$ and at $r_s=4$ $\gamma^{(3)}$ takes the value given by (A34) and taking account of the fact that $\gamma^{(3)}$ must become zero at $r_s \rightarrow \infty$, we approximate $\gamma^{(3)}$ by the formula

$$\gamma^{(3)}_{\text{corr.}} = \gamma_h{}^{(3)} \exp(-0.278 r_s) \,. \tag{A40}$$

This $\gamma^{(3)}_{\text{corr.}}$ is shown in Fig. 1.

Magnetic Susceptibilities of Non-Ferromagnetic Transition Metals

By Masao SHIMIZU

Department of Physics, Faculty of Science, Tokyo Metropolitan University, Tokyo

and Takeshi TAKAHASHI

Faculty of Liberal Arts, Meijo University, Nagoya

(Received August 1, 1960)

The increases of the magnetic susceptibilities with temperature for non-ferromagnetic transition metals are investigated by making use of the band picture. If the Fermi surface at the absolute zero of temperature is in the neighbourhood of a minimum of the electron state density, the susceptibility increases with temperature at lower temperatures. Instead of the band with a minimum of the electron state density we use the band where two standard bands are superposed. The spin paramagnetic susceptibilities of this band are calculated numerically at arbitrary temperatures in the several cases of the position of the Fermi surface and the shape of the band, and it is shown that the susceptibilities increase with temperature at higher temperatures. By comparing our theoretical results with the experimental results for the susceptibilities of pure chromium and dilute alloys of iron in chromium at higher temperatures, the position and the shape of the Fermi surface in the neighbourhood of the minimum of the state density for chromium are discussed.

§ 1. Introduction

Among non-ferromagnetic transition metals there are many metals whose paramagnetic susceptibilities increase with temperature. We show in Table I their susceptibilities and the temperature dependences at room temperature [1),2),3),4)], where the signs of plus and minus represent the increase and the decrease with temperature respectively.

It will be difficult to understand this phenomenon by the Heitler-London model. Of course, it may be possible to consider that these transition metals are antiferromagnetic and their Néel temperatures are rather high. However, for some metals their susceptibilities increase even at about 2000°K. If these metals were antiferromagnetic, their Néel temperatures should be higher than 2000°K. Such an interpretation is improbable.

Making use of the band theory, Stoner[5)] has shown that if there is a minimum in the state density of the band and if the Fermi energy at 0°K is at the minimum, the magnetic susceptibility increases with temperature. This fact will be explained simply in the following way. The number of electrons and the total magnetic moment of electrons are given respectively by

$$\left.\begin{aligned} N&=\int_0^\infty \frac{\nu(\mathcal{E})d\mathcal{E}}{\exp[(\mathcal{E}-\mathcal{E}_F-\mu_B H)/kT]+1}+\int_0^\infty \frac{\nu(\mathcal{E})d\mathcal{E}}{\exp[(\mathcal{E}-\mathcal{E}_F+\mu_B H)/kT]+1}\,, \\ \frac{M}{\mu_B}&=\int_0^\infty \frac{\nu(\mathcal{E})d\mathcal{E}}{\exp[(\mathcal{E}-\mathcal{E}_F-\mu_B H)/kT]+1}-\int_0^\infty \frac{\nu(\mathcal{E})d\mathcal{E}}{\exp[(\mathcal{E}-\mathcal{E}_F+\mu_B H)/kT]+1}\,, \end{aligned}\right\} \tag{1}$$

where $\mathcal{E}$ is the energy of an electron, $\mathcal{E}_F$ the Fermi energy and $\nu(\mathcal{E})$ the density of states. From the first equation $\mathcal{E}_F$ is determined as a function of temperature, then from the second the susceptibility is obtained.

At low temperature integrals in (1) are expanded by series, and the paramagnetic susceptibility is given by

$$\chi=\frac{M}{H}=2\mu_B^2\nu(\mathcal{E}_0)\left\{1+\frac{\pi^2}{6}\left[\frac{\nu''(\mathcal{E}_0)}{\nu(\mathcal{E}_0)}-\left(\frac{\nu'(\mathcal{E}_0)}{\nu(\mathcal{E}_0)}\right)^2\right](kT)^2\right\}, \tag{2}$$

where $\mathcal{E}_0$ is the Fermi energy at 0°K, $\nu'(\mathcal{E})=d\nu(\mathcal{E})/d\mathcal{E}$ and $\nu''(\mathcal{E})=d^2\nu(\mathcal{E})/d\mathcal{E}^2$. If we assume for $\nu(\mathcal{E})$ the usual form $\mathcal{E}^{1/2}$ or $\mathcal{E}^n$, the sign of the temperature coefficient of the susceptibility is negative. Elcock *et al.*[6] calculated susceptibilities numerically from (1), and found that for these cases the temperature coefficients are negative at all temperatures.

On the other hand, if $\mathcal{E}_0$ is at a minimum of the state density the temperature coefficient becomes positive, because $\nu'(\mathcal{E}_0)$ is zero and $\nu''(\mathcal{E}_0)$ is positive. The transition metals, whose susceptibilities increase with temperature, have the lower values of susceptibilities and specific heats at low temperature (both are proportional to $\nu(\mathcal{E}_0)$) than those of two neighbouring elements in Table I. This fact is consistent with the above discussion. But (2) is valid for $T \ll \mathcal{E}_0/k$, and at arbitrary temperature where this condition is not necessarily satisfied we must work out numerical calculations with (1).

The purpose of this paper is to investigate the temperature dependence of the magnetic susceptibility at arbitrary temperature in the case where the Fermi energy at 0°K is in the neighbourhood of a minimum of the state density and to discuss the band shape in the neighbourhood of the minimum by comparing our results with the experimental results.

On the other hand it is supposed that the thermal expansion of these metals may affect their susceptibilities. But a simple calculation by the Stoner theory shows that this effect is considerably small (Appendix).

Table I. The magnetic susceptibilities, $\chi_{\mathrm{mole}} \times 10^6$, and their temperature dependences, $d\chi_{\mathrm{mole}}/dT \times 10^8$, at room temperature of non-ferromagnetic transition metals are shown. $d\chi_{\mathrm{nole}}/dT \times 10^8$ are shown in parentheses. The values are adopted from references 1, 2, 3 and 4. The susceptibility of W is nearly independent of temperature at room temperature, but at high temperature it increases with temperature ($d\chi_{\mathrm{mole}} dT \times 10^8 = 0.5$ at 1500°K).

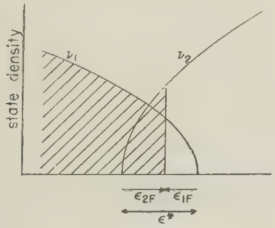

Fig. 1. Superposition of two "standard" bands. ε^* is the overlapping of bands, ε_{1F} and ε_{2F} are the Fermi energies.

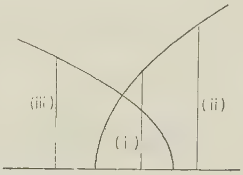

Fig. 2. Three cases in Eq. (6).

§ 2. Calculation of Paramagnetic Susceptibilities for Two Standard Bands Superposed

By superposition of two "standard" bands we approximate a band which has a minimum in the state density (Fig. 1); the state density is given by

$$\nu(\mathcal{E}) = \nu_1(\mathcal{E}) + \nu_2(\mathcal{E}), \quad \nu_1(\mathcal{E}) = a_1 \mathcal{E}^{1/2}, \quad \nu_2(\mathcal{E}) = a_2 \mathcal{E}^{1/2}. \tag{3}$$

For the left band in Fig. 1 $\mathcal{E}$ is measured from the top to the left, while for the right band $\mathcal{E}$ is measured from the bottom to the right. We represent the overlapping of bands by $\mathcal{E}^*$, the Fermi energies by $\mathcal{E}_{1F}$ and $\mathcal{E}_{2F}$ ($\mathcal{E}^* = \mathcal{E}_{1F} + \mathcal{E}_{2F}$), and their values at 0°K by $\mathcal{E}_{10}$ and $\mathcal{E}_{20}$ respectively.

For this band (1) becomes as follows:

$$\left.\begin{aligned}(N_1-N)/(kT)^{3/2}&=a_1[F_{1/2}(\eta_1+\beta')+F_{1/2}(\eta_1-\beta')]-a_2[F_{1/2}(\eta_2+\beta')+F_{1/2}(\eta_2-\beta')]\,,\\ M/\mu_B(kT)^{3/2}&=a_1[F_{1/2}(\eta_1+\beta')-F_{1/2}(\eta_1-\beta')]+a_2[F_{1/2}(\eta_2+\beta')-F_{1/2}(\eta_2-\beta')]\,,\end{aligned}\right\} \tag{4}$$

where

$$F_{1/2}(\eta)=\int_0^\infty\frac{x^{1/2}dx}{e^{x-\eta}+1}\,,\quad x=\mathcal{E}/kT,\quad \eta_1=\mathcal{E}_{1F}/kT,\quad \eta_2=\mathcal{E}_{2F}/kT,\quad \beta'=\mu_BH/kT\,,$$

and N_1 is the total number of states in the left band. Putting $\mathcal{E}^*=kT^*$, we have

$$\eta_1+\eta_2=T^*/T. \tag{5}$$

The first equation of (4) becomes

$$F_{1/2}(\eta_1)-pF_{1/2}(\eta_2)=\left\{\begin{array}{ll}\dfrac{2}{3}\dfrac{1-pr^{3/2}}{(1+r)^{3/2}}\left(\dfrac{T^*}{T}\right)^{3/2}, & \text{for } \mathcal{E}_{10}>0,\ \ \mathcal{E}_{20}>0 \text{ (Fig. 2 (i))};\\ -\dfrac{2}{3}p\left(\dfrac{r}{1+r}\right)^{3/2}\left(\dfrac{T^*}{T}\right)^{3/2}, & \text{for } \mathcal{E}_{10}<0,\ \ \mathcal{E}_{20}>0 \text{ (Fig. 2 (ii))};\\ \dfrac{2}{3}\dfrac{1}{(1+r)^{3/2}}\left(\dfrac{T^*}{T}\right)^{3/2}, & \text{for } \mathcal{E}_{10}>0,\ \ \mathcal{E}_{20}<0 \text{ (Fig. 2 (iii))},\end{array}\right\} \tag{6}$$

where $p=a_2/a_1$ and $r=\mathcal{E}_{20}/\mathcal{E}_{10}$.

From the second equation of (4)

$$\chi/(2\,\mu_B{}^2a_1\mathcal{E}^{*1/2})=[F'_{1/2}(\eta_1)+pF'_{1/2}(\eta_2)](T/T^*)^{1/2}\,, \tag{7}$$

where $F'_{1/2}(\eta)=dF_{1/2}(\eta)/d\eta$. The first term in the right-hand side of (7) is the contribution from the holes of the left band and the second is that from the electrons of the right band. η_1 and η_2 are determined as functions of temperature from (5) and (6), and then χ is given as a function of temperature by (7).

If $T\to0$,

$$\frac{\chi}{2\mu_B{}^2a_1\mathcal{E}^{*1/2}}\to\left\{\begin{array}{ll}\dfrac{1+pr^{1/2}}{(1+r)^{1/2}}\,, & \text{for } 0<r;\\ \dfrac{1}{(1+r)^{1/2}}\,, & \text{for } -1<r<0;\\ p\left(\dfrac{r}{1+r}\right)^{1/2}, & \text{for } r<-1\,.\end{array}\right\} \tag{8}$$

If $T\to\infty$, η_1 and η_2 approach their limiting values $\eta_1{}^\infty$ and $\eta_2{}^\infty$ given by

$$F_{1/2}(\eta_1{}^\infty)=pF_{1/2}(\eta_2{}^\infty)\,, \tag{9}$$

then

$$\chi/(2\mu_B{}^2a_1\mathcal{E}^{*1/2})\to[F'_{1/2}(\eta_1{}^\infty)+pF'_{1/2}(\eta_2{}^\infty)](T/T^*)^{1/2}\,. \tag{10}$$

At intermediate temperatures we calculate susceptibility numerically from (5), (6) and (7) We make use of the numerical values of $F_{1/2}(\eta)$ which have been given by McDougall an Stoner[7]. The results of our calculations for the temperature variations of the susceptibilit at several values of r when $p=1$ and 10 are shown in Fig. 3.

At higher temperatures susceptibilities increase infinitely with temperature. This behavio is due to the fact that we use the "open" band shown in Fig. 1, because in this case th number of the electrons which contribute to the susceptibility increases infinitely with increasin temperature. According to Elcock[8] a "closed" band composed of the superposition of tw standard bands (Fig. 4) gives a temperature decrease of susceptibility at higher temperature Of course, since the real band is closed, our calculation is not appropriate at higher tempera tures. However, because the usual temperature region will be rather "low" compared with the total width of a band, it is enough to use an open band.

On the other hand, at low temperature susceptibility is determined by $\nu(\mathcal{E}_0)$. There are two dips in the band given by (3). The shape of the band given by (3) will be rather different from that of the real band in the neighbourhood of the "minimum", then the calculated susceptibilities at low temperature will be unreliable.

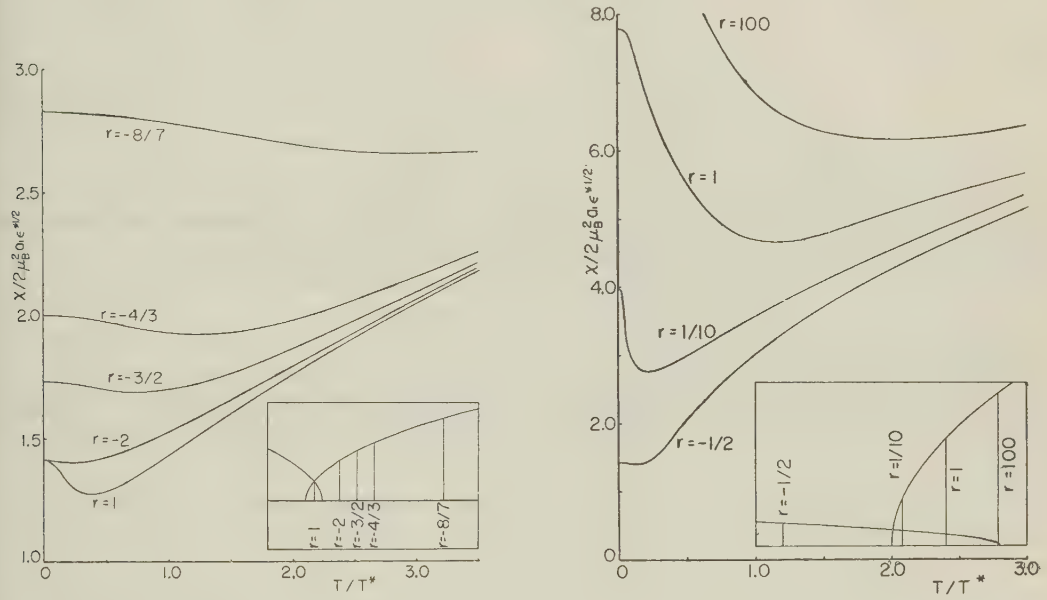

Fig. 3 (a). Fig. 3 (b).

Fig. 3. The calculated temperature-variations of the susceptibilities. (a) $p=1$, and (b) $p=10$.

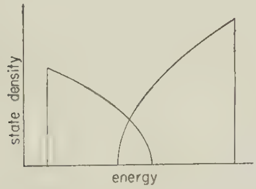

Fig. 4. "Closed" band composed by the superposition of two standard bands.

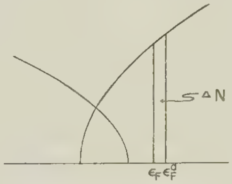

Fig. 5. Variation of the Fermi energy due to alloying. ε_F and $\varepsilon_F{}^a$ represent the Fermi energies of a pure metal and a dilute alloy respectively.

§ 3. Paramagnetic Susceptibilities of Dilute Alloys of Transition Metals

Now we consider dilute alloys in which a small amount of another metal is alloyed in the transition metals discussed above. Let the susceptibility of a transition metal be χ and that of its dilute alloy with another metal be $\chi+\Delta\chi$ and we obtain

$$\frac{\mathcal{E}^*}{\mu_B{}^2}\frac{\Delta\chi}{\Delta N}=\frac{pF''_{1/2}(\eta_2)-F''_{1/2}(\eta_1)}{pF'_{1/2}(\eta_2)+F'_{1/2}(\eta_1)}\frac{T^*}{T}, \tag{11}$$

where $F''_{1/2}(\eta)=d^2F_{1/2}(\eta)/d\eta^2$ and ΔN is the increase of the number of electrons (Fig. 5). Here we have assumed that the band shape is not affected by alloying and the additional electrons are distributed in the same band.

With these assumptions and assuming a proper band we can easily explain the increase of the specific heat, which is proportional to T at low temperature, when another metal is alloyed.

For $T\to 0$,

$$\frac{\varepsilon^*}{\mu_B^2}\frac{\Delta\chi}{\Delta N}\to\left\{\begin{array}{ll}\frac{1}{2}\frac{(1+r)(p-r^{1/2})}{pr+r^{1/2}}, & \text{for } 0<r;\\ \frac{1}{2}(r+1), & \text{for } -1<r<0;\\ \frac{1}{2}\frac{r+1}{r}, & \text{for } r<-1,\end{array}\right\} \tag{12}$$

and for $T\to\infty$,

$$\frac{\varepsilon^*}{\mu_B^2}\frac{\Delta\chi}{\Delta N}\to\frac{pF''_{1/2}(\eta_2^\infty)-F''_{1/2}(\eta_1^\infty)}{pF'_{1/2}(\eta_2^\infty)+F'_{1/2}(\eta_1^\infty)}\frac{T^*}{T}\propto T^{-1}. \tag{13}$$

As shown in the following section, this result agrees qualitatively with the experimental results obtained by Newmann and Stevens[9], *i.e.* in dilute alloys of iron in chromium $\Delta\chi$ follows the Curie law at higher temperatures (they explain this result with the Mott-Stevens model, namely they attribute $\Delta\chi$ to the effect of the two localized electrons of an iron atom).

§ 4. Comparison with Experimental Results

The results obtained above contain many parameters which cannot be determined definitely. So we ought to be satisfied with rather rough estimations in the following way. Now, we rewrite (11) and (13), and compare with the experimental results obtained by Newmann and Stevens[9].

If we neglect the difference between densities of pure chromium and dilute alloys of iron in chromium, and that between the atomic weights of chromium and iron,

$$\Delta N=1.16\times 10^{22}\,qx \quad \text{per gram,} \tag{14}$$

where x is the fraction of Fe atoms and q the increase of electrons per iron atom. Then (11) and (13) become

$$\Delta\chi=0.00721\,qx\frac{pF''_{1/2}(\eta_2)-F''_{1/2}(\eta_1)}{pF'_{1/2}(\eta_2)+F'_{1/2}(\eta_1)}\frac{1}{T}, \tag{11'}$$

and for $T\to\infty$

$$\Delta\chi\to 0.00721\,qx\frac{pF''_{1/2}(\eta_2^\infty)-F''_{1/2}(\eta_1^\infty)}{pF'_{1/2}(\eta_2^\infty)+F'_{1/2}(\eta_1^\infty)}\frac{1}{T}. \tag{13'}$$

η_1^∞ and η_1^∞ are determined by the value of p (see (9)), and then the slope of $1/\Delta\chi$ vs. T is determined by p, also.

Although it seems to be reasonable to take 2 for the value of q, we will regard q as a parameter for the time being. It is possible to obtain an agreement between our theoretical calculations and the experimental observations of susceptibilities if q is larger than 2 and p is larger than 10. We will use $p=10$ in the following consideration.

In Fig. 6 the measured values of susceptibilities for chromium are compared with the theoretical values of susceptibilities for $p=10$, $r=-2$, $T_{20}(=\mathcal{E}_{20}/k)=350°\text{K}$ and $p=10$, $r=1/10$, $T_{20}=250°\text{K}$. In Fig. 7 the measured $\Delta\chi$ of Cr-Fe alloy (1.05% Fe) is compared with the theoretical $\Delta\chi$ for the same parameters with those mentioned above. The values of a_1 in Fig. 6 and of q in Fig. 7 are determined to get an agreement between the theoretical values and the experimental values for susceptibilities at high temperature. It is difficult to determine the value of r precisely, because the curves are not so different for both cases where $r=-2$ and 1/10.

If the Fermi energy is nearer to the "minimum" (r is smaller) than these cases, it seems to be impossible to fit the calculated curves with the experimental results for both χ and $\Delta\chi$ by using the same values of parameters.

And if the Fermi energy is in the left-hand of the "minimum" ((iii) in Fig. 2), it is quite mpossible to get a satisfactory agreement between our calculations and experimental results or both χ and $\Delta\chi$. Anyhow it can be said that the order of magnitude of T_{20} for Cr is iven by the value obtained above($\sim$300°K).

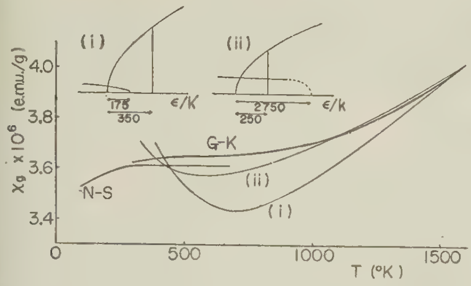

Fig. 6. Comparison between the theoretical susceptibilities and the experimental ones for chromium.

(i) Calculated for $p=10$, $r=-2$, $T_{20}=350$°K and $\mu_B{}^2k^{1/2}a_1=1.56\times10^{-8}$, e.m.u. g^{-1} deg$^{-1/2}$,

(ii) Calculated for $p=10$, $r=1/10$, $T_{20}=250$°K and $\mu_B{}^2k^{1/2}a_1=1.23\times10^{-8}$ e.m.u. g^{-1} deg$^{-1/2}$,

G-K: Experimental result by McGuire and Kriessman[1],

N-S: Experimental result by Newmann and Stevens[9].

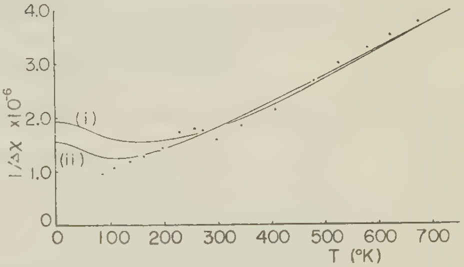

Fig. 7. Comparison between the theoretical susceptibilities and the experimental ones for 1.05% Fe in Cr.

(i) Calculated for $p=10$, $r=-2$, $T_{20}=350$°K, $q=4.8$,

(ii) Calculated for $p=10$, $r=1/10$, $T_{20}=250$°K, $q=5.8$,

Dots are experimental results by Newmann and Stevens[9].

The above-mentioned analysis is consistent with the experimental results on the low-emperature specific heat of Cr-Fe alloy obtained by Wei *et al.*[11] According to their neasurements, when the fraction of Fe atom, x, is small, γ increases rapidly with x, where T is the low-temperature specific heat. Because γ is proportional to $\nu(\mathcal{E}_0)$, if we assume that he band shape is not different from that of pure chromium when a small amount of iron toms is alloyed, we can expect that the slope of the state density vs. energy at $\mathcal{E}_0$ is steeper. To obtain a rough estimation we neglect the left half of the band shown in Fig. 1, *i.e.* $(\mathcal{E})=a\mathcal{E}^{1/2}$ and $a=(3/4)N\mathcal{E}_0{}^{-3/2}$, and we have $C/Nk=(\pi^2/2)(kT/\mathcal{E}_0)$, where C is the electronic pecific heat per mole. Then $\Delta\gamma/\Delta N=\pi^2k^2/(6\,\mathcal{E}_0)=\pi^2k/(6\,T_0)$. As $\Delta N=Lq\,x$, $\Delta\gamma=3.2\,qx/T_0$ cal. nole^{-1} deg^{-2}, where L is Avogadoro's number. Comparing this with the observed value, $\gamma/x=0.041$ cal. mole^{-1} deg^{-2}, we get

$$T_0=80\,q\,.$$

his is consistent with the result obtained above from the analysis of the magnetic suscepti-ility.

5. Conclusion

From the theoretical point of view we see that if the Fermi energy is at the minimum of he state density the magnetic susceptibility increases not only at low temperature but also t any temperature. Especially, from the comparison between the theoretical result and the xperimental one for chromium we can conclude as follows; (1) there is a minimum in the tate density of the band of chromium and the slope of the state density vs. energy above he minimum is considerably steeper than that below the minimum (*i.e.* $p\gg1$), (2) the Fermi nergy of chromium at 0°K is a little higher than the minimum, and (3) the magnetic sus-eptibility of Cr-Fe alloy can also be interpreted qualitatively by the band model.

This work was completed while one of the authors (T. T.) held a grant from Foundation or In-service Trainining and Welfare of the Private School Personnel.

Appendix

According to (2) in the text the magnetic susceptibility at low temperature is

$$\chi=2\,\mu_B^2\nu(\mathcal{E}_0)\,. \qquad \text{(A-1}$$

In order to estimate the effect of the thermal expansion on the susceptibility, we put

$$\nu(\mathcal{E})=4N\mathcal{E}^{1/2}/(3\,\mathcal{E}_0^{3/2}),\quad \mathcal{E}_0=(\hbar^2/2\,m^*)(3\pi^2N/V)^{2/3}\,,$$

where m^* is an effective mass of the electrons. Then

$$\chi=3^{1/3}\pi^{-4/3}N^{1/3}\mu_B^2\hbar^{-2}m^*V^{2/3}\,. \qquad \text{(A-}$$

The temperature variation of χ is

$$\begin{aligned}\left(\frac{\partial\ln\chi}{\partial T}\right)_P&=\left(\frac{\partial\ln\chi}{\partial\ln V}\right)_T\left(\frac{\partial\ln V}{\partial T}\right)_P+\left(\frac{\partial\ln\chi}{\partial T}\right)_V\\&=\left(\frac{2}{3}+\frac{\partial\ln m^*}{\partial\ln V}\right)_T\left(\frac{\partial\ln V}{\partial T}\right)_P+\left(\frac{\partial\ln m^*}{\partial T}\right)_V\,.\end{aligned}$$

As $(\partial\ln V/\partial T)_P=3\alpha$ and $(\partial\ln m^*/\partial\ln V)_T=\frac{1}{3}[\partial\ln(m^*/m)/\partial\ln r_s]_T$, we obtain

$$\left(\frac{\partial\ln\chi}{\partial T}\right)_P=\left\{2+\left(\frac{\partial\ln(m^*/m)}{\partial\ln r_s}\right)_T\right\}\alpha\,, \qquad \text{(A-}$$

Table II. The temperature increases of the magnetic susceptibilities and the thermal expansion coefficients of Cr, Mo and Ti.

		Cr	Mo	Ti
$\left(\frac{\partial\ln\chi}{\partial T}\right)_P\times10^4$	room temp.	+0.5	+0	+3.5
	1500°K	+2	+1	—
$\alpha\times10^4$	room temp.	0.08	0.05	0.09
	1500°K	0.14		—

where α is the thermal expansion coefficient and r_s the mean distance between electrons. Here we neglect the explicit temperature dependence of the effective mass.

According to the results obtained by Brooks *et al.* the values of $[\partial\ln(m^*/m)/\partial\ln r_s]_T$ for Li, Na, and Rb are -0.01, $+0.07$ and $+0.12$ ($\ll 2$) respectively[12]. Assuming that the second term of the right-hand side of (A-3) can also be neglected for transition metals we obtain

$$(\partial\ln\chi/\partial T)_P=2\alpha\,. \qquad \text{(A-4)}$$

For example the temperature increases of the magnetic susceptibilities and the thermal expansion coefficients of Cr, Mo and Ti are shown in Table II. It is seen that the effect of the thermal expansion is considerably small to explain the temperature increases of the magnetic susceptibilities for these metals.

The Magnetic Properties of Single Crystals of Chromium Selenide

By Ichiro TSUBOKAWA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan.

(Received August 4, 1960)

The magnetic susceptibilities of the single crystals as well as powder specimen of chromium selenides with the composition, $CrSe_{1.00}$, $CrSe_{1.04}$ and $CrSe_{1.07}$ were measured from the boiling point of liquid helium up to 900°K. The susceptibility vs. temperature curves showed a break at 279°K, 271°K and 232°K for $CrSe_{1.00}$, $CrSe_{1.04}$ and $CrSe_{1.07}$ respectively. The anisotropy of the susceptibility increases rapidly from these breaking points to lower temperatures. There exists also a peak of the specific heat just above the room temperature which, however, lies a little higher than the breaking point mentioned above. This peak temperature of specific heat is considered to be the antiferromagnetic Néel point. Asymptotic Curie temperature, θ_p, Curie constant C_M and spin quantum number S were determined from the susceptibility data in the paramagnetic region.

1. Introduction

The magnetic susceptibility of chromium selenide, CrSe, was once measured by Haraldsen and Kowalski[1] in the temperature range from the boiling point of liquid air to 630°K and by the author[2] from the helium temperature to 400°K. From these results, it was seen that the susceptibility of the powdered specimen of this compound increases steadily with decreasing temperature. Since the asymptotic Curie temperature, θ_p, obtained from the measurements mentioned above takes a value -200°K, an antiferromagnetic ordering of spins will be expected in the crystal lattice of this compound at low temperatures. Recently Corliss and Hastings[3] observed by means of neutron diffractometer an antiferromagnetic spin ordering below room temperature. However, no peak of susceptibility corresponding to the antiferromagnetic Néel point was found by the above authors. It was also shown theoretically that a relation $T_N \geq |\theta_p|/5$[4] holds for the antiferromagnetic substances with NiAs structure. Hence, the Néel temperature is expected to be sufficiently higher than 4.2°K. From these points of view, magnetic and thermal properties of a single crystal of this compound were investigated.

§2. Specimens and Experimental Results

Three powder specimens of chromium selenides with the compositions $CrSe_{1.00}$, $CrSe_{1.04}$ and $CrSe_{1.07}$, were prepared by the solid reaction method. Powdered chromium (99.3%) and selenium (99.99%) were sealed in evacuated silica tubes in the desired ratios and heated in an electrical furnace. The highest temperatere reached 1100°C. All the specimens were confirmed to be of the NiAs structure by means of the Debye–Scherrer technique. In order to prepare single crystals of these compounds, the powdered specimens obtained above were put again into evacuated silica tubes, 15 mm in diameter, as shown in Fig. 1. This silica tube was connected to a balloon of soft rubber, half filled with argon gas, so as to keep normal pressure in the silica tube. Since the melting point of the compound lies just above 1500°C, the specimen was heated in a siliconit furnace up to about 1600°C and cooled slowly at the rate of 1.5°C per minute. A single crystal obtained by this method, 15 mm in diameter and about 20 mm in length, had a cleavage plane $(10\bar{1}0)$. No appreciable deviation in the composition of the crystal from that of the original powder specimen was detected by chemical analysis.

The temperature depencence of the susceptibility of the compound in powdered form was taken from the helium temperature up to 900°K with a magnetic balance[5], the result being shown in Fig. 2. As it shows, the susceptibility decreases at first rapidly and then slowly and after showing a breaking point at

279°K, it decreases again rapidly with a further rise of temperature. With the increase of selenium content, the breaking point falls down slightly, although the general aspect of the curve remains unchanged. As seen from the inverse susceptibility curves plotted in Fig. 2, the Curie-Weiss law holds for the susceptibilities of these compounds above th breaking point. The asymptotic Curie point θ_p and the Curie constant C_M obtained ar tabulated in Table I, together with the averag spin quantum number, S for chromium ion which is calculated from C_M with assumin that the Landé factor is equal to two,

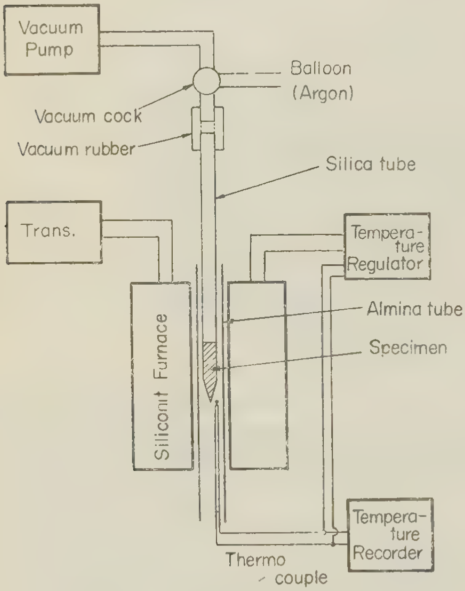

Fig. 1. Schematic diagram of the apparatus to make a single crystal.

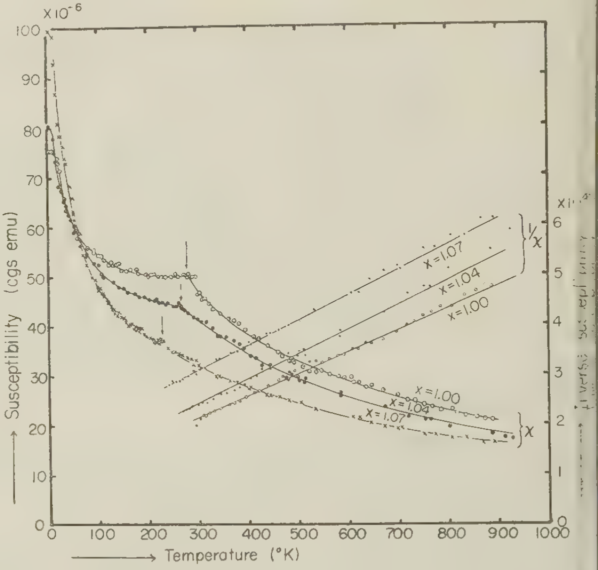

Fig. 2. Susceptibility vs. temperature curves for polycrystalline $CrSe_{1.00}$, $CrSe_{1.04}$ and $CrSe_{1.07}$. Inverse susceptibilities are also ploted.

Teble I. Paramagnetic Curie point θ_p, Curie constant C_M, spin quantum number S and the temperature of breaking point on χ–T curve, of $(\chi_c-\chi_a)=0$ and of C_p maximum.

Compounds	θ_p	C_M	S	Temperature		
				of breaking point on χ–T curve	of $(\chi_c-\chi_a)=0$	of C_p max.
$CrSe_{1.00}$	−200° K	∼ 3.0	4/2	279° K	278° K	320° K
$CrSe_{1.04}$	−190° K	∼ 2.7	3.8/2	271°	271°	—
$CrSe_{1.07}$	−320° K	∼ 2.7	3.8/2	232°	256°	—

Next, the susceptibilities, χ_c, along c-axis and χ_a, along a-axis, were measured with a magnetic balance. These results are shown in Fig. 3 (a), (b) and (c) for each specimen. As is shown, a remarkable anisotropy in the susceptibility is present below the temperature of the breaking point. χ_a decreases slightly with the rise of temperature from helium point, then reaches a constant value at about 60°K, while χ_c decreases continuously with rising temperature.

The torque curves in the a-c plane of th crystal mentioned above were taken with magnetic torsion balance, a few of the result being shown in Fig. 4 (a) and (b). The curve in the figures were taken for a specimen wit the composition $CrSe_{1.00}$ at the temperature of 4.2°K and 86°K respectively. The angula dependence of torque value in the a-c plan is expressed simply by sin 2θ. Also the H plot of the measured torque value is show in Fig. 5. As seen from it the torque valu changes linearly with the square of the field strength. Hence, the torque value will be expressed by the expression

$$L=\frac{1}{2}m(\chi_c-\chi_a)H^2\sin 2\theta\ .$$

$(\chi_c-\chi_a)$ is obtained from the torque values at $\theta=45°$, as a function of temperature, the result being shown in Fig. 6. It was confirmed that the result obtained agrees with that from the direct measurement of susceptibility of the single crystal. The difference takes a positive value at low temperatures, decreases in value with rising temperature and shows a negative value just below room temperature. With the increase of the selenium content the difference of the susceptibility changes its sign at lower temperatures.

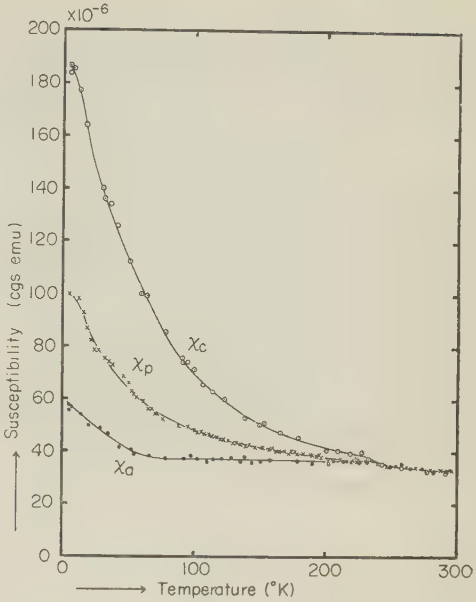
(b)



(c)

Fig. 3. χ_c, χ_a and powder susceptibility χ_p vs. temperature curves for $CrSe_{1.00}$ (a), $CrSe_{1.04}$ (b) and $CrSe_{1.07}$ (c).

Specific heats were measured for the compound $CrSe_{1.00}$ from 100°K to 400°K. The result is shown in Fig. 7. A peak in specific heat vs. temperature curve is seen at 320°K, which coincides nearly with the breaking point in the susceptibility curve mentioned above. *X*-ray powder photographs were taken at room temperature and −70°C and showed the diffraction lines due to the *NiAs* structure, and the change in the lattice parameters was found to be of the order of the thermal expansion, showing that no lattice change occurred during heating of the specimen up to 320°K.

§ 3. Discussions

Corliss and Hastings[3] confirmed the existence of antiferromagnetic ordering of ionic spin moments in powder specimens of chromium selenide below room temperature. The diffracted intensity of neutrons due to antiferromagnetic ordering was found to decrease with the rise of temperature but a faint long range order scattering remained yet up to room temperature. However, they have not yet succeeded in finding the Néel point of this compound. It was again pointed that the asymptotic Curie point is about 200°K. Although two critical temperatures 279°K (the breaking point of susceptibility-temperature curve) and 320°K (a peak point of specific heat) were obtained as the possible Néel point of this crystal, the latter may be the true Néel point, because specific heat is the more intrinsic properties than the susceptibility, and further, this assumption is more consistent with the result of neutron diffraction experiment than to take the former.

It is noted that the temperature dependence of the susceptibilities in the c-plane as well as along the c-axis for chromium selenide below the estimated Néel point are quite different from that of the ordinary antiferromagnetic crystals. In ordinary crystals the susceptibility parallel to spin axis decreases with lowering temperature and that perpendicular to spin

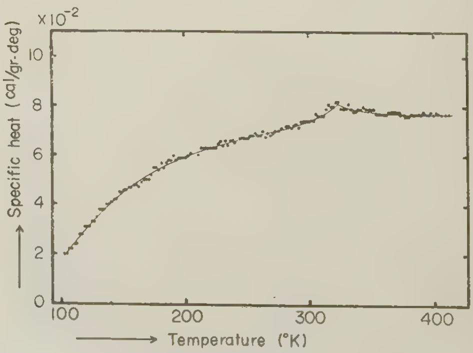

Fig. 7. Specific heat vs. temperature curve for $CrSe_{1.00}$.

axis is constant below Néel point, so that the values of χ_c and χ_a should not be greater than the one at Néel point. It is desirable to investigate the spin ordering of a single crystal of this compound with a neutron diffractometer just above and below room temperature.

Considering from the fact that χ_c and χ_a below 50°K rise rapidly with the lowering of temperature, it may be assumed that there are paramagnetic islands in the crystal as has been done in the case of cobaltous oxide.

The Change of the Curie Temperature of Iron-Nickel Alloys Due to Hydrostatic Pressure

By Takejiro KANEKO

The Research Institute for Iron, Steel and Other Metals, Tohoku University

(Received August 5, 1960)

The change of the Curie temperature due to hydrostatic pressure was measured for two iron-nickel alloys with a nickel concentration of 30 and 32 atomic percent respectively. Hydrostatic pressure was produced with an apparatus of Bridgman's type and the measurements of magnetization were performed by the ballistic method. The change of the Curie temperature due to pressure was estimated to be $-3\cdot 10^{-3}$ and $-2.7\cdot 10^{-3}$ deg. $kg^{-2}\,cm^2$ for specimens with a nickel concentration of 30 and 32% respectively. Based on Smoluchowski's fomula, the volume dependence of saturation magnetization at absolute zero $1/I_0\cdot\partial I_0/\partial\omega$ and that of the molecular field coefficient $1/N\cdot\partial N/\partial\omega$ for a 30% nickel alloy were found to be 27 and -16 from the experimental results. And then taking into consideration the volume dependence of the saturation magnetization at absolute zero, the relations among the volume dependence of the Curie temperature, molecular field coefficient and exchange integral are discussed.

§ 1. Introduction

According to several authors the magnetic properties of an iron-nickel alloy with a nickel concentration of about 30 atomic percent show a remarkable pressure dependence: Ebert and Kussmann[1)] measured its magnetization at various temperatures under the action of high hydrostatic pressure, and based on the fact that the ferromagnetic magnetization does not vanish even by the action of infinitely large pressure, they concluded that the Curie temperature of the alloy mentioned above did not change with hydrostatic pressure. On the other hand Patrick[2)] measured the change of the Curie temperature due to pressure by the A. C. transformer method and obtained a value $-5.8 \cdot 10^{-3}$ deg./atoms. Since the spontaneous magnetization should vanish at Curie temperature, however, the method of measurement used by Ebert and Kussmann may be more desirable than that used by Patrick for the purpose of finding out the change of the Curie temperature. So that the present author measured the change of the Curie temperature with nearly the same method as that used by Ebert and Kussmann for two iron-nickel alloys with a nickel concentration of 30 and 32 atomic percent respectively.

§ 2. Specimen and Experimental Procedure

Two iron-nickel alloys, containing 30 and 32 atomic percent of nickel, were melted in a vacuum induction furnace, cast in a metal mould, 20 mm in diameter, forged and then machined into rods, 70 mm in length and 3 in diameter. They were then annealed at 650°C for about 60 hours and, in order to maintain the γ phase (f.c.c. structure) which is stable at high temperature for these alloys, rapidly quenched in ice-water. It could be confirmed that the specimens consisted merely of f.c.c. structure since the alloy had the Curie temperature which coincided with that of γ-phase alloy.

Hydrostatic pressure was produced by means of an equipment of Bridgman's type[3] using paraffine oil as the pressure fluid. A part of the equipment is shown in Fig. 1. High pressure container *A* is made of non-magnetic copper-beryllium alloy, 14 mm in outside diameter and 3 mm in inside diameter. Specimen *B* was inserted in this container and sealed with a Bridgman's type of packing. The measurements of magnetization were performed by the ballistic method. A search coil *C* was wound around the pressure container. The liquid in the container *A* was compressed by means of primary and transmitting pistons under the action of primary pressure, which was measured by using the Bouldon's tube. The pressure in the container was calculated from the ratio of cross-sectional areas of primary and transmitting pistons. In this case, it has to be taken into account that there are errors of a few percent because of the indirect measurement of pressure. In order to investigate the temperature dependence of magnetization, all of these were immersed in heat bath *D*. Temperature in the heat bath was measured with a thermocouple *E* placed outside the pressure container and the specimen was kept at the same temperature in each case of measurement for more than 30 minutes. The magnetizing solenoid *F* can produce a sufficient uniform magnetic field within 0.1% for the specimens.

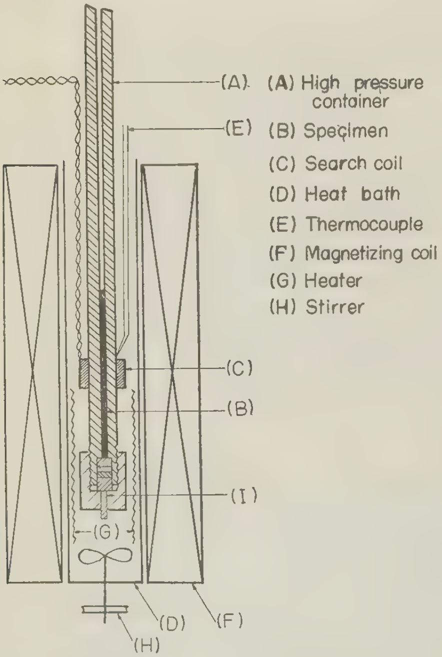

Fig. 1. Schematic diagram of a part of the measuring equipment.

§ 3. Results and Discussion

In Figs. 2 and 3 are shown the magnetization curves of a specimen with a nickel concentra-

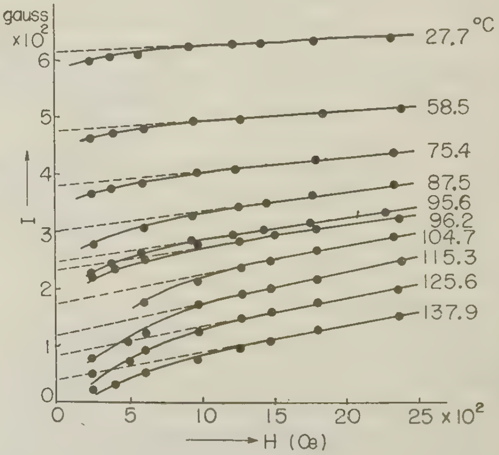

Fig. 2. The curves of magnetization versus magnetic field at various temperatures under normal pressure. (70Fe-30Ni alloy)

tion of 30% under a pressure of 1 as well as 3000 kg cm^{-2}, respectively, at various temperatures. Spontaneous magnetization was obtained by the extrapolation of the magnetization to $H=0$ after technical saturation. It was found that the magnetization was saturated nearly completely above the field strength of 1500 Oe for various temperatures. And the spontaneous magnetization versus temperature curves are shown in Fig. 4. The Curie temperature at each pressure was obtained by plotting the square of magnetization with the temperature as in Fig. 4. From these results the change of the Curie temperature with pressure for a specimen with a nickel concentration of 30% was found to be -3.10^{-3} deg. kg^{-1} cm^2. A specimen with a nickel concentration of 32% was measured by the same procedure as above. The results of measurement are shown in Fig. 5. From these results, the change of the Curie temperature with pressure was found to be $-2.7\cdot10^{-3}$ deg.kg^{-1} cm^2. The tendencies of the change of the Curie temperature due to pressure for the two alloys agreed with those of Patrick's results.

△: under 3200 kg cm^{-2}

As to the origin of the pressure dependence of the Curie temperature mentioned here, the variation of the exchange interaction as well as that of saturation magnetization at absolute zero by the application of pressure should be considered, though the latter would not absolutely be independent of the former. However, the measurement of the pressure dependence of the saturation magnetization has scarcely been done, so that the effect of pressure[4] on the Curie temperature has hitherto been discussed merely by taking the variation of exchange interaction into account. Recently the pressure dependence of the specific magnetization $1/\sigma_0\cdot\partial\sigma_0/\partial P$ was estimated directly by Kondorskii[5] for iron-nickel alloys. For an alloy with a nickel concentration of 38% this author obtained a rather large value, $-54\cdot10^{-7}\,\mathrm{kg^{-1}\,cm^2}$. So that the change of the Curie temperature caused by the second factor mentioned above should be taken into account.

As for the pressure dependence of the saturation magnetization, the theoretical result by Smoluchowski[5] can be applied: Let the saturation magnetizations per unit volume at a finite temperature and at absolute zero be denoted here by I and I_0 respectively, and also I_0 be assumed to be given by

$$I_0=n\mu_B g\bar{s}\ , \tag{1}$$

where n is the number of magnetic atoms, μ_B the Bohr magneton, g Lande's facter and $\mu_B g\bar{s}$ the average magnetic moment. And if the temperature dependence of the saturation magnetization at constant volume is represented by a Brillouin function, then, by using a thermodynamical relation

$$\frac{\partial V}{\partial H}=-\frac{\partial(VI)}{\partial P}\ , \tag{2}$$

the following equations are obtained:

$$\frac{1}{I_0}\cdot\frac{\partial I_0}{\partial\omega}=-\left\{\frac{1}{\theta}\cdot\frac{\partial\theta}{\partial\omega}\cdot\frac{\partial I/\partial T)_v}{(\partial I/\partial T)_v-I/T}-\frac{I-(1/\kappa)\cdot(\partial\omega/\partial H)}{I-T(\partial I/\partial T)_v}\right\}\Big/\left\{1-\frac{(\partial I/\partial T)_v}{(\partial I/\partial T)_v-I/T}\right\}, \tag{3}$$

$$\left(\frac{\partial I}{\partial T}\right)_v=\left(\frac{\partial I}{\partial T}\right)_P-\frac{3\alpha}{\kappa}\cdot\left(\frac{\partial\omega}{\partial H}\right)_P-3\alpha I\ .$$

These equations give the relation between the volume dependence of the saturation magnetization at absolute zero and that of the Curie temperature. Here ω means the relative volume change $\Delta V/V$, κ the volume compressibility and α the linear thermal expansion coefficient. putting the observed values of the quantities on the right-hand side of equation (3), we obtained

$$\frac{1}{I_0}\cdot\frac{\partial I_0}{\partial\omega}=27\ . \tag{4}$$

Here the observed values at 30°C under 1 kg cm^{-2} were used; $\alpha^*=1.1\cdot10^{-5}\,\mathrm{deg^{-1}}$., $1/\kappa^*=1.5\cdot10^6\,\mathrm{kg\,cm^{-2}}$, $\partial\omega/\partial H^*=2.3\cdot10^{-8}\,\mathrm{Oe^{-1}}$[4], $I=605$ gauss, $(\partial I/\partial T)_P=-4.5$ gauss deg^{-1}.

As for the change of the Curie temperature due to pressure, the value from iso-volume I-T curves should be chosen, but taking into account the fact that the Curie temperature decreases lineally with pressure[2], the isobar curve can be used instead of iso-volume curves. Hence, in order to obtain equation (4), the value $1/\theta\cdot\partial\theta/\partial\omega=11$ from the isobar curve in Fig. 4 is used.

From equation (4) the pressure dependence of the specific magnetization at absolute zero, $1/\sigma_0\cdot\partial\sigma_0/\partial\ P$, was obtained as

$$\frac{1}{\sigma_0}\cdot\frac{\partial\sigma_0}{\partial P}=-180\cdot10^{-7}\,\mathrm{kg^{-1}\,cm^2}\ . \tag{5}$$

According to Kondorskii's result, $1/\sigma_0\cdot\partial\sigma_0/\partial P$ increases from $-11\cdot10^{-7}$ to $-54\cdot10^{-7}\,\mathrm{kg^{-1}\,cm^2}$ as the nickel concentration decreases from 45 to 38%, so that the present result shown in equation (5) may be reasonable.

As for the variation of the molecular field coefficient N with the volume change, the following relation was used by Smoluchowski:

$$\frac{1}{N}\cdot\frac{\partial N}{\partial\omega}=\frac{1}{\theta}\cdot\frac{\partial\theta}{\partial\omega}-\frac{1}{I_0}\cdot\frac{\partial I_0}{\partial\omega}\ . \tag{6}$$

Inserting the values obtained above for $1/\theta\cdot\partial\theta/\partial\omega$ and $1/I_0\cdot\partial I_0/\partial\omega$ into the equation (6), the result

$$\frac{1}{N}\cdot\frac{\partial N}{\partial\omega}=-16\ , \tag{7}$$

$$N=\frac{2zJ}{ng^2\mu_B{}^2}\ . \tag{8}$$

In this equation n would also be considered to be pressure dependent since for the proposed model due to Smoluchowski it is possible to assume that magnetic and non-magnetic atoms of nickel coexist. Such assumption was once proposed in the case of pure nickel, in which it was considered that different states of atoms e.g. atoms in singlet and triplet states coexist. By the application of pressure they would transform into each other, so that n may be changed. Therefore the result obtained above does not directly represent the dependence of exchange integral J on the interatomic distance.

Magnetic Resonance in $MnCO_3$

Muneyuki DATE

Department of Physics, Faculty of Science, Osaka University, Osaka

(Received August 6, 1960)

Magnetic resonance of the single crystal of $MnCO_3$ was investigated using microwave frequencies 9 to 36 kMc/sec. Parasaitic ferromagnetic resonance was observed at 4.2°K which can be explained by the theory of magnetic resonance developed for α-Fe_2O_3 by Motizuki and Pincus. The effective field H_{DM} due to the Dzyaloshinsky-Moriya interaction was obtained to be 3.7 K Oe and the other resonanue constant $\sqrt{2H_E \mathrm{H}_A'}$ to be 1.4 K Oe, where H_E is the exchange field and H_A' the anisotropy field in the basal plane.

§ 1. Introductions

Dzyaloshinsky[1] has pointed out that the parasitic ferromagnetism of α-Fe_2O_3 and several other substances can be explained by assuming an anisotropic exchange interaction of the form $\vec{D}(\vec{S}_1 \times \vec{S}_2)$. Subsequently Moriya[2] has shown that such an exchange term can be derived by considering the spin-orbit coupling in the superexchange mechanism and that the constant vector $\vec{D}$ contains spin-orbit coupling constant in the first order.

Attempt to obtain the resonance formula containing such an anisotropy term has been made by Motizuki[3] and by Pincus[4]. They showed that the experimental results for α-Fe_2O_3 obtained by Anderson et al[5]. and Kumagai et al[6]. can be explained by introducing a new effective field H_{DM} due to the Dzyaloshinsky-Moriya interaction. Theoretical treatment of the magnetic resonance in α-Fe_2O_3 was first made by Shimizu[7], but he treated phenomenologically the weak ferromagnetism which appears in α-Fe_2O_3 without looking into the origin of the parasitic ferromagnetism. Pincus pointed out that, beside the energy of spin canting due to the Dzyaloshinsky-Moriya interaction, a very small anisotropy energy in the basal plane has an important effect on the frequency of the oscillation of the weak ferromagnetic moment in the basal plane and he showed that the frequency formula of this mode is given by

$$\left(\frac{\omega}{\gamma}\right)^2 = H_0(H_0 + H_{DM}) + 2H_E H_A' , \qquad (1)$$

where H_0, H_E, H_A' and H_{DN} represent the external field, the exchange field, the anisotropy field in the c-plane, and the effective exchange field due to the $\vec{D}(\vec{S}_1 \times \vec{S}_2)$ term, respectively. Eq. (1) is valid for magnetic fields applied in the c-plane. When the external field is not in the c-plane, the following equation is to be used:

$$\left(\frac{\omega}{\gamma}\right)^2 = H_0 \sin\theta(H_0 \sin\theta + H_{DM}) + 2H_E H_A' , \qquad (2)$$

where θ is the angle between the c-axis and the magnetic field. Using eqs. (1) and (2), the experimental results obtained by Anderson and Kumagai were satisfactorily explained by Pincus.

It must be noted, however, that the existing experimental results on α-Fe_2O_3 are not satisfactory to test the applicability of the theory developed by Motizuki and Pincus because of the following reason. The effective fields H_{DM} and $\sqrt{2H_EH_A'}$ of α-Fe_2O_3 were determined as 1.3×10^4 and 4.1×10^3 Oe, respectively, but these large values mean that only a limited portion of eq. (1) could be verified by experiments which made use of the usual microwave frequencies and magnetic fields. In fact, the experimental points fall on an approximately linear portion corresponding to intermediate frequencies and fields. Perhaps one or two mm-waves may be necessary to observe the asymptotic part of eq. (1) for high field, which is not an easy matter with the present microwave techniques.

Other than α-Fe_2O_3, however, there are several magnetic substances showing weak ferromagnetism. A few carbonate, such as $CoCO_3$ and $MnCO_3$ are known to be the typical examples. The magnetic properties of $MnCO_3$ indicate that eqs. (1) and (2) could be checked fully with the use of the usual microwaves.

The magnetic susceptibility of this crystal was measured by Borivik-Romanov and Orlova[8], who showed that below the Néel temperature T_N of 32°K the canted spins are in the basal c-plane. Recently neutron diffraction study of the powdered specimen was performed by Pickart[9]. The induced moment due to Dzyaloshinsky-Moriya interaction was obtained as $0.2\mu_B$ from which we can infer that the effective field H_{DM} may be small compared with that in α-Fe_2O_3. The purpose of this paper is to report the experimental result of the magnetic resonance observed in the natural single crystal of $MnCO_3$ at different temperatures and the analysis of the data obtained.

§ 2. Experimental Procedure

The single crystal of $MnCO_3$ used in our experiment is a natural rhodochrosite obtained from Osarizawa Mine, Akita Prefecture, Japan, in Aipril 1955. The crystal structure of $MnCO_3$ is the well known calcite type, having a rhomcohedral unit cell of $a=5.84$Å and $\alpha=47°46'$. The single crystal of $MnCO_3$ is very cleavable as calcite is

Microwave frequencies used for our experiment are 9 to 36 kMc/sec supplied from klystrons 2K25, 2K33, and 35V10. Usual transmission method was adopted. Low temperature cryostats are the same as those described in the preceding paper[10].

§ 3. Experimental Results

Paramagnetic resonance was observed at room temperature in the whole frequency range. Part of the results are shown in Fig. 1 and 2. It must be noted that there is a considerable angular dependence of the resonance line width which can not be explained by dipolar interaction and the usual exchange narrowing effect. Detailed calculation shows that the pure dipole width along the c-axis is larger than that found experimentally, which

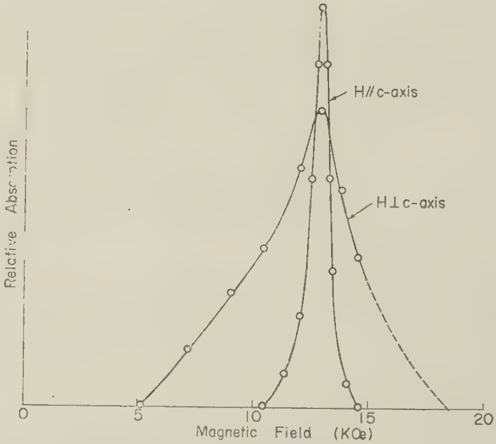

Fig. 1. Resonance line shapes in paramagnetic $MnCO_3$ single crystal at room temperature (36.43 kMc/sec).

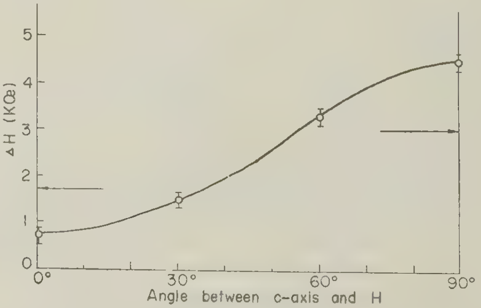

Fig. 2. Angular dependence of resonance line width in paramagnetic $MnCO_3$ at 36.43 kMc/sec. Arrows show the calculated dipolar widths.

means that the usual exchange narrowing occurs for this case. On the other hand, the calculated dipolar width in the c-plane is smaller than that found by experiment which can not be explained by the current theory of line width. Line broadening due to the anisotropic exchange interaction of the $\vec{D}(\vec{S}_1\times\vec{S}_2)$ form might be important for this case. The g-value is isotropic and is 2.00 ± 0.01.

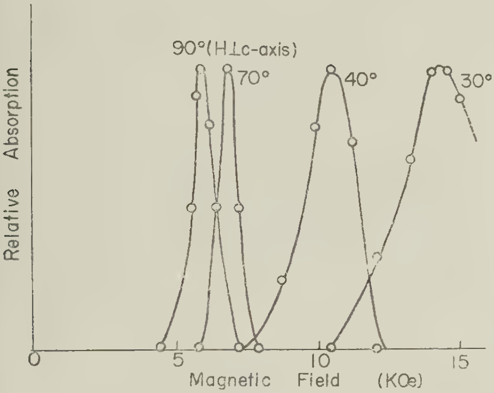

Fig. 3. Resonance line shapes in $MnCO_3$ single crystal at 4.2°K (22.34 kMc/4ec). Angles show the declination from the c-aqis.

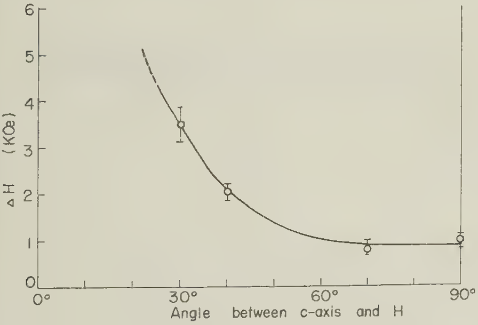

Fig. 4. Angular dependence of resonance line width in $MnCO_3$ at 4.2°K (22.34 kMc/sec).

The experimental results of the resonance curves at 4.2°K are shown in Fig. 3. Considerable angular dependence was observed, which may be due to the parasitic ferromagnetism appeared in $MnCO_3$ below 32°K. Observation of the angular dependence of the resonance line was also made and the results are shown in Fig. 4. The angular and the frequency dependences of the resonance points are shown in Fig. 5. In the c-plane no anisotropy was observed in accordance with the theoretical expectation of Motizuki and Pincus. The full lines drawn in Fig. 5 are the theoretical curve due to eq. (2). The coincidence between theory and experiment is satisfactory.

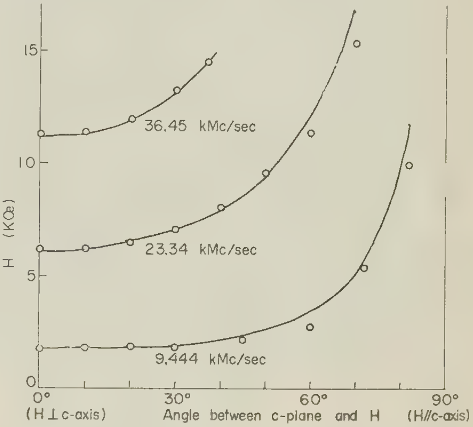

Fig. 5. Angular and frequency dependence of resonance points in $MnCO_3$ at 4.2°K (H // c-plane).

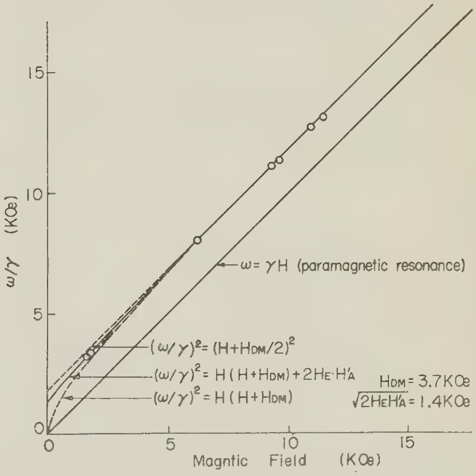

Fig. 6. Frequency field diagram of the resonance points in $MnCO_3$ at 4.2°K. (H // c-plane).

Now let us consider the resonance constants H_{DM} and $2H_EH_A'$. The frequency field diagram of the resonance points are shown in Fig. 6. The experimental points lie on the asymptotic line described by $\omega/\gamma=H+3.7/2$, except for two resonance points belonging to the 9 kMc/sec region. Thus we obtain the resonance constant H_{DM} to be 3.7°K Oe. So far the resonance in the asymptotic line has not been observed in α-Fe_2O_3. Then we obtain the constant $2H_EH_A'$ by satisfying two resonance points in the 9 kMc/sec region. Thus $2H_EH_A'=2.0$ K Oe^2 was decided as being the most favourable value. For comparison, the asymptotic line and the resonance curve of $H_A=0$ are shown in Fig. 6. The coincidence of the theory with the experiment is satisfactory at 4.2°K. Detailed measurement of the temperature dependence of the magnetic resonance have not been performed because of the experimental difficulties near 30°K. However our preliminary data show that eqs. (1) and (2) are valid for all temperatures below 30°K, while the short range order effect was found to survive even at considerably high temperatures, resulting in a broadening of the paramagnetic resonance.

The author wishes to express his cordial thanks to Profs. Itoh and Nagamiya and Dr. Motizuki for their valuable discussions and stimulations during the course of the experiment. He is also indepted to Profs. Kiriyama and Yoshimura for supplying a natural single crystal of $MnCO_3$. A part of the experiment was subsidized by a grant from the Ministry of Education.

Direct Viewing of Imperfections in Germanium p-n Junction

Masami TOMONO

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo

(Received Sept. 2, 1960)

A p-n junction was made by alloying indium on an n-type germanium pellet and it was put into an electrolyte solution of copper salt. When suitable reverse voltage was applied on the junction by a charged condenser, copper shaded pattern was deposited on the opposite side of the alloyed surface in accordance with the density of the reverse current flowing through every part of the p-n junction. By this method, the breakdown at the imperfections of p-n junction due to the defects in the germanium crystal, those at the periphery of p-type recrystallized layer, and those inside p-n junction grown in alloying process were observed. Then, the cross section was made referring to the pattern, and several kinds of the imperfections of p-n junction were observed under microscope.

§ 1. Introduction

Previously, the author observed imperfect germanium p-n junction under the microscope, and investigated the electrical characteristics of the alloyed p-n-p transistor with such imperfect emitter junction¹⁾. At the same time, he assumed various types of imperfection of the p-n junction, and supposed that an m-n junction nearly $1\,\mu$ in diameter and making imperfect rectifying contact with the germanium might be a kind of the imperfection and the large saturation current in the reverse direction flew through the part, or in some cases, the breakdown voltage of the junction became strikingly low. If such small imperfections exist, their finding will be extremely difficult even by the observation of cross section of the *p-n* junction with a microscope. So far relatively large imperfections of the *p-n* junction have been reported frequently but the relation-ship with the degradation of the electrical characteristics of the junction has not been clarified in most cases[2),3)]. Thus, for finding such defect, two-step procedure would become necessary: firstly to find its approximate location from external and secondly to examine that portion carefully. For the silicon *p-n* junction, it has been well known, from light emitting phenomenon at the part of the junction where breakdown occurs with reverse voltage applied, that breakdown easily occurs at the worked parts of the grown junction[4)], the indented part, the prominent lines of etch pits, the junction-periphery and the misfit boundary of the *p-n* junction made by impurity diffusion[5)], and that wide area of junction emits light by internal field emission[6)]. As for germanium, the light emitting phenomenon was also reported but the correlation with the imperfections of *p-n* junction has not been clear[7)]. It has been known that, when copper is deposited on a germanium surface electrolytically, shaded pattern of copper is developed according to the density of the current flowing through the part of the surface into the copper salt solution[8),9)]. The conventional method using copper sulphate solution for this purpose, however, fails to developed plated pattern sharp enough to permit detection of fine imperfections of *p-n* junction. The author used the method improved by Tokuyama[10)] to get a sharp deposited pattern on on the opposite germanium surface corresponding to the density of reverse current which flows through the imperfection of the *p–n* junction. The purpose of this paper is to present such improved method of plating as well as the results of investigation of some imperfections of *p-n* junction which were detected using this method.

§ 2. Method of Experiment

A p^+-*n* junction about 1 mm in diameter was made by alloying indium at about 500°C on an *n*-type germanium pellet 60 to 100 μ thick and 2.5Ω cm in resistivity. The germanium surface on that side alloyed with indium was covered with shellac, and its p^+ electrode was biased negative in adequated plating electrolyte. The germanium surface not alloyed with indium was so placed as to face a platinum electrode which was bised positive. Between the electrodes a current was then caused to flow for electroplating on the *n*-type germanium surface. In this situation, it is expected that if any local imperfections exist within *p-n* junction, the current flow should be concentrated to those areas of the germanium surface which correspond to the imperfections, resulting in the correspondingly shadded pattern of copper plating. The conventional method using copper sulphate solution for this purpose[8),9)], however, failed to get sharp plated pattern with high fidelity. The use of the plating solution of the following specification by Tokuyama[10)] made it possible to get comparatively good results.

20% solution of $CuSo_4$	5% (volume)
H_2O_2 (30%)	5% (volume)
HF (48%)	5% (volume)
Deionized water	85% (volume)

The plating in this solution by continuous current under constant voltage permitted to obtain some reproducible deposited pattern corresponding relatively large imperfections within *p-n* juntion. This plating method will be described "continuous current method" in report. However, this method was not satisfactory to reveal relatively small imperfections within *p-n* junction. The author could get sharp deposited pattern for this case with reproducibility and high fidelity by the following method[10)]. The circuit used is as shown in Fig. 1. First, a switch S_1 was operated to etch side, with another switch S_2 closed, to bias the sample positive and the platinum electrode negative, thus the surface of *n*-type germanium was cleaned by electrolytic etching. After this, the switch S_1 was operated to plating side, with the switch S_2 opened, to allow a condenser *C* to be charged at a voltage of V. Next, S_2 was closed, then at the initial instant a relatively large discharging current is caused by the condenser *C* but after discharging from *C* an only relatively small voltage is applied between the electrodes as the voltage V is lowered due to a series resistance *R*. This method[10)] is described "pulse method" in this paper. The values actually used by the author are; V: 3 to 100 volts, R: 500 kΩ and C: 2 μF.

The value of V should be selected properly according to the properties of the sample, and for detection of the breakdown characteristic of each prat of p-n junction, it should be increased from a small values gradually. In this case, for developing the copper plating pattern for one value of V firstly and thereafter examining it with respect to another value of voltage, it is imperative that the deposited copper of the first time should be completely dissolved by the electrolytic etching prior to repeating electroplating for another value of V, otherwise, being affected by the first plating, the deposited pattern in the second case may not perfectly develop. The time which was allowed for plating was adjusted properly in the range of 15 to 300 seconds as required for a completely developed deposited pattern to be seen with the eye. The sample to which copper locally deposited in this way observed on the surface alloyed with indium to examine the configuration of the portions around indium dots. Next, the alloyed indium dot was amalgamated with mercury. This amalgam was then dissolved away with nitric acid so that recrystallized p-type germanium layer was exposed, and as needed, this p-type layer was further applied with chemical etching to permit the examination of the imperfections within recrystallized layer and also the finding of the relationship between the pattern of deposited copper on the opposite surface of germanium and the imperfections in the recrystallized layer. Finally, cross sections of those portions to which much copper was deposited were observed with a microscope to clarify through what imperfection in p-n junction an excess reverse current flew.

§ 3. Result of Experiment

3.1 Plating Pattern Under Constant Voltage and Continuous Current

For an ordinary p-n junction having relatively good reverse characteristics, it is frequently seen that a spot pattern develops relatively uniformly but at random on the surface of n-type germanium as shown in Fig. 2, if the sample is applied with plating by continuous current at a relatively low voltage without the condenser C in Fig. 1. On the other hand, for a sample having relatively poor reverse characteristics in which location of the imperfection within p-n junction is unknown, sometimes no specific pattern develops as shown in Fig. 3(a) with the plating at a low voltage (3V in this example), though specific pattern may develop as shown in Fig. 3(b) if the plating is carried out at a higher voltage (26V in this example). Another example is shown in Fig. 4 for the sample with considerably poor reverse characteristics. (a) gives the plating pattern at 2V on a sample which was made by alloying indium to the indented part on the germanium surface. A semicircular black pattern on the right-hand side of the sample is not caused by the copper deposition but represents a stepped part shaded by the illumination at the periphery of the backside of indium dot electrolytically etched more deeply than other parts. (b) shows the plating pattern at 6V on a sample of imperfect p-n junction which was made by alloying thin indium layer on germanium as reported by the author previously[1]. The patterns in both figures, though not sharp, indicate that considerably clear imperfection exists within p-n junticon. Fig. 5 shows the plating pattern for a sample which has poor reverse characteristics but in which location of the imperfection withoin p-n junction is not known. (b) gives a photograph of the sample subjected to the electrolytic etching of (a). At first, no specific evidence of abnormality could be observed on the surface of n-tpye germanium, but after the removal of surface layer by electrolytic etching, imperfection of germanium sigle crystal analogous in configuration to the semicircular deposited pattern has been revealed.

3.2 Plating Pattern under Pulse Method

A description that follows is of plating pattern developed under pulse method of Fig.

1. Fig. 6 shows the reproducibility of the plating pattern obtained under pulse method in Fig. 1. The sample used was made by alloying indium on an n-type germanium, but the periphery of the p-n junction was not removed by etching. Of course, this sample permitted comparatively large reverse current and was not so good in its characteristics. (a) shows the deposited pattern by this method where V in Fig. 1 is 100 V. In this case, very sharp pattern compared with Fig. 4 was developed at those areas of the opposite surface which correspond to the periphery of p-n junction. (b) shows. the sample after copper

deposit had been completely dissolved by forward current. (c) shows the pattern which was resubjected to the pulse method. It is found that the reproducibility of the plating pattern is considerably high. From those figures, it was perceived that along the periphery of the alloyed junction there was an area with low breakdown voltage and on the backside of this area copper deposited in a ring form. The similar plating pattern has been obtained on many samples. A ring-formed plating pattern developed on the backside of n-type germanium under pulpse method (V of Fig. 1:100V) is shown in Fig. 7 in comparison with the results of observation of the same sample from the alloyed side. This sample permits relatively large flow of reverse current because the periphery of its p-n junction has not been removed by etching. As the photograph in (b) was printed out with the negative film turned over, the photograph in (a) showing the backside and that in (b) showing the front surface have the same sense. The periphery of an exposed p-type recrystallized layer formd by indium overspreading[11] in (b) is quite analogous in shape to the copper plating pattern

in (a), but it is also seen that the marked copper deposition is limited only to a part of the backside region corresponding to the exposed p-type layer. In Fig. 8, the results of comparative observation between the plating pattern by pulse method (V:100V) and cross-section of junction are shown on the sample which permitted relatively large reverse current because of not being applied with electrolytic etching after alloying· (a) shows cross-section of the junction, and (b) shows plating pattern on the portion at which the

cross-section was taken. As seen from the cross-section of (a), copper deposited markedly on the backside corresponding to the exposed *p*-type recrystallized layer especially to such part that *p*-type germanium layer has overspread and grown where germanium bulk did scarcely melt. It is apparent that non-uniform contacting area exists between the overspread *p*-type germanium layer and the base *n*-type germanium at the right-hand end. Fig. 9 shows an example of plating by pulse method (V of Fig. 1:100V) on the sample which was applied with the electrolytic etching to remove the periphery of alloyed dot[2),12)]. The sample was improved in characteristics to have more than 100V breakdown voltage. (a) shows the cross-section of sample, indicating that the periphery of the junction has been scooped out enough not to leave imperfect part as seen in Fig. 8. (b) shows the plating pattern on the backside surface. With respect to the part at which the cross-section was taken, (b) is aligned with (a). A double concentric black pattern at the periphery in (b) is not caused by the copper deposition but represents a stepped part which was formed by electrolytic etching to clean the germanium surface on the backside and is shaded by the illumination. Copper is deposited in spots approximately uniformly over the opposite surface of *p-n* junction indicating that breakdown has not occurred with 100V at any part of the whole *p-n* junction. The periphery of *p-n* junction is completely free from imperfection. This represents a typical case where imperfection of the periphery of *p-n* junction has been completely removed by the electrolytic etching. Needless to say, however, sometimes the imperfection may remain partilly at the periphery after the electrolytic etching. Sometimes, a special etching pattern as shown in Fig. 10 is observed on the surface of a germanium. Such a pattern extends from the front to the backside surface of the germanium pellet in some cases but does not in the other. Selecting a germanium pellet on one surface of which such special bar-shaped etching pattern exists but on the backside none appears, the author applied the alloying of indium on that surface which has the pattern. This sample permitted a flow of extremely high reverse current. Fig. 11 shows photographs of a sample with the bar-shoped imperfection. The indium was alloyed on the imperfection. It has been verified experimentally that such sample in general has badly poor reverse characteristics as described later. (a) shows the deposited pattern by pulse method (V in Fig. 1:100V) on the oposite side of the surface alloyed with indium. Marked copper plating pattern has developed at such a location as is slightly to the inside of the periphery of alloyed part and had no anomaly before alloying. (b) shows a condition of the recrystallized surface which appeared after the indium dot on the surface of the sample was removed as amalgam with mercury and the exposed *p*-type germanium was etched chemically with dilute CP-4. Printing of the photograph for (b) was made with the negative film turned over. From (b), it is seen that etch pits are prominently developed and dislocations are concentrated especially to those parts where copper deposition is prominent in (a). Fig. 12 shows the the results of observation on sample was made by first giving a scratch in X shape with a diamond and then alloying indium thereto on a germanium pellet. This sample also is poor in characteristics because of its high reverse current. (a) shows pattern of copper plating (V:100V) to the oposite side of the surface alloyed with indium. Copper deposition is made on three of those places where the scratch intersects the periphery of the alloyed indium dot. but at the other place, no copper is deposited. Regarding to this place, it is seen from (b) that the scratch is very narrow compared with other three places. (b) shows the sample after the indium is removed with mercury and the exposed *p*-type layer was etched chemically with dilute CP-4. Printing of (b) was made with the negative film turned over. Immediately to the inside of two parts at which the scratches intersect the right-hand periphery, two groups of prominent etch pits are observed. Certainly, these positions may correspond to the positions on the backside at which copper was deposited. Fig. 13 shows a different kind of copper plating pattern. (b) in the same figure shows the plating pattern developed by the pulse method. It is featured particulary by a semicircular plating pattern located near the center, in addition to the ones along the periphery of the indium alloyed part. In (a), a cross-section photograph is given for the part corresponding to the cutaway part of (b). Prominent copper deposition pattern at the periphery of indium dot on the left-hand in (b) corresponds to the *p*-type germanium recrystallized layer which was grown by over-spreading on the surface of germanium remaining not fused into an indium melt and which made imperfect contact with the germanium bulk as mentioned earlier. Significance of the semicircular plating pattern in the center is that a slight deviation of the germanium pellet surface from (111) plane results in a small inclination of bottom of the *p*-type recrystallized layer in (a) to back surface of the germanium bulk, reducing the distance gradually to a minimum at the part where the semicircular plating pattern develops. In this case, the minium distance is about 13μ. It is belived that at the time of application of 100V pulse voltage the punch-through has occurred at this minimum-distance part and large current has flowed. Finally in Fig. 14 is shown an example of copper plating patterns by pulse method found frequently to the samples which are still badly poor in reverse characteristics after the removal of the periphery of alloyed part by electrolytic etching. It is seen that copper is markedly deposited to relatively small locallized area. Though copper deposition by pulse method in this figure is considerably sharp compared with the blurred one under constant voltage in Fig. 4(b), it seems that the cause of both cases is the same. In Fig. 14, it is remarkable that no copper deposition appears at the part of etch pits produced by electrolytic etching. This fact is perceived also in Fig. 3, Fig. 12 and Fig. 13.

3.3 Relations between Copper Plating Pattern and Reverse Characteristics of *p-n* Junction

A *p-n* junction, which is made by alloying indium on a germanium pellet with a bar-shaped imperferction or scratch on the surface as shown in Fig. 11 and Fig. 12, has an extremely low breakdown voltage. As an example of this, result on a sample which has a scratch on one surface nearly as in Fig. 12 is shown in Fig. 15. A breakdown occurs at a very low voltage, and reverse current increases approximately owing to the the Ohm's law nearly up to 8V. Beyond 8V, occurrence of a second breakdown is seen. (a) in Fig. 16 shows a germanium pellet on which many rod-shaped etching patterns are observed. A, B, C,····in the figure are the rod-shaped patterns. As seen from these examples, the rod-shaped patterns may be either imperfection involved previously in the germanium crystal or scratches incurred in working proceess.

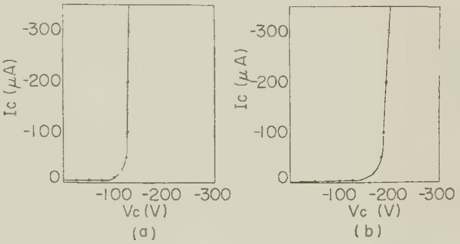

Fig. 17. Comparison of reverse characteristics between *p-n* junctions made from germanium with and without rod-shaped etch patterns.

(a) With rod-shaped pattern.

(b) Without rod-shaped pattern.

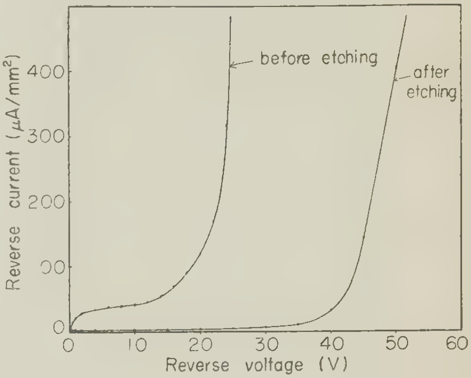

Fig. 18. Comparison of revers characteristics before and after removal of imperfections at periphery of *p-n* junction by electrolytic etching.

Samples with and without these kinds of imperfection were selected each by fives and alloyed with indium to make the respective *p-n* junctions. The average reverse characteristics of each group of *p-n* junctions are as shown in Fig. 17. (a) is for samples with imperfections on the surface, and (b) for samples without them. It is apparent that the former is lower in breakdown voltage, though not so low as in Fig. 15. Fig. 18 shows comparison of reverse characteristics between two cases: in one case, a sample was as in Fig. 6, 7 and 8, not applied with etching and in the other, the same sample was applied with electrolytic etching enough to remove imperfections at the periphery of *p-n* junction nearly campletely. From these figures it is known that the sample which is poor in reverse characteristics before electrolytic etching is remarkably improved after etching.

§ 4. Dicussion of Results

4.1 Copper Plating Method

As earlier mentioned, copper electrolyte in § 2 permits revelation of imperfections of *p-n* junction with a good contrast as well as a comparatively good reproducibility. With this electrolyte, well contrasted plating pattern can be obtained under pulse method as shown in Fig. 1. Alternatively, if a copper plating is applied at a relatively low voltage V by the method above, an observation of the resulted pattern is made and after reversal of the current for dissolving the deposited copper, a second copper plating is applied at a higher voltage and if this process is repeated with the successively increased plating voltages, it is expected possible to see how breakdown is caused by the imperfections of *p-n* junction at the respective breakdown voltages. The details of this method will be reported by Tokuyama[13]. Fig. 4 and Fig. 5 show the samples containing in *p-n* junction small localized imperfections which break down at a very low voltage without utilization of pulse method or make non-rectifying contact. In Fig. 3, breakdown does not occur with 3V but does locally with 26V. In Fig. 7, Fig. 8, etc., breakdown occurs at relatively high voltage, but Fig. 9 indicates that breakdown never occurs with 100V.

4.2 Relations Between Lattice Defect and Breakdown

The patterns shown in Fig. 3 is probably due to the same cause as in Fig. 5, and the breakdown voltage in these cases is again relatively low. As seen from (b) of Fig. 5, the cause may consist in a special defect present in a germanium single crystal. This defect is considered to be probably a dislocation array due to the misfit at fine domain boundary which is produced as the single crystal grows out of a melt. With respect to the possibility of such locallized boundary being produced in the growing process of germanium single crystal, the author has had an experimental evidence. Bar-shaped defect in (b) of Fig. 11 as seen from the side alloyed with indium is an example of such defect shown in Fig. 10 and is deemed not to be merely a small angle grain boundary. This defect extends very short in the publling-up direction of the single crystal (that is, in the direction perpendicular to the photograph). Based on the observation on a great number of germanium single crystals, it is believed that the defect mentioned above is formed by a germanium melt which is locally included in the grown crystal, as reported in a following paper to be published shortly[14]. When indium is alloyed on such defect as seen from (b) of Fig. 11 copper deposition does not occur along the whole length of the defect at the alloyed part but does only in that part corresponding to the bottom of the pan-shaped recrystallized layer. (b) makes it clear that many dislocations crowd together in bar shape in the recrystallized germanium layer corresponding to that part where copper deposition occurs. Fig. 3 and Fig. 5 described above seem to show the similar phenomenon. As for the sample which is given a scratch with diamond on the germanium surface, the same phenomenon is observed as shown in Fig. 12. The reason why the bottom part of the *p-n* junction of Fig. 12 has not been affected at all is merely that the depth of scratch is so small that at that part the scratch has completely fused into an indium melt. On a side wall of the pan-shaped recrystallized layer, this scratch causes a crowded dislocation array to appear in the recrystallized *p*-type layer as shown in (b) of Fig. 12. At the part where the dislocation array exists in the recrystallized layer, breakdown is liable to occur as clearly shown in (a) of Fig. 12. Though badly low in sharpness because of low voltage and continuous current, the plating pattern in (a) of Fig. 4 has the same cause as in Fig. 12. The fact that copper has not deposited by pulse method at the part where etch pits exist at random as described in 3.2 indicates that the breakdown voltage owing to these isolated dislocations is considerably high (refer to Fig. 3, Fig. 12, Fig. 13, Fig. 14, etc.). The details of this will also be reported by Tokuyama[13]. It is believed that the cause for the poor reverse characteristics of *p-n* junctions described above is such that when dislocations crowd together across the *p-n* junction very thin indium parts exist locally in the *p*-type recrystallized germanium layer and it comes into direct contact with the *n*-type germanium, thereby shorting the *p-n* junction. This supposition may be supposed from a known fact that arsenic and antimony are liable to diffuse along the medium angle grain boundary of the germanium single crystal[15]. Examples in Fig. 11 and Fig. 12 conespond to such case possibly and the reverse current owing to the Ohm's law as shown in Fig. 15 is convincing from this supposition. Moreover, this will apply for some cases where relatively large reverse current flows at a voltage of 1 to 2V, resulting in the application of copper plating on the backside as shown in (a) of Fig. 4 and Fig. 5. The details well be reported by Tokuyama[13]. As for the cases in Fig. 3 and Fig. 17 where defect within germanium bulk causes the breakdown voltage to be lowered but the reverse current at low voltage is not so high, number of dislocations across the *p-n* junction is not so large as in the above-mentioned case and invasion of indium to the part of dislocations may not be remarkable, therefore the lowering of the breakdown voltage may be due to any other cause. In this case, the dislocation will not so crowd as in Fig. 11 and Fig. 12 indeed, but dislocation array, namely, grain boundary surely exists. Conversion to *p*-type of such grain boundary is well known[16]. In this case *p*-type layer enters locally at *p-n* junction from *p*-type recrystallized layer into bulk germanium. Every part of the layer thus entered is not uniform but at some part a transition to the *n*-type through a weak *n*-type from an extremely weak *p*-type may be made. At such part, breakdown voltage may be lowered. As another cause for the lowered breakdown voltage, a deviation of the junction from a plane may also be considered[17].

4.3 Breakdown at Periphery of *p-n* Junction

For a sample which is, as shown in Fig. 6, not applied with etching after indium alloying, the periphery of *p-n* junction is liable to break down. This is a well-known fact[2),12),18]. In such part where the periphery of alloyed indium is out of true circle and takes an irregular shape, a larger number of weakpoints exists as clearly seen from the left-halves of photographs (a) and (b) of Fig. 7. Unlimited to these examples, such a tendency as mentioned above has been verified by the author on many samples. A comparison between (a) and (b) of Fig. 8 indicates that the structure with low breakdown voltage exists at the end of thin *p*-type recrystallized layer which was extruded by the so-called overspreading from the indium dot in (a). The process of this overspreading may be such that an indium melt nearly saturated with germanium in the heating process of alloying decreases in viscosity at the maximum temperature which takes place in the final stage of the heating process, and it spreads to some extent over the bulk germanium hitherto exposed. In the subsequent cooling process, recrystallization of *p*-type germanium takes place on the germanium part covered with indium by overspreading[11]. This recrystallized *p*-type germanium, however, is difficult to fit to the base germanium, because the germanium surface has not been wetted enough with indium melt obstructed by the oxide, etc. as a result of which there may be lattice defect due to misfit and other various defective structures between the base germanium and the recrystallized layer. As the surface tension of the indium melt increases in the cooling process of alloying, the part which spreads later recontracts partially and results in an exposed *p*-type recrystallized layer on the surface. Because of these defects at the periphery with overspreading structure, breakdown may be liable to occur as reported in a separate paper[13]. To some extent, the imperfection in the overspread end may be supposed from the right-hand end of Fig. 8(a). As seen from (a), of Fig. 9, breakdown at the periphery disappears if the imperfections of *p-n* junction periphery are compeletely removed.

4.4 Punch-Through

A semicircular plating pattern in the center of (b) of Fig. 13 is considered to be caused by a punch-through phenomenon as described in 3.2. For a *p-n* junction with highly doped *p*-type layer which was made by alloying indium on an *n*-type germanium pellet 2.5Ωcm in resistivity, the thickness of the space charge layer when the *p-n* junction is applied with a voltage of 100V in the reverse direction is about 17μ by the following equation[19]:

$$W_s=(2\kappa/q)^{1/2}(V/N_d)^{1/2},$$

where W_s, κ, V and N_d denote thickness of space charge layer, dielectric constant, voltage applied to the space charge layer and number of doner impurities in a unit volume of *n*-type germanium, respectively. The thickness of the *n*-type germanium measured at the position where copper is deposited in semicircular shape is 13 μ based on the photograph in (a) of Fig. 13. The possibility of punch-through occurring at this position is easily supposed.

4.5 Other Cases

For a sample which has badly poor reverse characteristics after complete removal of the imperfections at *p-n* junction periphery, it is sometimes seen that relatively small deposition of copper takes place at some places corresponding to the inside of the *p-n* junction. This may be cause with little doubt by an *m-n* junction, that is, a small indium part left in the *p*-type recrystallized layer and coming into direct contact with the *n*-type germanium, as published by the author previously[1)]. In (b) of Fig. 4 showing a sample which was prepared by alloying thin indium layer to the *n*-type germanium as published by the author previously, the existence of such *m-n* junction at two parts may be shown by the plating pattern though blurred since pulse method is not used. This will be published in detail by Tokuyama[13)].

Acknowledgment

The author wishes to acknowledge the cooperation of Mr. T. Tokuyama and Mr. K. Uehara who supplied many useful data.

Microwave Spectrum of Formaldehyde
I. *K*-type Doubling Spectra

Takeshi OKA,* Hiromasa HIRAKAWA,† and Koichi SHIMODA
Department of Physics, Faculty of Science,
University of Tokyo, Tokyo, Japan

(Received, July 2, 1960)

Microwave spectral lines for the direct transitions between the *K*-type doublets were measured from 3 kMc to 40 kMc for H_2CO and for its isotopically substituted molecules HDCO, $H_2C^{13}O$ and H_2CO^{18}. The observed spectra and the previously reported data for H_2CO were analyzed by a digital computer by the use of Kivelson and Wilson's method for the centrifugal distortion correction.

The asymmetry parameter b and B-C were obtained for each isotopic species as follows:

	B-C (Mc/sec)	b
H_2CO	4832.13±0.01	−0.0098370±0.0000010
$H_2C^{13}O$	4595.47±0.02	−0.0093205±0.0000010
H_2CO^{18}	4391.08±0.02	....
HDCO	5347.77±0.04	−0.0161170±0.0000020
D_2CO	6097.35±0.02	−0.0271170±0.0000020

It was found that the observed frequencies fit well to those calculated from the centrifugal distortion constants which were derived by the vibration-rotation interaction theory.

§ 1. Introduction

Formaldehyde is a planar, slightly asymmetric top molecule with rather large electric dipole moment (μ=2.33 Debye). The direct transitions between the *K*-type doublets provide abundant and strong spectral lines all over the microwave region.

The *K*-type doubling lines of H_2CO were first measured and assigned in the *K*-band region by Sharbaugh and Bragg.[1] Lawrance and Strandberg extended the measurement from 7 to 72 kMc and analyzed the spectrum by a semi-classical treatment of centrifugal distortion.[2a)] Though the rotational constants obtained by them are quite reasonable, the centrifugal distortion constants used in the analysis can not be explained from the vibration-rotation theory.

An extensive study for this molecule as well as for the isotopically substituted molecules has been carried out in this laboratory.[3a)3b)3c)3d)4a)4b)4c)] Hirakawa, Miyahara and Shimoda measured the *K*-type doubling spectral lines of H_2CO, $H_2C^{13}O$ and H_2CO^{18} down to 2.8 kMc using an S band wave guide cell.[3a)] Hirakawa, Oka and Shimoda synthesized deuterated samples and measured the *K*-type doubling lines for HDCO and D_2CO from 2.8 kMc to 20 kMc.[3b)]

These *K*-type doubling lines are so strong that some of them were used for the maser experiments.[4a)4b)4c)5)]

At this stage it is quite necessary to obtain accurate rotational constants and molecular structure for the formaldehyde molecule. One of the difficulties in the analysis of the spectra is the rather large effects of the centrifugal distortion. The treatment of the centrifugal distortion has been reported by several authors.[2a)2b)2c)6a)6b)6c)6d)] Hillger and Strandberg[2b)] and Kivelson and Wilson[6a)] proposed independently a convenient approximate formula for the centrifugal distortion of *K*-type doubling lines. The more accurate Kivelson and Wilson's first order treatment which was applied in the analysis of the spectra of SO_2 and O_3 was adopted in this report. The same trial was done by Erlandsson for the *K*-type doubling lines of H_2CO from K=1 to K=3.[7)] But the centrifugal distortion constants obtained by him can not be explained by the vibration-rotation interaction theory either.

---

* Present address; Department of Chemistry, Faculty of Science, University of Tokyo, Tokyo, Japan.

† Present address; Japan Atomic Energy Research Institute, Ibaraki, Japan.

In this report the reasonable centrifugal distortion constants calculated from the vibration-rotation interaction theory have been used in the calculation. The discussions about the molecular structure and the calculation of the vibration-rotation interaction quantities will appear in the second and the third part of this series, which will hereafter be referred to as II and III, respectively.

§2. Experimental

a. Sample

Well dried paraformaldehyde powder was heated slowly to evolve formaldehyde monomer. The spectra of $H_2C^{13}O$ and H_2CO^{18} species were measured with their natural abundances. The deuterated formaldehyde monomer was evolved by heating deuterated calcium formate with a sand bath. The deuterated calcium formate was prepared by the following procedure:

$$(COOH)_2 \xrightarrow{\text{deuteration}} (COOD)_2 \xrightarrow{\text{distillation}} DCOOD \xrightarrow{CaO} Ca(DCOO)_2 .$$

As the yield of formaldehyde monomer from the decomposition of calcium formate is not

high,[8] the formaldehyde was trapped by dry ice and was led to the sample cell.

b. Spectrograph

The microwave spectrometer used was of the conventional type with 100 kc sinusoidal Stark modulation. The klystrons which were used to cover from 2.8 kMc to 40 kMc were 723A, 2K22, 2K26, 7V40, 2K25, X-13, X-12, and 35V10. S, X, and K band wave guides were used for the absorption cell. The ultimate sensitivities for the spectrograph using these cells were about $1\times10^{-8}\,\mathrm{cm}^{-1}$, $3\times10^{-8}\,\mathrm{cm}^{-1}$ and 2×10^{-7}, respectively. In searching for the high J, K lines which were very weak by the Boltzmann factor, the wave guide was heated to increase the intensities of the spectral lines.

c. Observed Spectra

The observed K-type doubling lines are shown in Figs. 1~5 and Tables II~VI with their calculated intensities. As the statistical weight due to the nuclear spin is three times larger for the K=odd states than for the K=even states for H_2CO, the spectral lines for K=odd states are stronger. The situation is reversed in the case of D_2CO.

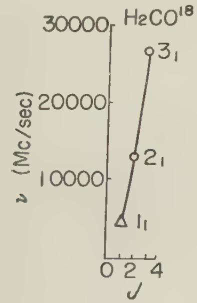

Fig. 5.

The calculation of the intensity was done by the use of the following formulas.

H_2CO

$$\begin{cases} K_{-1}\ \text{even} & \alpha=795\times10^{-14}\lambda\nu^2\exp(-E_{\mathrm{rot}}/kT) \\ K_{-1}\ \text{odd} & \alpha=2.39\times10^{-13}\lambda\nu^2\exp(-E_{\mathrm{rot}}/kT) \end{cases}$$

HDCO $\alpha=2.35\times10^{-13}\lambda\nu^2\exp(-E_{\mathrm{rot}}/kT)$

D_2CO

$$\begin{cases} K_{-1}\ \text{even} & \alpha=1.21\times10^{-13}\lambda\nu^2\exp(-E_{\mathrm{rot}}/kT) \\ K_{-1}\ \text{odd} & \alpha=6.05\times10^{-14}\lambda\nu^2\exp(-E_{\mathrm{rot}}/kT) \end{cases}$$

where λ is a line strength and ν is a frequency.

The intensities for the spectral lines of $H_2C^{13}O$ and H_2CO^{18} were derived by multiplying the corresponding lines of H_2CO with the natural abundance ratios of C^{13} and O^{18}, respectively.

§ 3. Centrifugal Distortion

One of the difficulties in the analysis of the spectrum of such a light molecule as formaldehyde is the effect of centrifugal distortion. The rotational Hamiltonian derived from the vibration-rotation interaction theory can be written to the second order of approximation as follows.[6a]

$$H=\frac{1}{2}\sum_{\alpha,\beta}\sigma_{\alpha\beta}P_\alpha P_\beta+\frac{1}{4}\sum_{\alpha,\beta,\gamma,\delta}\tau_{\alpha\beta\gamma\delta}P_\alpha P_\beta P_\gamma P_\delta \quad (1)$$

The first term is the rotational energy of the rotor averaged by the vibrational wave functions. The second term is the energy of the centrifugal distortion. The actual value for the coefficients $\tau_{\alpha\beta\gamma\delta}$ will be treated in III. It will be shown from symmetry consideration that many of these coefficients vanish. For a planar molecule with C_{2v} symmetry such as H_2CO and D_2CO, Eq. (1) can be reduced to the form

$$\begin{aligned} H=&\frac{1}{2}\sum_{\alpha}\sigma_{\alpha\alpha}P_\alpha^2+\frac{1}{4}\sum_{\alpha}\tau_{\alpha\alpha\alpha\alpha}P_\alpha{}^4 \\ &+\frac{1}{4}\sum_{\alpha\beta}\tau_{\alpha\alpha\beta\beta}(P_\alpha{}^2P_\beta{}^2+P_\beta{}^2P_\alpha{}^2) \\ &+\frac{1}{2}\tau_{xzxz}(P_x{}^2P_z{}^2+P_z{}^2P_x{}^2)\,. \end{aligned} \quad (2)$$

For a planar molecule with C_s symmetry such as HDCO, Eq. (1) becomes

$$\begin{aligned} H=&\frac{1}{2}\sum_{\alpha}\sigma_{\alpha\alpha}P_\alpha{}^2+\frac{1}{2}\sigma_{xz}(P_xP_z+P_zP_x) \\ &+\frac{1}{4}\sum_{\alpha}\tau_{\alpha\alpha\alpha\alpha}P_\alpha{}^4+\frac{1}{4}\sum_{\alpha,\beta}\tau_{\alpha\alpha\beta\beta}(P_\alpha{}^2P_\beta{}^2+P_\beta{}^2P_\alpha{}^2) \\ &+\frac{1}{2}\tau_{xzxz}(P_x{}^2P_z{}^2+P_z{}^2P_x{}^2) \\ &+\frac{1}{2}\sum_{\alpha,\beta,\gamma}\tau_{\alpha\alpha\beta\gamma}(P_\alpha{}^2P_\beta P_\gamma+P_\gamma P_\beta P_\alpha{}^2) \end{aligned} \quad (3)$$

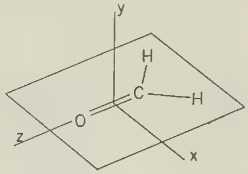

Fig. 6.

In these formulas the z axis is taken as the C_2 axis of symmetry and the y axis is taken perpendicular to the molecular plane as shown in Fig. 6.

Eq. (3) shows that the principal axes of inertia fixed to the equilibrium position of the particles are no longer the principal axes due to the vibration-rotation interaction. When the in-plane rotation of the molecule-fixed x, z axes by an angle $\theta=\sigma_{xz}/(\sigma_{xx}-\sigma_{zz})$ is carried out, the off-diagonal term quadratic in angular momentum operators is shown to be negligible to the second order of approximation. The last term in Eq. (3) has no diagonal elements for the equilibrium asymmetric rotor wave function and its effect is of the fourth order. Thus Eq. (3) takes the same form as Eq. (2) to the second order of approximation.

It is seen from the form of Eq. (2) that the rotational Hamiltonian accurate to the second order of approximation does not mix the Four group of the asymmetric rotor wave functions O$^{\pm}$, E$^{\pm}$. Thus for a low J, K levels Eq. (2) can be solved exactly. They are useful in discussing the low J, K transitions.

For high J, K levels the eigenvalues of the Eq. (2) can not easily be derived. Kivelson and Wilson devised a method to solve the problem by the first order perturbation theory,[6b)] that is, the last three terms in Eq. (2) are averaged by the asymmetric rotor wave functions which are derived from the first term of Eq. (2). This approximation is thought to be very good in the case of C_{2v} formaldehyde molecules because the second order perturbation which was neglected contains only the terms

$$\sum_{J,'K'}\frac{|\langle JK|H_{\mathrm{cent}},J'K'\rangle|^2}{W_{JK}-W_{J'K'}},$$

with $K'=K\pm 2$ and $K\pm 4$ for which the denominator will be very large.

The energy is written as follows[6a)]

$$W=W_0+A_1W_0^2+A_2W_0J(J+1)+A_3J^2(J+1)^2+A_4J(J+1)\langle P_z^2\rangle+A_5\langle P_z^4\rangle+A_6\langle P_z^2\rangle W_0 \quad (4)$$

where W_0 is the pure rotational energy and A_i's are related to the centrifugal distortion constants and rotational constants. $\langle P_z^2\rangle$ and $\langle P_z^4\rangle$ are the mean value of P_z^2 and P_z^4 respectively averaged by the asymmtric rotor wave functions. They are calculated by the method of continued fraction proposed by Kivelson and Wilson.[6b)] Among the seven centrifugal distortion constants appearing in Eq. (2), only four are independent in the case of a planar molecule because of the following relations

$$\begin{aligned}\tau_{yyyy}&=\frac{C^4}{B^4}\tau_{xxxx}+\frac{C^4}{A^4}\tau_{zzzz}+\frac{2C^4}{A^2B^2}\tau_{xxzz}\\ \tau_{xxyy}&=\frac{C^2}{B^2}\tau_{xxxx}+\frac{C^2}{A^2}\tau_{xxzz}\\ \tau_{yyzz}&=\frac{C^2}{A^2}\tau_{zzzz}+\frac{C^2}{B^2}\tau_{xxzz}\,.\end{aligned} \quad (5)$$

Thus the total energy can be expressed by ten quantities: three rotational constants, four centrifugal distortion constants and the three rotational quantum numbers. From Eq. (4) and Eq. (5), the frequencies for the K-type doubling spectral lines can be derived as

$$\nu=\nu_0+\tilde{\boldsymbol{\tau}}\boldsymbol{R}\boldsymbol{W} \quad (6)$$

with $\boldsymbol{\tau}=\begin{pmatrix}\tau_{xxxx}\\ \tau_{zzzz}\\ \tau_{zzxx}\\ \tau_{zxzx}\end{pmatrix}$ and $\boldsymbol{W}=\begin{pmatrix}J(J+1)\Delta W\\ (W_u+W_l)\Delta W\\ J(J+1)\Delta\langle P_z^2\rangle\\ \Delta\langle P_z^4\rangle\\ \Delta\{W\langle P_z^2\rangle\}\end{pmatrix}$

where Δ means the difference of the quantities in the upper state from that in the lower state and w denotes the eigenvalue $w(b)$ in the rotational energy expression

$$W_0=\frac{B+C}{2}J(J+1)+\left(A-\frac{B+C}{2}\right)w(b)\,. \quad (7)$$

$\boldsymbol{R}$ is a matrix of four rows and five columns whose elements are derived after tedious calculations, and are listed in Table I. In the derivation of the $\boldsymbol{R}$ matrix the relation

Table I. The **R** matrix

$-\frac{B^4-C^4}{8bB^4}$	$\frac{C^2(B+C)^2}{16A^2B^2b^2}$	$-\frac{AC(B^2+C^2)}{2B^4}$	$\frac{A^2C^2}{B^4}$	$\frac{C^2(B+C)}{2bB^3}$
$\frac{C^4}{8bA^4}$	$\frac{C^4}{16b^2A^4}$	$\frac{C^3}{2A^2B}$	$\frac{C^2}{B^2}$	$\frac{C^3}{2bA^2B}$
$\frac{C^4}{4bA^2B^2}$	$-\frac{C^3(B+C)}{8b^2A^3B}$	$\frac{C^2(B^2+2AC)}{2AB^3}$	$-\frac{2AC^2}{B^3}$	$-\frac{C^2(B+2C)}{2bAB^2}$
0	0	$\frac{1}{2}$	$-\frac{A^2}{B^2}$	$-\frac{1}{2b}$

$1/A+1/B=1/C$ was used. This relation is exact for the rotational constants appearing in Eq. (5) since they are equilibrium values, but only approximate for those in Eq. (4). The difference is of the second order and will be neglected in the present treatment. Less accurate formula for the K-type doubling lines proposed by Hillger and Strandberg and that by Kivelson and Wilson were useful in the first crude determination of the molecular constants and centrifugal distortion correction and is rewritten here.[2b)6b)]

$$\nu=\nu_0[1+T_1J(J+1)K+T_2(K-1)J(J+1)+T_3K(K^2+2)+T_4K(K-1)(2K-1)+T_5K(K^2-1)] . \qquad (8)$$

§ 4. Analysis of the Spectra

K-type doubling lines were analyzed by Eqs. (6) and (8). First, a rough determination of $A-(B+C)/2$ and the asymmetry parameter $b=(C-B)/(2A-B-C)$ was done by Eq. (8). Then the calculated values were refined by more precise calculation using Eq. (8). It was recognized that the dependences of the coefficients to be multiplied to τ_{xxxx}, τ_{xxzz}, and τ_{zzzz} on the rotational quantum numbers did not differ greatly from each other. By this fact it was given up to determine the centrifugal distortion constants from the observed spectra but rather it was tried to fit the calculated frequencies to the observed ones

with the smallest modification of the calculated centrifugal distortion constants.

The procedure employed in the analysis of the spectra was as follows:

i) Rotational energy tables were prepared by the use of the continued fraction method, around the probable values of the asymmetry parameters. The approximate value for the asymmetry parameter was obtained from the King, Hainer and Cross's table for low *J*, *K* transitions. Accurate calculations of eigenvalues were necessary because the trasitions between *K*-type doublets correspond to $\varDelta J=0$ and $\varDelta K=0$. The differences between the eigenvalues of the same *J*, *K* but the +and−matrices multiplied by a rather large quantity $A-(B+C)/2$ are observed directly. It was seen that a complete linearlity existed when the step of the asymmetry parameter was less than 0.00001 and $w(b)$ in Eq. (7) were calculated to ten figures. The digital parametron computer PC-1 was used throughout.

ii) B-C was calculated from the 1_1 and 2_1 lines by means of the exact formulas obtained by solving Eq. (2)

$$\nu_{1_1}=B-C+\frac{1}{4}(\tau_{xxxx}-\tau_{yyyy})+\frac{1}{2}(\tau_{xxzz}+2\tau_{xzxz}-\tau_{yyzz})$$

$$\nu_{2_1}=3(B-C)+\frac{15}{4}(\tau_{xxxx}-\tau_{yyyy})+\frac{3}{2}(\tau_{xxzz}+2\tau_{xzxz}-\tau_{yyzz})\,, \tag{9}$$

with the calculated centrifugal distortion constants and observed the frequencies.

iii) Probable value of the asymmetry parameter which could be obtained by the approximate formula Eq. (8) was assumed, and the rotational constants were determined either by the *R*-branch frequencies if available or by the calculated inertia defect.

iv) The elements of the **R** matrix and **W** vector in Eq. (6) were calculated by the digital computer PC-1 and the centrifugal distortion corrections were made by using the centrifugal distortion constants obtained from vibration-rotation theory.

v) The calculated centrifugal distortion correc-

tions were added to the rigid rotor frequencies and the discrepancy between the calculated and the observed frequencies was minimized by adjusting the asymmetry parameter and centrifugal distortion constants. The minimization was done by putting larger weights on the low J, K transitions because the neglect of higher order quantities will affect high J, K levels more than low J, K levels.

3_1	−15.79	26331.05	26330.64	0.59	1.6×10^{-7}

It was found that the observed frequencies could be made to fit well to the calculated ones by a small adjustment on τ_{xxxx}. The final results are shown in Table II∼VI. It is seen that the agreement is quite satisfactory in spite of the neglect of higher order quantities in the vibration-rotation interaction theory and the approximate equilibrium structure used in the calculation.

The rotational constants and the centrifugal distortion constants adopted for the analysis of the spectra are listed in Tables VII.

§ 5. Discussions

In Table VIII, $B-C$, $A-(B+C)/2$, and b obtained for H_2CO are compared with the previous values obtained by other workers. It will be seen that the difference between the Lawrance and Strandberg's or Erlandsson's data and the value obtained in the present work is beyond the experimental error. This is due to the difference in the estimation of the distortion corrections. For example, it is seen in Table II that the distortion correction in this paper for the 2_1 line of H_2CO is −7.71 Mc while theirs are −0.56 Mc and −0.57 Mc. As is seen from the Eq. (9) the centrifugal distortion correction for this frequency contains the term $3\tau_{zzzz}$ which can not be so small as was adopted by them. It can be said that the centrifugal distortions are made fairly well by less accurate centrifugal distortion constants. This is the reason why it was given up to determine the centrifugal distortion constants from the frequencies by the least-squares method. The situation is quite different from the cases of SO_2 and O_3. For these molecules the b-type transitions $\varDelta J=0$ or ± 1 and $\varDelta K=\pm 1$ are observed and τ_{zzzz} plays the most important role in determining

Erlandsson(7)	4829.7	245686	−0.009829
This work	4832.17±0.01	245610	−0.009837

the centrifugal distortion corrections.[6c)6d)] The centrifugal distortion formula for a symmetric top molecule can partly explain the correction for these molecules, while in the case of K-type doubling spectrum, the centrifugal distortion correction itself is the result of the K-type doubling of $\langle P_z^2\rangle$ and $\langle P_z^4\rangle$.

Many unassigned spectral lines have been observed. In the cases of HDCO and D_2CO, where the sample was evolved by heating the calcium formate, some of them are due to the impurities evolved in the decomposition. In the cases of H_2CO some of them were ascribed to the spectral lines of methanol which was produced in the decomposition of para-formaldehyde. Other numerous lines may be due to the vibrationally excited formaldehyde molecule. These lines will be measured hereafter by using a high temperature spectrograph.

§ 6. Acknowledgement

The authors are indebted to Mr. Akira Miyahara for his collaboration with us in the preliminary measurement of the spectra, and to Mr. Kunitaka Kondo for his help in some of the calculation.

They owe much to Prof. Yonezo Morino of the Department of Chemistry for his discussions and continued interest to this work.

They are also grateful to Prof. Hidetoshi Takahashi who allowed us to use the digital computer PC−1. Without the computer the tedious calculations of the rotational energy, $\langle P_z^2\rangle$, and $\langle P_z^4\rangle$ would have been impossible.

Microwave Spectrum of Formaldehyde
II. Molecular Structure in the Ground State

By Takeshi OKA*

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo, Japan

(Received, July 2, 1960)

Rotational constants for the isotopic formaldehyde molecules H_2CO, $H_2C^{13}O$, H_2CO^{18}, HDCO and D_2CO were determined from the parameters used in the analysis of K-type doubling spectra and the frequencies of $1_{01} \leftarrow 0_{00}$ transitions. In the cases of isotopic species for which the R-branch transitions were not measured, the calculated inertia defect was used in the determination of the rotational constants.

From the rotational constants, the zero-point structure of formaldehyde molecule, r_z, was determined by a new method taking into account the zero-point vibration-rotation interaction and electronic interaction. The following zero-point molecular structure was obtained;

$$r_{C-H} = 1.117_4 \pm 0.002\ \text{A}$$
$$\angle HCO = 122°5' \pm 20'$$
$$r_{C=O} = 1.206_3 \pm 0.002\ \text{A} \qquad \text{planar.}$$

All of the rotational constants calculated from these geometrical parameters fit to the observed values within the experimental error. In contrast to the previous researches, ∠HCO is much larger than 120°. It was also confirmed that the formaldehyde molecule is completely planar in the ground vibrational state.

§1. Introduction

Investigations on the structure of the formaldehyde molecule have been worked out by several workers.[1)2)3)4)5)] In 1934, Dieke and Kistiakowsky obtained two rotational constants from the analysis of the fine structure of ultraviolet spectrum.[1)] Their values were accurate and agreed very well with the Lawrance and Strandberg's values from microwave spectrum worked out 15 years later.[4)] Since three independent quantities are necessary to determine the molecular structure of formaldehyde on the assumption of C_{2v} planar structure, Dieke and Kistiakowsky assumed ∠HCH to be 110° and obtained C=O bond length to be 1.270 A. Herzberg assumed C−H bond length in formaldehyde to be equal to the value in ethylene, that is, 1.071 A and obtained $r_{C=O} = 1.225$A and $\angle HCH = 123°26'$.[3)] Lawrance and Strandberg analyzed the microwave spectrum of H_2CO and $H_2C^{13}O$ and obtained $r_{C=H} = 1.12 \pm 0.01$A, $r_{C-O} = 1.21 \pm 0.01$A and $\angle HCH = 118° \pm 1$.[4)] In 1954 Davidson, Stoicheff and Bernstein studied the fine structure of the vibration-rotation bands in infra-red and Raman spectra of HDCO and determined the structure of formaldehyde molecule with several assumptions.[5)] There is also an electron diffraction study by Stevenson, Luvalle and Schomaker which indicated the C=O distance to be 1.21±0.01 A.[2)]

By the use of the parameters from the extensive analysis of the H_2CO, $H_2C^{13}O$, H_2CO^{18}, HDCO and D_2CO in the first part of this series of reports on the microwave spectrum of formaldehyde, the accurate determination of molecular structure will be carried out in the present paper.

Usually the structure of a molecule is determined by fitting the calculated moments of inertia obtained by assumed structural constants to the observed ones. The structure thus obtained is the effective r_0 structure But the observed moments of inertia by no means give the exact inter-nuclear distances because they are affected by the zero-point vibration-rotation and electronic interaction The former effect is rather large in the case of light molecules such as formaldehyde and cannot be neglected in the accurate structural determination. If spectral lines of the molecu structuralle in the vibrationally excited states were observed sufficiently enough, this effect might be subtracted to give the equilibrium r_e structure. However this was impossible in the case of formaldehyde, and it was tried to obtain the zero point structure denoted by r_z, by subtracting from the observed moments of inertia the harmonic vibration-rotation interactions terms. These harmonic terms can be calculated when the normal vibration calculation is complete, and will be discussed in the third part of this series.

---

* Present address: Department of Chemistry, Faculty of Science, University of Tokyo, Tokyo, Japan.

The inertia defect is mainly due to these harmonic terms. Usually a molecule is said to be planar when the inertia defect $\Delta = I_{cc} - I_{bb} - I_{aa}$ is nearly equal to zero. But recently Costain and Dowling suggested the two N-H bonds in NH_2CHO to be 7° and 12° out of plane of the molecule though the inertia defect is nearly equal to zero.$^{6)}$ Strictly speaking, the planarity of a molecule can only be concluded after the calculation of the inertia defect. This was tested in the case of formaldehyde, and this molecule was actually shown to be planar.

The second interaction due to the bonding electrons must also be considered. Since the two π electrons protruding out of the plane of molecule and the two lone-pair electrons of oxygen atom are out of the C=O axis, the effect of these electrons was not negligible in determining the internuclear distances.

§ 2. Rotational Constants

The asymmetry parameter

$$b = \frac{C - B}{2A - B - C}$$

and $B - C$ have been obtained in I for H_2CO, $H_2C^{13}O$, HDCO and D_2CO. Another quantity is necessary to determine the rotational constants A, B, and C. The R-branch $1_{01} \leftarrow 0_{00}$ transitions which have the frequencies $B + C$ and appear in the millimeter wave region have been observed for $H_2CO^{4)}$ and $HDCO^{7)}$ as 72838.14 Mc and 64472.12 Mc, respectively, and the rotational constants of these isotopic species can be determined accurately. The centrifugal distortion correction adopted for these lines were −0.30 Mc and −0.38 Mc, respectively, which were calculated from the centrifugal distortion constants used in the analysis in I.

For $H_2C^{13}O$ and D_2CO, the R-branch transitions which would appear at 71027 Mc and 58473 Mc respectively, could not be measured. The calculated inertia defect was used to determine the rotational constants for these species. From the values of $A - C$, $B - C$ and calculated moments of inertia, the smallest rotational constant C can be determined as

$$C = \sqrt{(A - C)(B - C) - \frac{ABC\Delta \times 10^{-5}}{5.05531}}. \qquad (1)$$

The close agreement between the calculated and the observed inertia defect in the cases of H_2CO and HDCO indicates that the rotational constants determined in this way are fairly accurate. But the probable errors for B and C are larger in this case than those determined from the R-branch transition.

In the case of H_2CO^{18} for which only $B - C$ was obtained owing to the weakness of the spectrum, the largest rotational constant A was assumed to be equal to that of H_2CO. This assumption seems to be quite reasonable in view of the fact that A of H_2CO and $H_2C^{13}O$ are nearly equal. Thus the rotational constants and the effective moments of inertia for formaldehyde molecules were determined as listed in Table I. The observed inertia defects 0.0574 amu A² for H_2CO and 0.0679 amu A² for HDCO are seen to agree very well with the calculated values 0.0561 and

§ 3. Vibration-Rotation Interaction

Usually the structure of a molecule is determined directly from the effective moments of inertia obtained from the experiment. These structures are called zero point structure and are denoted by r_0. However this is not correct because of the vibration-rotation and electronic interaction. For this reason the r_0 structure may be called effective structure. Costain[8)] showed that the substituted bond length r_s devised by Kraitchman[9)] represent fairly well the equilibrium bond length. In the following treatment the molecular structure in the ground vibrational state will be searched for.

As was shown by Nielsen[10)], the rotational energy of a vibrating molecule is expressed as follows.

$$
\begin{aligned}
&\mathrm{H}=\mathrm{H}^{(0)}+\mathrm{H}^{(2)}\,,\\
&\mathrm{H}^{(0)}=\frac{1}{2}\sum_{\alpha}\frac{P^2{}_{\alpha}}{I^{(e)}_{\alpha\alpha}}\,,\\
&\mathrm{H}^{(2)}=\sum_{\alpha,\beta}\sum_{s}\Bigg[\frac{1}{4\pi}\sqrt{\frac{h}{c}}\left\{\frac{3k_{sss}}{\omega_s{}^{3/2}}a_s{}^{(\alpha\beta)}+\sum_{s'}{}'\frac{k_{sss'}}{\omega_{s'}{}^{3/2}}a_{s'}^{(\alpha\beta)}\right\}\\
&\qquad+\frac{h}{8\pi^2c}\left\{4\sum_{s'}{}'\frac{\omega_s}{\omega_s{}^2-\omega_{s'}{}^2}\zeta_{ss'}^{(\alpha)}\zeta_{ss'}^{(\beta)}-\frac{1}{\omega_s}\left(A_{ss}^{(\alpha\beta)}-\sum_{\xi}\frac{a_s{}^{(\alpha\xi)}a_s{}^{(\beta\xi)}}{I^{(e)}_{\xi\xi}}\right)\right\}\Bigg]\frac{P_\alpha P_\beta}{I^{(e)}_{\alpha\alpha}I^{(e)}_{\beta\beta}}\left(v_s+\frac{1}{2}\right)\\
&\qquad+\frac{1}{4}\sum_{\alpha,\beta,\gamma,\delta}\tau_{\alpha\beta\gamma\delta}P_\alpha P_\beta P_\gamma P_\delta\,. \qquad (2)
\end{aligned}
$$

Due to the perturbation Hamiltonian $\mathrm{H}^{(2)}$, the effective moments of inertia $(I_{\alpha\alpha})_{\mathrm{eff}}$ will differ from the equilibrium value $I^{(e)}_{\alpha\alpha}$. The terms in Eq. (2) can be interpreted as follows. The terms in $\mathrm{H}^{(0)}$ express the energy of the rotation of a molecule whose component atoms are at their equilibrium positions and are rotating with the molecule-fixed axes determined by the Eckart's condition. The five terms in the perturbation $\mathrm{H}^{(2)}$ are due to four kinds of effect. The first two which include the anharmonic potential constants k_{sss} and $k_{sss'}$ represent the variation in the rotational energy owing to the shift of the equilibrium position of the vibrating nuclei due to the anharmonicity of the potential. The third term represents the Coriolis interaction. When the nuclei are vibrating about their equilibrium positions, the molecule does not rotate smoothly due to the Coriolis interaction. Each nucleus vibrates back and forth about the molecule-fixed axes in a perpendicular direction to their intrinsic vibrational displacements. This situation can be understood if we consider a diatomic molecule vibrating in a stretching mode. Owing to the Coriolis interaction the nuclei vibrate in a perpendicular direction to the internuclear axis fixed by the Eckart's condition. This motion couples with other vibrations in the direction and when the vibrations are averaged out, the rotational energy differs slightly from the original value and gives the third term. The fourth term represents the mean square amplitude of vibration in the normal coordinate expansion of the moment of inertia. The fifth term comes from the shift of the equilibrium positions of nuclei due to the centrifugal distortion of the molecule. In the present analysis the fifth term has been considered separately as shown in I and the obtained moments of inertia includes the effect of the first four terms. *The first two terms represent the real shift of the equilibrium nuclear positions, while the latter two are only the result of averaging over the vibrations.* From the above physical interpretation all the harmonic vibration-rotation terms were subtracted from the effective moments of inertia to obtain the zero point molecular structure.

It was shown that the effective moments of inertia obtained from the rotational constants are expressed as[11)]

$$
\begin{aligned}
(I_{\alpha\alpha})_{\mathrm{eff}}=I^{(e)}_{\alpha\alpha}-\sum_{s}\left(v_s+\frac{1}{2}\right)\Bigg[&\frac{1}{2\pi}\sqrt{\frac{h}{c}}\left\{\frac{3k_{sss}}{\omega_s{}^{3/2}}a_s{}^{(\alpha\alpha)}+\sum_{s'}{}'\frac{k_{sss'}}{\omega_{s'}{}^{3/2}}a_{s'}{}^{(\alpha\alpha)}\right\}\\
&+\frac{h}{\pi^2c}\left\{\sum_{s'}{}'\frac{\omega_{s'}{}^2}{\omega_s(\omega_s{}^2-\omega_{s'}{}^2)}(\zeta_{ss'}^{(\alpha)})^2+\frac{3}{4}\frac{A_{ss}^{(\alpha\alpha)}}{\omega_s}\right\}\Bigg]-\frac{h^3}{8\pi^2}C_\alpha\tau_{zzzz}I^2_{\alpha\alpha} \qquad (3)
\end{aligned}
$$

with

$$C_x = C_z = -2\ , \quad C_y = 3\ .$$

In deriving the above expression from Eq. (2), the relation

$$\sum_{\xi} \frac{a_s{}^{(\alpha\xi)} a_s{}^{(\beta\xi)}}{I_{\xi\xi}^{(e)}} = -4 \sum_{s'} \varphi_{ss'}^{(\alpha)} \varphi_{ss'}^{(\beta)} + 4A_{ss}^{(\alpha\beta)}$$

was used.[11] The last term in Eq. (3) came from these centrifugal distortion terms which was reduced to quadratic form in angular momentum operators by the commutation relation. The harmonic terms in Eq. (3) was obtained by the calculation of the vibration-rotation interaction.

§ 4. Electronic Interaction

Usually it is assumed in the calculation of the moments of inertia that all electrons are fixed at the positions of nuclei. This is not actually the case and in such a light molecule as formaldehyde which has a double bond, this effect is by no means negligible.

The effect of electrons in a molecule on the value of the moments of inertia has been considered by Johnson and Strandberg[12] and by Rosenblum, Nethercot and Townes[13] in the cases of H_2CCO and CO, respectively. It was shown by Johnson and Strandberg that the rotational Hamiltonian, taking into account the motion of electrons, is written as

$$H = \frac{1}{2} \sum \sum [I^n + I^e]_{ij}^{-1} P_i P_j + \frac{mv}{e} \sum_i \sum_j G_{ij} \frac{P_i P_j}{I_i^n}\ . \tag{4}$$

where $[I^n]$ is the moments of inertia tensor of nuclear system and $[I^e]$ is the inertia tensor of the electrons about the nuclear axes. $[I^n + I^e]$ is the usual inertia tensor calculated on the assumption that the electrons are fixed at the nuclei. The error introduced by assuming the nuclear axes to be the atomic axes is negligibly small. G_{ij}'s in Eq. (4) are related to the g tensor of the rotational magnetic moments as

$$\frac{2v}{e} M_p G_{ij} = g_{ij}$$

where g_{ij} are components of the familiar g tensor of the rotational magnetic moments and are measured by microwave Zeeman effect. In the case of a molecule with C_{2v} symmetry, the off-diagonal elements of I^e tensor and g tensor vanish from the symmetry. Even for the case of HDCO where C_{2v} symmetry does not exist, the off-diagonal terms in these tensors can safely be neglected because they are of the second order quantity. Then from the Eq. (4) the variation of the moments of inertia ΔI_{ii} due to the electronic interaction can be written as

$$\Delta I_{ii} = \frac{m I_{ii}}{M_p} g_{ii}\ . \tag{5}$$

The same formula can be obtained by the extension of the formulation given by Rosenblum et al for the case of a diatomic molecule to the case of an asymmetric rotor. The neglect of $\sum_i m_i r_i^2$ they did is unnecessary.

The value of g tensor for H_2CO, HDCO, and D_2CO have been obtained by Kondo et al and is listed in Table II.[14]

Table II. g-values of formaldehyde molecule.[14]

Molecules	g_{aa}	g_{bb}	g_{cc}
H_2CO	-2.90 ± 0.05	-0.35 ± 0.10	-0.02 ± 0.10
HDCO	-2.00 ± 0.05	-0.32 ± 0.10	-0.02 ± 0.10
D_2CO	-1.46 ± 0.05	-0.29 ± 0.10	-0.02 ± 0.10

Johnson and Strandberg reported in their paper on H_2CCO, that the largest of this correction was ΔI_{aa} which still was negligible. Since the data of Zeeman effect was absent for the molecule, they estimated g_{aa} to be $+0.48$ by taking only the σ bonding electrons in the C-H bond into acount. However this seems to be smaller than the actual value. As is seen from Table II, g_{aa} of formaldehyde molecule is very large. The same situation exists in the case of CO molecule where g_{bb} is also very large in view of the relatively large moment of inertia perpendicular to the CO axis. Both of them are interpreted by taking into account of the two π electrons on the CO bond and in the case of H_2CO two lone-pair electrons on the oxygen atom.[14]

§ 5. Molecular Structure

The zero-point moments of inertia and the effect of zero-point vibration and electronic interaction are listed in Table III. Since the rotational constants are more accurate for H_2CO and HDCO than those for other isotopic species, it was not tried to make a least-squares-fit. The difference between the C—H bond and C—D bond was taken into account.

First, H···H and D···D distances were

determined from the smallest moments of inertia of H_2CO and D_2CO. The CO distance was determined from several sets.

H_2CO, $H_2C^{13}O$ ······ $1.206_3 \pm 0.002$ A
H_2CO, H_2CO^{18} ······ $1.201_1 \pm 0.005$ A
H_2CO, D_2CO ······ $1.204_9 \pm 0.001$ A
(C−H=C−D assumed)

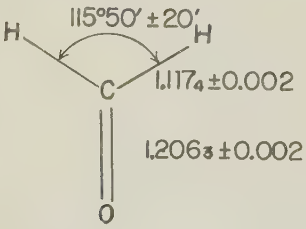

Fig. 1. Molecular structure of formaldehyde.

From these values the first set was adopted and C−H and C−D distances and HCO and DCO angles were taken as independent quantities. The final molecular structure thus determined is denoted by r_z and is shown in Fig. 1. The moments of inertia calculated from these values are listed in Table III. The satisfactory agreement of the calculated values with the observed ones for all the moments of inertia shows that this molecule is completely planar. For the purpose of comparison the effective molecular structure r_0 which was obtained from the effective moments of inertia with the neglect of the difference between C−H and C−D bonds, and the substituted molecular structure r_s obtained by the Costain's method are also listed in Table IV. It is seen that the values of bond distances decrease in the order $r_z > r_0 > r_s$. This is reasonable because the substituted bond length is nearer to the equilibrium value while the molecular structure obtained in this report is of the zero point value.

§6. Discussions

The structure of formaldehyde molecule has been discussed by several authors. The structures previously obtained are listed in Table IV with the present values. It will be pointed out that HCO angle is fairly larger than 120°.

HCO angles in other compounds possessing HCO group are listed in Table V. For most of them ∠HCO's are larger than 120°C.

Torkington explained the Herzberg's value where HCO angle is less than 120° considering the H^+CHO^- resonating structure.[15] This explanation is not compatible with the present result. The Urey-Bradly type potential constants used by Miyazawa in the normal vibration calculation of formaldehyde showed that the force between the two hydrogen atoms was negligible, and rather large van der Waals repulsive force exists between the non-bonded hydrogen and oxygen atoms.[16] This force will explain the fact that HCO angle in formaldehyde is larger than 120°. In ethylene molecule where also CCH angle is larger than 120°, the deviation from 120° is less than that of formaldehyde. (∠HCH=11.76±0.5°[17]). This agrees with the result of normal vibration calculation in which the repulsive force between the non-bonded carbon and hydrogen atoms was shown to be smaller because of the larger interatomic separation. Recently the structure of ethylene was determined by Bartell and Bonham by means of electron diffraction study in which they reported the angle HCH to be 115.5±0.6°[18]. The fact that ClCO angle in phosgene molecure is 124.3° can also be explained from this point of view.[19]

Theory of Non-linear Responses

By Osamu NAKADA
Hitachi Central Research Laboratory
Kokubunji, Tokyo

(Received August, 23, 1960)

A phenomenological equation for a non-linear response to a time-dependent excitation is presented. The response function is expressed as a series of multiple integrals containing the excitation, where the first term corresponds to Boltzmann's linear superposition term. The non-linearity of an excitation-response system can be characterized, according to our formulation, by higher order after-effect functions. Associated equations including Fourier representations and the inversion formulae are derived. The generalized Kramers-Kronig relations between the real and imaginary parts of Fourier transforms of higher order after-effect functions are also derived. Applications of the theory to sinusoidal and step function-like excitations, especially with exponential after-effect functions, are discussed in detail.

§ 1. Introduction

The phenomena of retarded non-linear responses to time-dependent external excitations are commonly found in various fields of physics and engineering. Electric currents in some kinds of circuits manifest such non-linear characteristics. The other conspicuous examples are found in the viscoelasticity of high polymeric substance, especially in the deformation of filamentous or crystalline polymers.[1)]

The phenomenological theory of the stationary linear response is well established on the basis of Boltzmann's superposition principle.[2)] [11)] But the corresponding general treatment of the stationary non-linear response seems to be lacking, though Leaderman[3)], Burte and Halsey[4)], Sawaragi and Tokumaru[5)] and other investigator proposed several specialized models in order to explain non-linear viscoelasticity phenomena. Yamamoto[6)] and Segawa[7)] discussed the non-linearity of viscoelasticity on the basis of a three-dimensional Maxwell or Voigt models. Recently Saito[8)] suggested a possibility of generalization of Boltzmann's equation up to higher order terms of excitations.

On the other hand the non-linearity introduces also serious problems in the treatment of the automatic control where the linear response theory has usually been most effectively applied.[9)] The conventional describing function method fails in treating the non-linear transients.

In the following we derive a general expression for the non-linear responses to time-dependent excitations.

§ 2. Series Expansion of the Response Function

We denote the excitation by $\sigma(t)$, and the resulting response by $\varepsilon(t)$. We will express by $\phi_n(t)\,(n=1, 2, \cdots)$ a series of complete normalized orthogonal functions defined in $\{-\infty<t<+\infty\}$, and expand $\sigma(t)$ and $\varepsilon(t)$ by means of $\phi_n(t)$:

$$\sigma(t)=\sum_{i\ 1}^{\infty} a_i\phi_i(t)\ , \tag{1}$$

$$\varepsilon(t)=\sum_{i=1}^{\infty} b_i\phi_i(t)\ . \tag{2}$$

The expansion coefficients a_i and b_i are given, according to the definition of $\phi_n(t)$, by

$$a_i=\int_{-\infty}^{\infty} \sigma(t)\bar{\phi}_i(t)dt\ , \tag{3}$$

$$b_i=\int_{-\infty}^{\infty} \varepsilon(t)\bar{\phi}_i(t)dt\ , \tag{4}$$

where $\bar{\phi}_i(t)$ means the complex conjugate of $\phi_i(t)$. Now we will make following assumptions.

ASSUMPTION I. The excitation is not preceded by the response. (Causality)

ASSUMPTION II. Each of orthogonal expansion coefficients b_i's of the response function $\varepsilon(t)$, defined by Eq. (4), can be expanded in Taylor series of orthogonal expansion coefficient a_i's of the excitation function $\sigma(t)$, defined by Eq. (3). (Convergence)

THEOREM I. If Assumptions I and II are satisfied in the excitation and the response, the response function $\varepsilon(t)$ can be expressed as either

$$\varepsilon(t)=\int_{-\infty}^{\infty}\sigma(t_1)J_1(t,t_1)dt_1+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t_1)\sigma(t_2)J_2(t,t_1,t_2)dt_1dt_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t_1)\sigma(t_2)\sigma(t_3)J_3(t,t_1,t_2,t_3)dt_1dt_2dt_3+\cdots, \tag{5}$$

or

$$\varepsilon(t)=\int_{-\infty}^{\infty}\sigma(t-\tau_1)J_1(t,\tau_1)d\tau_1+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t-\tau_1)\sigma(t-\tau_2)J_2(t,\tau_1,\tau_2)d\tau_1d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t-\tau_1)\sigma(t-\tau_2)\sigma(t-\tau_3)J_3(t,\tau_1,\tau_2,\tau_3)d\tau_1d\tau_2d\tau_3+\cdots. \tag{5'}$$

Here $J_n(t,t_1,t_2,\cdots,t_n)$'s or $J_n(t,\tau_1,\tau_2,\cdots,\tau_n)$'s are characteristic after-effect function (or weighting functions) of the excitation-response system, and they are restricted by the condition:

$$J_n(t,t_1,t_2,\cdots,t_n)=0 \qquad \text{when any } t_i>t\,, \tag{6}$$
$$J_n(t,\tau_1,\tau_2,\cdots,\tau_n)=0 \qquad \text{when any } \tau_i<0\,. \tag{6'}$$

PROOF: As the response $\varepsilon(t)$ is completely determined once given the excitation $\sigma(t)$ in the range of $-\infty<t<\infty$, each b_i should be a unique function of the set of a_i's. Recalling here Assumption II, we will expand each b_i in Taylor series of a_i's:

$$b_i(a_1,a_2,\cdots)=b_i(0,0,\cdots)+\sum_{j=1}^{\infty}\gamma_j{}^i a_j+\sum_{j,k=1}^{\infty}\gamma^i_{j,k}a_ja_k+\sum_{j,k,l=1}^{\infty}\gamma^i_{j,k,l}a_ja_ka_l+\cdots, \tag{7}$$

where

$$\begin{aligned}\gamma_j{}^i&=[\partial b_i/\partial a_j]_{a_j=0}\,,\\ \gamma^i_{j,k}&=\tfrac{1}{2}[\partial^2 b_i/\partial a_j\partial a_k]_{a_j,a_k=0}\,,\\ \gamma^i_{j,k,l}&=\tfrac{1}{6}[\partial^3 b_i/\partial a_j\partial a_k\partial a_l]_{a_j,a_k,a_l=0}\,.\end{aligned} \tag{8}$$

Substitution of Eqs. (7) and (3) into Eq. (2) leads, after interchanging the operations of integral and summation, to Eq. (5) with

$$\begin{aligned}J_1(t,t_1)&=\sum_{i,j=1}^{\infty}\gamma_j{}^i\phi_i(t)\bar{\phi}_j(t_1)\,,\\ J_2(t,t_1,t_2)&=\sum_{i,j,k=1}^{\infty}\gamma^i_{j,k}\phi_i(t)\bar{\phi}_j(t_1)\bar{\phi}_k(t_2)\,,\\ J_3(t,t_1,t_2,t_3)&=\sum_{i,j,k,l=1}^{\infty}\gamma^i_{j,k,l}\phi_i(t)\bar{\phi}_j(t_1)\bar{\phi}_k(t_2)\bar{\phi}_l(t_3)\,,\end{aligned} \tag{9}$$

$J_n(t,t_1,t_2,\cdots,t_n)$ means the weight factor for the simultaneous contributions from excitations at $t_1,t_2,\cdots,t_n$ to the response at t. Hence, in order to obey the law of causality (i.e. Assumption I), it should satisfy the condition (6). Changing the variables to $\tau_n=t-t_n$ in Eqs. (5) and (6), we obtain Eqs. (5′) and (6′). (Q. E. D.)

If we take account of Eqs. (6) or (6′), we can put upper limits of integrals in Eq. (5) or lower limits of integrals in Eq. (5′) equal to zero.

Next we consider the stationary response system.

ASSUMPTION III. If the response $\varepsilon(t)\equiv\varepsilon_1(t)$ occurs against the excitation $\sigma(t)=\sigma_1(t)$, the response $\varepsilon(t)\equiv\varepsilon_1(t-s)$ should occur against the excitation $\sigma(t)\equiv\sigma_1(t-s)$ for an arbitrary s. (Stationariness)

THEOREM II. If Assumption III as well as Assumptions I and II are satisfied, the response $\varepsilon(t)$ can be expressed as

$$\varepsilon(t)=\int_{-\infty}^{\infty}\sigma(t-\tau_1)J_1(\tau_1)d\tau_1+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t-\tau_1)\sigma(t-\tau_2)J_2(\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t-\tau_1)\sigma(t-\tau_2)\sigma(t-\tau_3)J_2(\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots\,, \tag{10}$$

where

$$J_n(\tau_1,\tau_2,\cdots,\tau_n)=0 \quad \text{when any} \quad \tau_i<0\,. \tag{11}$$

PROOF: The response $\varepsilon_1(t)$ to the excitation $\sigma_1(t)$ is, by Eq. (5′), written as

$$\varepsilon_1(t)=\int_{\infty}^{\infty}\sigma_1(t-\tau_1)\,J_1(t,\tau_1)dt_1+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma_1(t-\tau_1)\sigma_1(t-\tau_2)J_2(t,\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma(t-\tau_1)\sigma(t-\tau_2)\sigma(t-\tau_3)J_3(t,\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots\,. \tag{12}$$

Similarly the response for the excitation $\sigma_1(t-s)$ is given by

$$\varepsilon(t)=\int_{-\infty}^{\infty}\sigma_1(t-s-\tau_1)J_1(t,\tau_1)d\tau_1+\int_{-\infty}^{\infty}\int_{\infty}^{\infty}\sigma_1(t-s-\tau_1)\sigma_1(t-s-\tau_2)J_2(t,\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma_1(t-s-\tau_1)\sigma_1(t-s-\tau_2)\sigma_1(t-s-\tau_3)J_3(t,\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots\,. \tag{13}$$

According to Assumption III, the right-hand side of Eq. (13) should be equal to $\varepsilon_1(t-s)$, which is given from Eq. (12) by

$$\varepsilon_1(t-s)=\int_{-\infty}^{\infty}\sigma_1(t-s-\tau_1)\,J_1(t-s,\tau_1)d\tau_1+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma_1(t-s-\tau_1)\sigma(t-s-\tau_2)J_2(t-s,\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma_1(t-s-\tau_1)\sigma_1(t-s-\tau_2)\sigma_1(t-s-\tau_3)J_3(t-s,\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots\,. \tag{14}$$

Comparing term by term in the right-hand sides of Eqs. (13) and (14), we get

$$\begin{aligned} &J_1(t,\tau_1)\equiv J_1(t-s,\tau_1)\,,\\ &J_2(t,\tau_1,\tau_2)\equiv J_2(t-s,\tau_1,\tau_2)\,,\\ &J_3(t.\,\tau_1,\tau_2,\tau_3)\equiv J_3(t-s,\tau_1,\tau_2,\tau_3)\,, \end{aligned} \tag{15}$$

for arbitrary value of s. This means that $J_1, J_2, J_3, \cdots$ should not depend on t:

$$\begin{aligned} &J_1(t,\tau_1)\equiv J_1(\tau_1)\,,\\ &J_2(t,\tau_1,\tau_2)\equiv J_2(\tau_1,\tau_2)\,,\\ &J_3(t,\tau_1,\tau_2,\tau_3)\equiv J_3(\tau_1,\tau_2,\tau_3)\,. \end{aligned} \tag{16}$$

Substituting Eq. (16) to Eqs. (5′) and (6′) we get Eqs. (10) and (11). (Q. E. D.)

Lower limits of integrals in Eq. (10) can be put equal to zero according to Eq. (11). Eq. (10) gives a general relation between the excitation and the response in a stationary response system. If we neglect all higher terms in Eq. (10) it reduces to the wellknown Boltzmann's equation in the linear viscoelasticity. The higher order terms mean the multi-dimensional superposition of the simultaneous effect of excitations at past many instant. So Eq. (10) can be regarded as a natural generalization of Boltzmann's superposition principle, and the functions J_n may be called the n th order after-effect function (or weighting function).

Further if we can assume the response to be odd with respect to the excitation, i.e., if the response $-\varepsilon(t)$ is to occur against the excitation $-\sigma(t)$, the even order terms in Eq. (10) vanish.

By integrating Eq. (10) by parts, assuming $\sigma(-\infty)=0$, we obtain

$$\varepsilon(t)=\int_{-\infty}^{\infty}\sigma'(t-\tau_1)K_1(\tau_1)d\tau_1+\int_{\infty}^{\infty}\int_{-\infty}^{\infty}\sigma'(t-\tau_1)\sigma'(t-\tau_2)K_2(\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\sigma'(t-\tau_1)\sigma'(t-\tau_2)\sigma'(t-\tau_3)K_3(\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots, \tag{17}$$

where

$$K_1(\tau_1)=\int_{-\infty}^{\tau_1}J_1(\tau_1')d\tau_1',$$
$$K_2(\tau_1,\tau_2)=\int_{-\infty}^{\tau_1}\int_{-\infty}^{\tau_2}J_2(\tau_1',\tau_2')d\tau_2'd\tau_1, \tag{18}$$
$$K_3(\tau_1,\tau_2,\tau_3)=\int_{-\infty}^{\tau_1}\int_{-\infty}^{\tau_2}\int_{-\infty}^{\tau_3}J_3(\tau_1',\tau_2',\tau_3')d\tau_3'd\tau_2'd\tau_1'.$$

§ 3. Fourier Representation

Hereafter we will deal only with the stationary response system.

We will define the Fourier transforms $\bar{\sigma}(\omega)$, $\bar{\varepsilon}(\omega)$, $\bar{J}_1(\omega_1)$, $\bar{J}_2(\omega_1, \omega_2)$, etc. by

$$\bar{\sigma}(\omega)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\sigma(t)e^{-i\omega t}dt,$$
$$\bar{\varepsilon}(\omega)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\varepsilon(t)e^{-i\omega t}dt,$$
$$\bar{J}_1(\omega_1)=\int_{-\infty}^{\infty}J_1(\tau_1)e^{-i\omega_1\tau_1}d\tau_1, \tag{19}$$
$$\bar{J}_2(\omega_1,\omega_2)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}J_2(\tau_1,\tau_2)e^{-(i\omega_1\tau_1+i\omega_2\tau_2)}d\tau_1 d\tau_2,$$
$$\bar{J}_3(\omega_1,\omega_2,\omega_3)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}J_3(\tau_1,\tau_2,\tau_3)e^{-(i\omega_1\tau_1+i\omega_2\tau_2+i\omega_3\tau_3)}d\tau_1 d\tau_2 d\tau_3.$$

Then, starting from Eq. (10) and making use of the relations

$$\int_{-\infty}^{\infty}\delta(t)e^{-i\omega t}dt=1, \tag{20}$$
$$\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{-i\omega t}d\omega=\delta(t), \tag{20'}$$

we get

$$\bar{\varepsilon}(\omega)=\bar{\sigma}(\omega)\bar{J}_1(\omega)+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\bar{\sigma}(\omega_1)\bar{\sigma}(\omega_2)\bar{J}_2(\omega_1,\omega_2)\delta(\omega_1+\omega_2-\omega)d\omega_1 d\omega_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\bar{\sigma}(\omega_1)\bar{\sigma}(\omega_2)\bar{\sigma}(\omega_3)\bar{J}_3(\omega_1,\omega_2,\omega_3)\delta(\omega_1+\omega_2+\omega_3-\omega)d\omega_1 d\omega_2 d\omega_3+\cdots. \tag{21}$$

§ 4. Inversion Formulae

So far we regarded the quantity $\sigma(t)$ as the excitation and the quantity $\varepsilon(t)$ as the response. But depending on experimental condition we may as well observe $\sigma(t)$ as the response to the given excitation $\varepsilon(t)$. For this case we need only to interchange $\sigma(t)$ and $\varepsilon(t)$ in the above treatment. To avoid the confusion we will denote by $G_n(\tau_1, \tau_2, \cdots, \tau_n)$ the n th order after-effect function in the response $\sigma(t)$ to the excitation $\varepsilon(t)$. Fourier transform $\bar{G}_n$ is defined similarly as $\bar{J}_n$. The equations corresponding to Eqs. (10) and (21) are

$$\sigma(t)=\int_{-\infty}^{\infty}\varepsilon(t-\tau_1)G_1(\tau_1)d\tau_1+\int_{\infty}^{\infty}\int_{-\infty}^{\infty}\varepsilon(t-\tau_1)\varepsilon(t-\tau_2)G_2(\tau_1,\tau_2)d\tau_1 d\tau_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\varepsilon(t-\tau_1)\varepsilon(t-\tau_1)\varepsilon(t-\tau_3)G_3(\tau_1,\tau_2,\tau_3)d\tau_1 d\tau_2 d\tau_3+\cdots, \tag{22}$$

$$\bar{\sigma}(\omega)=\bar{\varepsilon}(\omega)\bar{G}_1(\omega)+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\bar{\varepsilon}(\omega_1)\bar{\varepsilon}(\omega_2)\bar{G}_2(\omega_1,\,\omega_2)\delta(\omega_1+\omega_2-\omega)d\omega_1d\omega_2$$
$$+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\bar{\varepsilon}(\omega_1)\bar{\varepsilon}(\omega_2)\bar{\varepsilon}(\omega_3)\bar{G}_3(\omega_1,\,\omega_2,\,\omega_3)\delta(\omega_1+\omega_2+\omega_3-\omega)d\omega_1d\omega_2d\omega_3+\cdots\,. \tag{23}$$

Substituting Eq. (23) into the right-hand side of Eq. (21), collecting the same order terms of $\bar{\varepsilon}(\omega)$, and comparing the both sides, we obtain the following inversion formulae.

$$\begin{aligned}
&\bar{G}_1(\omega)=1/\bar{J}_1(\omega)\,,\\
&\bar{G}_2(\omega_1,\,\omega_2)=-\bar{J}_2(\omega_1,\,\omega_2)/\bar{J}(\omega_1)\bar{J}(\omega_2)\bar{J}_1(\omega_1+\omega_2)\,,\\
&\bar{G}_3(\omega_1,\,\omega_2,\,\omega_3)=\left[\bar{J}_3(\omega_1,\,\omega_2,\,\omega_3)+\frac{2}{3}\sum_{\substack{(i,j,k)\\ \text{cyclic}}}\frac{J_2(\omega_i,\,\omega_j+\omega_k)\bar{J}_2(\omega_j+\omega_k)}{\bar{J}_1(\omega_j+\omega_k)}\right]\\
&\qquad\div\bar{J}_1(w_1)\bar{J}_1(\omega_2)\bar{J}_1(\omega_3)\bar{J}_1(\omega_1+\omega_2+\omega_3)\,.
\end{aligned} \tag{24}$$

§ 5. Kramers-Kroning relations

We will separate the real and imaginary parts of $\bar{J}_n(\omega_1,\,\omega_2,\,\cdots,\,\omega_n)$ defined by Eq. (19) as follows:

$$\bar{J}_n(\omega_1,\,\cdots,\,\omega_n)=\bar{J}_n'(\omega_1,\,\cdots,\,\omega_n)-i\bar{J}_n''(w_1,\,\cdots,\,\omega_n)\,. \tag{25}$$

Then, as is well-known, $\bar{J}_1'$ and $\bar{J}_1''$ are connected each other by the Kramers-Kronig relations[10 11]:

$$\bar{J}_1'(\omega)=\frac{2\omega}{\pi}\mathscr{P}\int_0^{\infty}\frac{J_1''(\omega')}{\omega'^2-\omega^2}d\omega'\,, \tag{26}$$

$$\bar{J}_1''(\omega)=-\frac{2}{\pi}\mathscr{P}\int_0^{\infty}\frac{\omega'\bar{J}_1(\omega)}{\omega'^2-\omega^2}d\omega'\,, \tag{27}$$

where $\mathscr{P}$ means to take Cauchy's principal value of integral. Taking account of the symmetry character of J_1' and $\bar{J}_1''$ we can either express the relations as

$$\bar{J}_1'(\omega)=\frac{1}{\pi}\mathscr{P}\int_{-\infty}^{\infty}\frac{\bar{J}_1''(\omega')}{\omega'-\omega}d\omega'\,, \tag{28}$$

$$\bar{J}_1''(\omega)=-\frac{1}{\pi}\mathscr{P}\int_{-\infty}^{\infty}\frac{\bar{J}_1'(\omega')}{\omega'-\omega}d\omega'\,. \tag{29}$$

These relations can be regarded as the consequences of the causality assumption, which postulates that the after-effect function $J_1(\tau)$ has non-vanishing values only in the range $0<\tau$. The situation is just similar for higher order functions $\bar{J}_2(\omega_1,\,\omega_2)$, $\bar{J}_3(\omega_1,\,\omega_2,\,\omega_3)$, $\cdots$ as for $\bar{J}_1(\omega)$, the causality being expressed by Eq. (11). Thus it will be possible to generalize the Kramers-Kronig relations to those higher order functions.

Now we begin with $\bar{J}_2(\omega_1,\,\omega_2)$. Referring to Eq. (19) and also to the causality relations (11) we can express $\bar{J}_2'$ and $\bar{J}_2''$ as

$$\bar{J}_2'(\omega_1,\,\omega_2)=\frac{1}{\sqrt{2\pi}}\int_0^{\infty}\int_0^{\infty}J_2(\tau_1,\,\tau_2)\cos(\omega_1\tau_1+\omega_2\tau_2)d\tau_1d\tau_2\,, \tag{30}$$

$$\bar{J}_2''(\omega_1,\,\omega_2)=\frac{1}{\sqrt{2\pi}}\int_0^{\infty}\int_0^{\infty}J_2(\tau_1,\,\tau_2)\sin(\omega_1\tau_1+\omega_2\tau_2)d\tau_1d\tau_2\,, \tag{31}$$

or

$$\bar{J}_2'(\omega_1,\,\omega_2)=\bar{J}_{cc}(\omega_1,\,\omega_2)-\bar{J}_{ss}(\omega_1,\,\omega_2)\,, \tag{32}$$

$$\bar{J}_2''(\omega_1,\,\omega_2)=\bar{J}_{sc}(\omega_1,\,\omega_2)+\bar{J}_{cs}(\omega_1,\,\omega_2)\,, \tag{33}$$

where

$$\bar{J}_{cc}(\omega_1, \omega_2)=\frac{1}{\sqrt{2\pi}}\int_0^\infty\int_0^\infty J_2(\tau_1, \tau_2)\cos\omega_1\tau_1\cos\omega_2\tau_2 d\tau_1 d\tau_2\ ,$$
$$\bar{J}_{sc}(\omega_1, \omega_2)=\frac{1}{\sqrt{2\pi}}\int_0^\infty\int_0^\infty J_2(\tau_1, \tau_2)\sin\omega_1\tau_1\cos\omega_1\tau_1 d\tau_1 d\tau_2\ , \quad \text{etc.}; \tag{34}$$

We apply the inverse Fourier transformation to $J_2(\tau_1,\tau_2)$ appearing in the integrand in the right-hand side of Eq. (32). Then

$$\bar{J}_2'=\frac{1}{\sqrt{2\pi}}\left(\frac{\pi}{2}\right)^2\int_0^\infty\cdots\int_0^\infty J_{sc}(\omega_1', \omega_2')\sin\omega_1'\tau_1'\cos\omega_2'\tau_2'\cos\omega_1\tau_1\cos\omega_2\tau_2 d\omega_1' d\omega_2' d\tau_1 d\tau_2$$
$$-\frac{1}{\sqrt{2\pi}}\left(\frac{2}{\pi}\right)^2\int_0^\infty\cdots\int_0^\infty J_{cs}(\omega_1', \omega_2')\cos\omega_1'\tau_1'\sin\omega_2'\tau_2'\sin\omega_1\tau_1\sin\omega_2\tau_2 d\omega_1' d\omega_2' d\tau_1 d\tau_2\ . \tag{35}$$

Integrating with respect to τ_1 and τ_2 we get

$$\bar{J}_2'(\omega_1, \omega_2)=\frac{1}{\sqrt{2\pi}}\cdot\frac{2}{\pi}\mathscr{P}\int_0^\infty J_{sc}(\omega_1', \omega_2)\frac{\omega_1'}{\omega_1'^2-\omega_1^2}d\omega_1'$$
$$+\frac{1}{\sqrt{2\pi}}\cdot\frac{2}{\pi}\mathscr{P}\int_0^\infty J_{cs}(\omega_1', \omega_2)\frac{\omega_1}{\omega_1'^2-\omega_1^2}d\omega_1'\ . \tag{36}$$

By the symmetry characters of $\bar{J}_{sc}$ and $\bar{J}_{cs}$

$$\bar{J}_2'(\omega_1, \omega_2)=\frac{1}{\sqrt{2\pi}}\cdot\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_{sc}(\omega_1', \omega_2)\frac{\omega_1'}{\omega_1'^2-\omega_1^2}d\omega_1'$$
$$+\frac{1}{\sqrt{2\pi}}\cdot\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_{cs}(\omega_1', \omega_2)\frac{\omega_1}{\omega_1'^2-\omega_1^2}d\omega_1'\ , \tag{36'}$$

and also by the symmetry we can easily verify

$$\frac{1}{\sqrt{2\pi}}\cdot\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_{sc}(\omega_1', \omega_2)\frac{\omega_1}{\omega_1'^2-\omega_1^2}d\omega_1'=0\ ,$$
$$\frac{1}{\sqrt{2\pi}}\cdot\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_{cs}(\omega_1', \omega_2)\frac{\omega_1'}{\omega_1'^2-\omega_1^2}d\omega_1'=0\ . \tag{37}$$

Adding Eqs. (36′) and (37) we get

$$\bar{J}_2'(\omega_1, \omega_2)=\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty \bar{J}_2''(\omega_1, \omega_2)\frac{1}{\omega_1'-\omega_1}d\omega_1'\ . \tag{38}$$

Since $\bar{J}_2'(\omega_1, \omega_2)$ should be a symmetric function with respect to ω_1 and ω_2 we have also the relation

$$\bar{J}_2'(\omega_1, \omega_2)=\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty \bar{J}_2''(\omega_1, \omega_2)\frac{1}{\omega_2'-\omega_2}d\omega_2'\ . \tag{38'}$$

In the similar manner we can derive the inverse relation

$$\bar{J}_2''(\omega_1, \omega_2)=-\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_1'(\omega_1', \omega_2)\frac{1}{\omega_1'-\omega_1}d\omega_1'=-\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty J_1'(\omega_1, \omega_2')\frac{1}{\omega_2'-\omega_2}d\omega_2'\ . \tag{39}$$

It is easy, though tedious, to extend the above treatment to higher order functions. Thus we get the generalized Kramers-Kronig relations

$$\bar{J}_n'(\omega_1, \cdots, \omega_n)=\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty \bar{J}_n''(\omega_1, \cdots, \omega_i', \cdots, \omega_n)\frac{1}{\omega_i'-\omega_i}d\omega_i'\ , \tag{40}$$

$$\bar{J}_n''(\omega_1, \cdots, \omega_n)=-\frac{1}{\pi}\mathscr{P}\int_{-\infty}^\infty \bar{J}_1'(\omega_1, \cdots, \omega_i', \cdots, \omega_n)\frac{1}{\omega_i'-\omega_i}d\omega_i'\ . \tag{41}$$

It is seen that Eqs. (38)–(41) as well as Eqs. (27) and (28) have just the similar forms which are known as Hilbert transforms in the theory of complex variable.[12] Though we derived the generalized Kramers-Kronig relations according to an elementary method, we may either prove them directly from the regularity of the complex function $\bar{J}_n(z_1, \cdots, z_n)$ in the right half plane of each z_i.[11-13]

It should be noted that the relations corresponding to Eqs. (25) and (26) do not hold for $\bar{J}_n(\omega_1, \cdots, \omega_n)$ for $n>1$. In fact, Eqs. (25) and (26) are equivalent to Eqs. (27) and (28) only as the consequence of the fact that $\bar{J}_1'(\omega)$ and $\bar{J}_1''(\omega)$ are odd and even functions of ω respectively while J_n' or J_n'' for $n > 1$ are neither odd nor even functions with respect to each of ω_i's does not hold for higher order functions with respect to each independent ω_i.

§ 6. Applications

i) Sinusoidal excitation

When the excitation is given by

$$\sigma(t)=\sigma_0 \cos \omega t\ , \tag{42}$$

the resulting response $\varepsilon(t)$ is calculated by substitution of Eq. (25) to Eq. (10) as follows:

$$\begin{aligned}\varepsilon(t)=\sigma_0[A_1 \cos \omega t+A_2 \sin \omega t]+\sigma_0^2[B_1 \cos 2\omega t+B_2 \sin 2\omega t+B_3]\\ +\sigma_0^3[C_1 \cos 3\omega t+C_2 \sin 3\omega t+C_3 \cos \omega t+C_4 \sin \omega t]+\cdots\ ,\end{aligned} \tag{43}$$

where

$$\begin{aligned}A_1&=\bar{J}_1'(\omega)\ ,\\ A_2&=\bar{J}_1''(\omega)\ ,\\ B_1&=\sqrt{\frac{\pi}{2}}\,\bar{J}_2'(\omega, \omega)\ ,\\ B_2&=\sqrt{\frac{\pi}{2}}\,\bar{J}_2''(\omega, \omega)\ ,\\ B_3&=\sqrt{\frac{\pi}{2}}\,\bar{J}_2'(\omega, -\omega)\ ,\\ C_1&=\frac{\pi}{2}\bar{J}_3'(\omega, \omega, \omega)\ ,\\ C_2&=\frac{\pi}{2}\bar{J}_3''(\omega, \omega, \omega)\ ,\\ C_3&=\frac{3\pi}{2}\bar{J}_3'(\omega, \omega, -\omega)\ ,\\ C_4&=\frac{3\pi}{3}\bar{J}_3''(\omega, \omega, -\omega)\ .\end{aligned} \tag{44}$$

The energy dissipation per one cycle Q is calculated as

$$\begin{aligned}Q=\int_{\text{one cycle}} \sigma d\varepsilon=\int_{\text{one cycle}} \sigma\frac{d\varepsilon}{dt}\, dt=\int_{\text{one cycle}} \sigma_0 \cos \omega t[\omega\sigma_0(-A_1 \sin \omega t+A_2 \cos \omega t)\\ +2\omega\sigma_0^2(-B_1 \sin 2\omega t+B_2 \cos 2\omega t)+3\omega\sigma_0^3(-C_1 \sin 3\omega t+C_2 \cos 3\omega t\\ -C_3 \sin \omega t+C_4 \cos \omega t)]dt=\pi(\sigma_0^2 A_2+3\sigma_0^4 C_2)\ .\end{aligned} \tag{45}$$

ii) *Step function-like excitation*

a) One step excitation

When we substitute

$$\sigma=\begin{cases}0\ , & t<0\ ,\\ \sigma_0\ , & t\geq 0\ ,\end{cases} \tag{46}$$

into Eq. (10) we get

$$\varepsilon(t)=\sigma_0 K_1(t)+\sigma_0^2 K_2(t, t)+\sigma_0^3 K_3(t, t, t)+\cdots\ . \tag{47}$$

This case corresponds to the creep process in the viscoelasticity phenomena. Then K_i mean the ith order creep function.

b) Two steps excitation

For the two steps excitation

$$\sigma=\begin{cases}0\,, & t<0\,,\\ \sigma_1\,, & 0\leq t<t_1\\ \sigma_1+\sigma_2\,, & t_1\leq t\,,\end{cases} \tag{48}$$

we obtain

$$\begin{aligned}\varepsilon(t)=&\sigma_1K_1(t)+\sigma_2K_1(t-t_1)+\sigma_1{}^2K_2(t,t)\\ &+2\sigma_1\sigma_2K_2(t,t-t_1)+\sigma_2{}^2K_2(t-t_1,t-t_1)\\ &+\sigma_1{}^3K_3(t,t,t)+3\sigma_1{}^2\sigma_2K_3(t,t,t-t_1)\\ &+3\sigma_1\sigma_2{}^2K_3(t,t-t_1,t-t_1)\\ &+\sigma_2{}^3K_3(t-t_1,t-t_1,t-t_1)\,.\end{aligned} \tag{49}$$

If we put $\sigma_1=-\sigma_2\equiv\sigma_0$ in Eq. (49), we obtain a recovery process following a creep,

$$\begin{aligned}\varepsilon(t)=&\sigma_0K_1(t)-\sigma_0K_1(t-t_1)+\sigma_0{}^2K_2(t,t)\\ &-2\sigma_0{}^2K_2(t,t-t_1)+\sigma_0{}^2K_2(t-t_1,t-t_1)\\ &+\sigma_0{}^2K_3(t,t,t)-3\sigma_0{}^3K_3(t,t,t-t_1)\\ &+3\sigma_0{}^3K_3(t,t-t_1,t-t_1)\\ &-\sigma_0{}^3K_3(t-t_1,t-t_1,t-t_1)+\cdots\,.\end{aligned} \tag{50}$$

Subtracting Eq. (50) from Eq. (47) and putting $t-t_1=s$, we get the recovery function $\varepsilon_r(s)$:

$$\begin{aligned}\varepsilon_r(s)=&\sigma_0K_1(s)+2\sigma_0{}^2K_2(s+\Delta t,s)-\sigma_0{}^2K_2(s,s)\\ &+3\sigma_0{}^3K_3(s+\Delta t,s+\Delta t,s)\\ &-3\sigma_0{}^3K_3(s+\Delta t,s,s)+\sigma_0{}^3K_3(s,s,s)\cdots\,,\end{aligned} \tag{51}$$

where $\Delta t\equiv t_1$. In the case of an odd response Eq. (51) reduces to

$$\begin{aligned}\varepsilon_r(s)=&\sigma_0K_1(s)+\sigma_0{}^3K_3(s,s,s)\\ &+[3\sigma_0{}^3\{K_3(s+\Delta t,s+\Delta t,s)\\ &-K_3(s+\Delta t,s,s)\}]+\cdots\,.\end{aligned} \tag{52}$$

§ 7. After-effect Functions

According to the treatment hitherto made, the non-linearity of an excitation-response system is characterized by the higher order after-effect functions $J_2, J_3, \cdots$ just as much as the linear response is characterized by the first order after-effect function J_1. So the experimental determination of the higher order after-effect functions becomes an important problem in order to describe the non-linear character in a compact way. Though a number of methods, rigorous or approximate, for the determination of J_1 have been proposed, the rigorous determination of the higher order functions seems to be rather troublesome, unless some limitations for their functional forms are introduced.

As the most simple and convenient approximation for J_1 the exponential function is commonly used. Generalizing this approximation to the higher order function we will tentatively assume

$$\begin{aligned}&J_1(\tau_1)=k_1e^{-\tau_1/T_1}\,,\\ &J_2(\tau_1,\tau_2)=k_2e^{-\tau_1/T_2}e^{-\tau_2/T_2}\,,\\ &J_3(\tau_1,\tau_2,\tau_3)=k_3e^{-\tau_1/T_3}e^{-\tau_2/T_3}e^{-\tau_3/T_3}\,.\end{aligned} \tag{53}$$

Then the following responses result for the sinusoidal and step function-like excitation.

i) *Sinusoidal excitation*

When the excitation is given by Eq. (42), $\bar{J}_1{}'$, $\bar{J}_1{}''$, $\bar{J}_2{}'$, $\cdots$ etc. in Eq. (44) are calculated as

$$\begin{aligned}&A_1=k_1T_1/(1+\omega^2T_1{}^2)\,,\\ &A_2=k_1\omega T_1{}^2/(1+\omega^2T_1{}^2)\,,\\ &B_1=k_2T_2{}^2(1-\omega^2T_2{}^2)/2(1+\omega^2T_2{}^2)^2\,,\\ &B_2=k_2\omega T_2{}^3/(1+\omega^2T_2{}^2)^2\,,\\ &B_3=k_2T_2{}^2/(1+\omega^2T_2{}^2)^2\,,\\ &C_1=k_3T_3{}^3(1-3\omega^2T_3{}^2)/4(1+\omega^2T_3{}^2)^3\,,\\ &C_2=k_3T_3{}^3(3\omega T_3-\omega^3T_3{}^3)/4(1+\omega^2T_3{}^2)^3\,,\\ &C_3=3k_3T_3{}^3/4(1+\omega^2T_3{}^2)^3\,,\\ &C_4=3k_3\omega T_3{}^4/4(1+\omega^2T_2{}^2)^2\,.\end{aligned} \tag{54}$$

ii) *One step excitation*

For the one step excitation (Eq. (29)), the integrated after-effect functions $K_1, K_2, K_3\cdots$ are given by

$$\begin{aligned}&K_1(t)=k_1T_1(1-e^{-t/T_1})\,,\\ &K_2(t,t)=k_2T_2{}^2(1-e^{-t/T_2})^2\,,\\ &K_3(t,t,t)=k_3T_3{}^2(1-e^{-t/T_3})^3\,.\end{aligned} \tag{55}$$

§ 8. Discussion

We derived the formula (10) starting from three assumptions of causality, convergence and stationariness. Among them the assumption of causality is self-evident and will be needless to discuss about it. The assumption of stationariness is needed for the after-effect functions to be independent on the absolute time. The formula (5) without the assumption of stationariness is more general than Eq. (10), but will be less convenient in actual applications. The assumption of the convergence of the series (7) will be the most essential in our formulation. It takes place of the assumption of the superposition in the linear theory of Boltzmann. Though it is much less stringent than the superposition assumption, it will still restrict severely the applicability of the theory. The existence of the subharmonic mode in the non-linear vibration, for instance, can not be proved by our treatment it will possibly correspond to a certain singular point of the function $b_i(a_1, a_2, \cdots)$.

Finally we will mention a property of the recovery function. In the recovery function (35) in an antisymmetric response, the terms in [ ] mean the deviation of the recovery function from the creep function. The absolute value of K_3 will monotonically increase with the increase of parameters, so that if K_3 is positive definite the deviation will be also positive and if K_3 is negative the deviation will also be negative. This property is confirmed partly, at least, by Leaderman's experiments on non-linear creep and recovery of rubbers.[3)]

Our theory is also applicable to an analytical treatment of non-linear automatic feedback control system, on which we shall discuss in a later report.

Acknowledgment

The author would like to express his sincere thanks to Professor N. Saito of Waseda University and K. Okano of Institute of Physical and Chemical Research for their valuable suggestions and kind discussions on the present subject. He is also grateful heartily to Dr. H. Kitagawa, Dr. M. Fukumura, Dr. S. Kawamatsu and many colleagues in his laboratory for their kind interest and encouragement throughout this work.

Theory of Electrochemical Diodes

By Isao OSHIDA

Kobayashi Institute of Physical Research,
Kokubunzi, Tokyo

(Received June 6, 1960)

The electric behaviour of electrochemical diodes, consisting of a pair of indifferent electrodes immersed in an electrolytic solution being capable of reversible oxidation-reduction, was investigated theoretically. The general current-voltage relation was obtained by solving the differential equation of diffusion of ions with the proper boundary conditions. The non-ohmic property, the shunting effect for rapidly changing voltage and the rectifying action were deduced.

§ Introduction.

Accompanied with the recent advance in the field of electronics, some attempts to use the element with electrolytic solution in electric circuits have appeared. Thus electrochemical diodes[1)2)], transistors[3)], switches[4)], and so on have been devised. In this paper, the electric behaviours of the electrochemical diodes were deduced theoretically on the ground of the equation of diffusion of ions. Similar treatment has appeared in the theory of polarography^5). However, in the case of polarography, the dimensions of the electrodes are extremely different, one being a small drop of mercury and the other a comparatively large unpolarizable electrode, and in the theoretical approach the latter is regarded as an infinitely large electrode at infinity. In the case of the electro-chemical diodes or triodes, such a treatment is not allowed. Mainly concerning a pair of similar electrodes, the equation of ionic diffusion could be solved. The general current-voltage behaviour was deduced, which shows the nonohmic saturation property and the shunting effect for rapidly changing voltage. The case of dissimilar electrodes was considered for those having cylindrical symmetry, which proved to show the rectifying character.

§ 2. Comparison of Ionic Diffusion and Translation.

An electrochemical diode with a pair of parallel-plate electrodes is the easiest for theoretical treatment, if the distance between the electrodes is so small that the convection of the solution is suppressed and that the end-effect can be neglected. Such a condition is realized, for example, by the clearance of a few tenths of a millimeter or less for the electrodes of ordinary dimension of a few centimeters. In such a narrow space, the diffusion of ion always surpasses the translational motion. On application of Einstein's formula for Brownian motion for the diffusion of ion,

$$\tau_1 = \frac{\lambda^2}{2D},$$

where D and λ are the coefficent of diffusion and the distance between the electrodes, respectively, the mean time interval τ_1 necessary for an ion to go across the gap λ can be estimated. On the other hand, if the electric field F exists between the electrodes, the time necessary for an ion to translate from an electrode to the other is

$$\tau_2 = \frac{\lambda}{BF},$$

where B is the mobility of the ion. If $\tau_2 \ll \tau_1$ the ion travels from one electrode to the other mainly by translation before the diffusion takes place in a sensible degree. On the other hand, when $\tau_1 \ll \tau_2$, an ion travels between the electrodes chiefly by diffusion. When

$$\lambda = \lambda_m = \frac{2D}{BF},$$

the both effects become to be of the same magnitude. If we put tentative values $D = 10^{-5}$ cm^2. sec^{-2}, $B = 5 \times 10^{-4}$ cm. volt^{-1}. sec^{-1} and $F = 1$ volt. cm^{-1}, λ_m becomes 0.4mm. Then it may be said that for a far smaller gap λ the diffusion predominates over the translation. This is the case which will be studied in the following.

§ 3. A Parallel-Plate Diode. The Fundamental Equation.

A pair of electrodes, parallel conductive plates, are immersed in an electrolytic solution executing oxidation and reduction completely reversibly. It is assumed that the exchange of electrons at the electrodes is very rapid and can be considered to be instantaneous. In practice, an aqueous solution of iodine and potassium iodide is used, in which the iodide ions I^- and triiodide ions I_3^- composed of I_2 and I^- are present. At the cathode, a reducing reaction

$$I_3 + 2e \rightarrow 3I^-$$

takes place, while at the anode an oxidizing reaction

$$3I^- - 2e \rightarrow I_3^-$$

occurs.

Here the more general cases are considered, in which the reduced species R and the oxidized species O can be transformed into one from the other by the exchange of n electrons:

$$O + ne \rightarrow R$$

$$R - ne \rightarrow O$$

Interesting properties are observed only when the concentration of one of the molecular species, the reduced or the oxidized, is very small compared to the other. So

$$C_O \ll C_R \qquad (1)$$

is assumed, where C_R and C_O are the concentrations of the reduced and the oxidized species respectively. The conclusions obtained are to be used also for the contrary case such as $C_R \ll C_O$ *mutatis mutandis.*

The diffusions of the both ionic species obey the equations

$$\frac{\partial C_R}{\partial t}=D_R\frac{\partial^2 C_R}{\partial x^2} \tag{2a}$$

$$\frac{\partial C_O}{\partial t}=D_O\frac{\partial^2 C_O}{\partial x^2} \tag{2b}$$

respectively. D_R and D_O are the coefficients of diffusion of both species and x is the coordinate. The cathode and the anode are located at $x=0$ and $x=L$, respectively, and accordingly L is the interval of the both electrodes.

There are two differential equations of second order, and accordingly there should be four boundary conditions. In the first place, there is no generation or cancellation of matter at the electrodes,

$$D_R\left(\frac{\partial C_R}{\partial x}\right)_{x=0}+D_O\left(\frac{\partial C_O}{\partial x}\right)_{x=0}=0, \tag{3a}$$

$$D_R\left(\frac{\partial C_R}{\partial x}\right)_{x=L}+D_O\left(\frac{\partial C_O}{\partial x}\right)_{x=L}=0. \tag{3b}$$

Secondly the anodic current,

$$i=nFAD_O\left(\frac{\partial C_O}{\partial x}\right)_{x=L}=-nFAD_R\left(\frac{\partial C_R}{\partial x}\right)_{x=L}, \tag{4a}$$

and the cathodic current,

$$i=nFAD_O\left(\frac{\partial C_O}{\partial x}\right)_{x=0}=-nFAD_R\left(\frac{\partial C_R}{\partial x}\right)_{x=0}, \tag{4b}$$

must be equal owing to the conservation of electric charge. Here F is Faraday's constant and A the area of the electrode. From (4a) and (4b), we have

$$\left(\frac{\partial C_O}{\partial x}\right)_{x=L}-\left(\frac{\partial C_O}{\partial x}\right)_{x=0}=0 \tag{5a}$$

$$\left(\frac{\partial C_R}{\partial x}\right)_{x=L}-\left(\frac{\partial C_R}{\partial x}\right)_{x=0}=0 \tag{5b}$$

(3a), (3b), (5a) and (5b) furnish only three boundary conditions, not four, because these equations are not independent of each other but one of them can be derived from the other three. The last condition is obtainable from Nernst's formula connecting the electrode potential E and the concentration C. Applying Nernst's equation to the both electrodes, we have

$$E_{x=0}=E^0+\frac{RT}{nF}\ln\frac{f_O C_O(0,t)}{f_R C_R(0,t)}, \tag{6a}$$

$$E_{x=L}=E^0+\frac{RT}{nF}\ln\frac{f_O C_O(L,t)}{f_R C_R(L,t)}, \tag{6b}$$

where E^0 means the standard electrode potential of the redox system, R the gas constant, T absolute temperature, and f_R and f_O the activity coefficients of the reduced and the oxidized forms in the solution respectively. Since the difference $E_{x=L}-E_{x=0}$ should be equal to the voltage V applied between the two electrodes, we get

$$\frac{RT}{nF}\left\{\ln\frac{f_O C_O(L,t)}{f_R C_R(L,t)}-\ln\frac{f_O C_O(0,t)}{f_R C_R(0,t)}\right\}=V,$$

or, assuming for the sake of simplicity $f_O=f_R=1$,

$$\frac{C_O(L,t)}{C_R(L,t)}\Big/\frac{C_O(0,t)}{C_R(0,t)}=\exp\left(\frac{nFV}{RT}\right). \tag{7}$$

Besides these boundary conditions, there are the initial conditions:

$$C_R=C_R^0 \tag{8a}$$

$$C_O=C_O^0 \tag{8b}$$

where C_R^0 and C_O^0 denote the initial stoichiometric concentration of the reduced and the oxidized ionic species respectively.

Introducing the assumption

$$D_R=D_O=D \tag{9}$$

to make the problem easy to handle, (3a) and (3b) become

$$\left(\frac{\partial C_R}{\partial x}\right)_{x=0}+\left(\frac{\partial C_O}{\partial x}\right)_{x=0}=0 \tag{10a}$$

$$\left(\frac{\partial C_R}{\partial x}\right)_{x=L}+\left(\frac{\partial C_O}{\partial x}\right)_{x=L}=0 \tag{10b}$$

respectively.

§ 4. The Steady State.

For steady state under a constant potential V, $\partial C/\partial t=0$ and, from (2a) and (2b), C_R and C_O should be linear function of x;

$$C_R=A_R x+B_R \tag{11a}$$

$$C_O=A_O x+B_O \tag{11b}$$

The initial conditions (8a) and (8b) are unnecessary in this case, but in place of them there should be the other conditions that the stoichiometric total amounts of the reduced and the oxidized species must be conserved as a whole after the steady state is build up. These conditions are

$$\int_0^L C_R dx=C_R^0 L \tag{12a}$$

and

$$\int_0^L C_O dx=C_O^0 L \tag{12b}$$

where C_R^0 and C_O^0 are the initial stoichometric concentrations of the both species respectively. The four constants A_R, B_R, A_O and B_O in (11a) and (11b) are determined by the four conditions (7), (10a), (12a) and (12b), thereby (5a), (5b) and (10b) are satisfied automatically.

The equation determining the coefficient A_O is

$$A_O^2-\frac{C_O^0+C_O^0}{L}\coth\frac{nFV}{2RT}\cdot A_O+\frac{C_O^0C_R^0}{L^2}=0 \quad (13)$$

which leads to

$$A_O=\frac{C_O^0+C_R^0}{2L}\coth\frac{nFV}{2RT}\cdot\left[1\pm\left\{1-\frac{4\,C_O^0C_R^0}{(C_O^0+C_R^0)^2}\tanh^2\frac{nFV}{2RT}\right\}^{\frac{1}{2}}\right]. \quad (14)$$

The lower sign should be chosen, because $V=0$ corresponds to the homogeneous concentration $A=0$.

Taking into consideration that

$$C_O^0\ll C_R^0 \quad (15)$$

and ignoring the small terms higher than the second power of C_O^0/C_R^0, we obtain

$$A_O=\frac{C_O^0}{L}\tanh\frac{nFV}{2RT}. \quad (16)$$

Then the concentration of the oxidized species is given by

$$C_O=\frac{C_O^0x}{L}\tanh\frac{nFV}{2RT}+C_O^0\left(1-\frac{1}{2}\tanh\frac{nFV}{2RT}\right). \quad (17)$$

The expression of the current i versus voltage V can be obtained from substitution of (17) in (4a) or (4b), that is

$$i=\frac{nFAD_OC_O^0}{L}\tanh\frac{nFV}{2RT}. \quad (18)$$

This is shown in Fig. 1, the dimensionless voltage V/V_0 being taken as the abscissa, where $V_0=2RT/nF$, and the dimensionless current i/i_0 as the ordinate, i_0 being $nFAD_O \times C_O^0/L$.

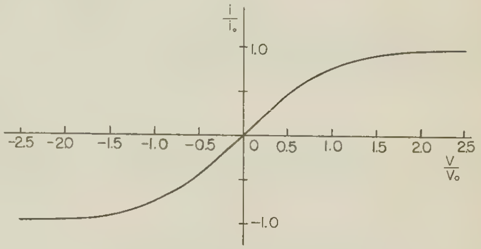

Fig. 1.

§ 5. The Indicial Admittance.

In this section, the case of suddenly applied constant voltage;

$$V=0 \text{ if } t<0,$$
$$V=V_0 \text{ (constant) if } t>0, \quad (19)$$

is studied. In this case, it is convenient to consider the deviation in the concentration from that of the steady state given by (17). Thus the quantity

$$\gamma=C_O-\bar{C}_O \quad (20)$$

is introduced, where $\bar{C}_O$ represents the steady-state C_O given by (17). For this γ, the boundary conditions are

$$(\gamma)_{x=0}=(\gamma)_{x=L}=0, \quad (21)$$

and the initial condition

$$(\gamma)_{t=0}=(C_O)_{t=0}-\bar{C}_O=C_O^0-\bar{C}_O=C_O^0\left(\frac{1}{2}-\frac{x}{L}\right)\tanh\frac{nFV}{2RT}. \quad (22)$$

γ satisfies also the equation of diffusion

$$\frac{\partial\gamma}{\partial t}=D\frac{\partial^2\gamma}{\partial x^2}. \quad (23)$$

To solve (23) under the conditions (21) and (22) is the typical problem occurring in the theory of heat conduction⁶⁾. The result is

$$\gamma=\frac{C_O^0}{\pi}\tanh\frac{nFV}{2RT}\cdot\sum_{s=1}^{\infty}\frac{1}{s}\exp\left(-\frac{4s^2\pi^2Dt}{L}\right)\cdot\sin\frac{2s\pi x}{L}, \quad (24)$$

and accordingly

$$C_O=C_O^0+C_O^0\tanh\frac{nFV}{2RT}\left[\frac{x}{L}-\frac{1}{2}+\frac{1}{\pi}\sum_{s=1}^{\infty}\frac{1}{s}\exp\left(-\frac{4s^2\pi^2Dt}{L^2}\right)\cdot\sin\frac{2s\pi x}{L}\right], \quad (25)$$

from which the current i is obtainable as a function of V and t, thus

$$i=\frac{nFAD_0C_0{}^0}{L}\tanh\frac{nFV}{2RT}\cdot\left[1+2\sum_{s=1}^{\infty}\exp\left(-\frac{4s^2\pi^2Dt}{L^2}\right)\right]. \tag{26}$$

Since the infinite series in the brackets is known as Jacobi's theta function, (26) can be written as

$$i=\frac{nFAD_0C_0{}^0}{L}\tanh\frac{nFV}{2RT}\cdot\vartheta_3\left(0\,\middle|\,\frac{4\pi iDt}{L^2}\right). \tag{27}$$

Introducing the quantities

$$\xi=\frac{4\pi Dt}{L^2}, \tag{28}$$

$$i_0=\frac{nFADC_0{}^0}{L}\tanh\frac{nFV}{2RT}, \tag{29}$$

the equation (27) can be written as

$$i=i_0\vartheta_3(0\mid i\xi)=i_0[1+2\sum_{s=1}^{\infty}\exp(-S^2\pi\xi)]. \tag{30}$$

Applying Jacobi's imaginary transformation

$$\vartheta_3(v\mid\tau)=\frac{\sqrt{i}}{\sqrt{\tau}}\exp\left(-\frac{v^2\pi i}{\tau}\right)\cdot\vartheta_3\left(\frac{v}{\tau}\,\middle|\,-\frac{1}{\tau}\right)$$

to (30); we obtain

$$i=\frac{i_0}{\sqrt{\xi}}\left[1+2\sum_{s=1}^{\infty}\exp(-s^2\pi/\xi)\right], \tag{31}$$

which is convenient for small t. The current-time relation calculated from (30) and (31) is shown in Fig. 2.

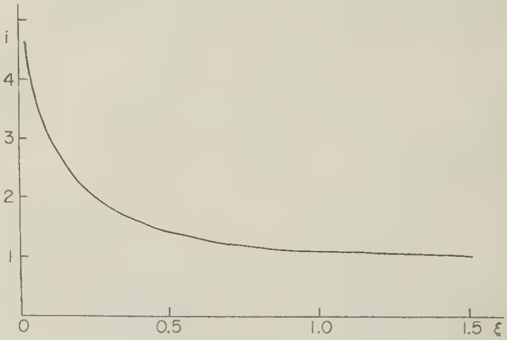

Fig. 2.

§6. The General Time-dependent Voltage.

Now the most general case in which the applied voltage V is any function $f(t)$ time,

$$V=0 \text{ if } t<0, \qquad V=f(t) \text{ if } t>0, \tag{32}$$

is considered. If V were a constant, the concentrations at the electrodes would be

$$(C)_{x=0}=C_0{}^0\left(1-\frac{1}{2}\tanh\frac{nFV}{2RT}\right), \qquad (C)_{x=L}=C_0{}^0\left(1+\frac{1}{2}\tanh\frac{nFV}{2RT}\right). \tag{33}$$

Since V is a function of time, we may put

$$\frac{C_0{}^0}{2}\tanh\frac{nFf(t)}{2RT}=g(t), \tag{34}$$

and

$$C-C_0{}^0=\varphi \tag{35}$$

and then the problem is reduced to finding the solution of

$$\frac{\partial \varphi}{\partial t} = D \frac{\partial^2 \varphi}{\partial x^2}\,, \tag{36}$$

which satisfies the time-dependent boundary conditions

$$\varphi = 0 \text{ all over, if } t<0,$$
$$(\varphi)_{x=0} = -g(t), \text{ if } t>0.$$
$$(\varphi)_{x=L} = g(t).$$

The solution is, after the case of heat conduction,

$$\begin{aligned}\varphi &= -\frac{8D\pi}{L^2}\sum_{s=1}^{\infty}\exp\left(-\frac{4s^2\pi^2 Dt}{L^2}\right)\sin\frac{2s\pi x}{L}\int_0^t g(\lambda)\exp\left(\frac{4s^2\pi^2 Dt}{L^2}\right)d\lambda \\ &= -\frac{4\pi D C_0{}^0}{L^2}\sum_{s=1}^{\infty} S\exp\left(-\frac{4s^2\pi^2 Dt}{L}\right)\sin\frac{2s\pi x}{L}\int_0^t \exp\left(\frac{4s^2\pi^2 D\lambda}{L^2}\right)\tan\mathrm{h}\,\frac{nFf(\lambda)}{2RT}d\lambda\,. \end{aligned}\tag{37}$$

The corresponding current is

$$i(t) = -\frac{8n\pi^2 FAD^2 C_0}{L^3}\sum_{s=1}^{\infty} s^2\exp\left(-\frac{4s^2\pi^2 Dt}{L^2}\right)\int_0^t \exp\left(\frac{4s^2\pi^2 D\lambda}{L^2}\right)\tan\mathrm{h}\,\frac{nFf(\lambda)}{2RT}d\lambda\,, \tag{38}$$

which gives the current for any change in voltage $f(t)$. For example, the linearly increasing voltage with a constant rate k

$$f(t) = kt\,, \tag{39}$$

leads to the current

$$i = i_0\left[\tan\mathrm{h}\,\beta kt + 2\beta k\sum_{S=1}^{\infty}\exp(-ps^2 t)\int_0^t \exp(ps^2\lambda)\sec\mathrm{h}^2\,\beta k\lambda d\lambda\right], \tag{40}$$

where

$$i_0 = \frac{nFAD_0C_0}{L}\,,$$

$$\beta = \frac{nF}{2RT}\,,$$

$$p = \frac{4\pi^2 D}{L^2}\,.$$

The current-time relation (40) is shown in Fig. 3, which is written for $i_0=1$, $\beta=1$, $k=1$ and $p=1$. The sudden rise of the current is observed; the transient phenomena means that the diode has the shunting effect for high frequency input signals.

§ 7. Co-axial Cylindrical Electrodes.

To study the case in which the sizes of the two electrodes are very different, the co-axial cylindrical electrodes, the cathode at $r=a$ and the anode at $r=b$, are considered. If it is assumed that

$$a \ll b\,, \tag{41}$$

the rectifying character appears as shown in the following.

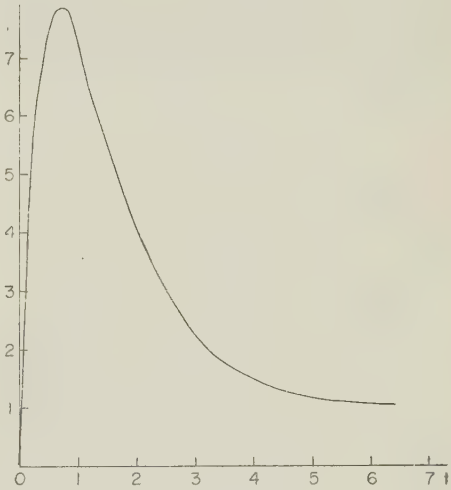

Fig. 3.

The equations of diffusion referred to the cylindrical coordinates, in which the concentrations are the functions of r only, are

$$\frac{\partial C_R}{\partial t} = \frac{D}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C_R}{\partial r}\right), \tag{42a}$$

$$\frac{\partial C_O}{\partial t}=\frac{D}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C_O}{\partial r}\right). \tag{42b}$$

The boundary conditions corresponding to (10a) and (10b) are

$$\left(\frac{\partial C_R}{\partial r}\right)_{r=a}+\left(\frac{\partial C_O}{\partial r}\right)_{r=a}=0\,, \tag{43a}$$

$$\left(\frac{\partial C_R}{\partial r}\right)_{r=b}+\left(\frac{\partial C_O}{\partial r}\right)_{r=b}=0\,, \tag{43b}$$

those corresponding to (5a) and (5b)

$$b\left(\frac{\partial C_O}{\partial r}\right)_{r=b}=a\left(\frac{\partial C_O}{\partial r}\right)_{r=a}=0\,, \tag{44a}$$

$$b\left(\frac{\partial C_R}{\partial r}\right)_{r=b}-a\left(\frac{\partial C_R}{\partial r}\right)_{r=a}=0\,, \tag{44b}$$

and that corresponding to (7)

$$\frac{C_O(b,\,t)}{C_R(b,\,t)}\Big/\frac{C_O(a,\,t)}{C_R(a,\,t)}=\exp\left(\frac{nFV}{RT}\right). \tag{45}$$

As only the steady state is considered here, C_O and C_R should satisfy

$$\frac{d}{dr}\left(r\frac{dc}{dr}\right)=0\,,$$

and so

$$C_O=\alpha_O \log \gamma+\beta_O \tag{46a}$$

$$C_R=\alpha_R \operatorname{lon} \gamma+\beta_R. \tag{46b}$$

With this type of solution, (44a) and (44b) satisfied automatically, so to determine the four constants α_O, β_O, α_R and β_R, the conditions corresponding to (12a) and (12b) should be adopted again. A procedure similar to §4 leads to, because of the conditions (1) and

$$a\ll b\,, \tag{47}$$

the expression of the steady current per unit length of the cylinder

$$i=2\pi nFD\alpha_O=2\pi nFDC_O^0\left\{\exp\left(\frac{nFV}{RT}\right)-1\right\}. \tag{48}$$

The result is shown in Fig. 4, for $2\pi nFDC_O^0=i_O=11.7$ and $\frac{RT}{nF}=V_O=0.0128$. A typical rectifying character can be observed. It is noted that the result does not contain C_R and a explicitly.

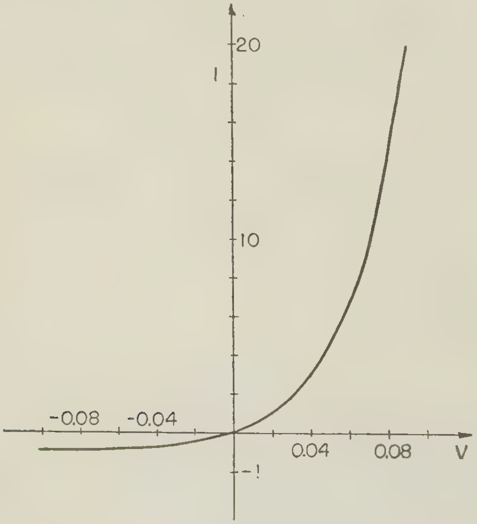

Fig. 4.

If the minority carrier is the reduced form, it is easy to see that the rectifying character is revered, that is the larger current flows when the outer electrode is in negative potential.

Acknowlegements.

The author expresses his hearty thanks to Dr. Yasundo Takahashi, Professor of California University, who kindly sent him the literature hardly available in Japan, to Professor Keiichi Eda of Gakushuin University for kind discussions, to Miss Mizuko Yoshida who helped him in numerical calculations and drawing the figures and Miss Mitsuko Hirose for her preparing the manuscript. This work was partly supported by a Scientific Research Expenditure of the Education Ministry.

Dielectric β-Relaxations in Some Linear High Polymers

By Kaoru YAMAFUJI

Department of Physics, Faculty of Science,
Kyusyu University, Hukuoka, Japan

(Received July 29, 1960)

The dielectric β-dispersions in the amorphous part of the linear high polymers may be roughly classified into two categories according to their mechanisms: the first is the dielectric dispersions in the polymers which have long flexible dipoles, and the second is those which have rather short dipoles rigidly attached to their main chains. While the β-dispersions in the polymers of the first group are inferred to be mainly due to the micro-Brownian motions of their long dipoles, no convincing theory referring to the mechanism of those of the second group has been proposed up to present.

In this paper, the dielectric β-dispersions of these second group polymers are investigated. The approximate magnitudes of some quantities appearing in our theory are evaluated by the observed values obtained from the mechanical dispersion. Taking account of the phenomenological nature of our theory, agreements between the theory and the observations may be satisfactory.

§1. Introduction

Since the existence of the mechanical β-dispersions for some linear high polymers was reported by several authors⁽¹⁾ in the early years of the nineteen fifties, a great number of investigations have been done up to now for the mechanical and dielectric dispersions in high polymers. As a result of these efforts, two or three kinds of mechanical and dielectric dispersions have been known for each of many linear high polymers. As there is no unified nomenclature for the specification of these dispersions, we shall call, them, in accordance with usual name, α-, β-, γ-dispersions and so on in their turns of appearance from high temperature and low frequency sides to low temperature and high frequency sides. However, this nomenclature makes the discussion of these dispersions much complicated, for the term α-, β-, or γ-dispersion means only the sequence of appearance from the high temperature and low frequency sides and there may be, therefore, various possible mechanisms for the β-, or γ-dispersions of the various kinds of polymers.

On the other hand, however, dielectric dispersions for the amorphous part seem to have a common nature.* Almost all of the dispersions are attributed to the deformations of the high polymer chains which are caused by the motions of the permanent dipoles under the effect of external electric field. Therefore, it may be somewhat useful to classify these dispersions from the side of the motions of the dipoles. There may be, roughly speaking, three kinds of such deformations of the chains due to the motions of the permanent dipoles. These are as follows:

(1) The deformations accompanied with rather large changes in the directions or locations of the dipoles and with large apparent activation energies.

(2) The deformations accompanied with rather large changes of the directions or locations of the dipoles but with comparatively small apparent activation energies.

(3) The deformations accompanied with rather small changes of the directions or locations of the dipoles and also with small apparent activation energies.

For a typical example of the deformations of the type (1), there would be the change of the dipole orientations due to the segmental rotations or translations of the main chains. Most of the α-dispersions are attributed to such deformations of the main chains. The mechanism and the properties of the α-dispersion have been discussed by many authors[2] and some convincing theories seem to have been established, although these theories seem to be not satisfactory in many points.[3]

---

* In this paper, we shall discuss only the dielectric disperions due to the amorphous part of the linear high polymers. The dieletric dispersions in the high polymers which have the hydrogen bonds are also excluded.

As is well known, the segmental rotations and translations of the main chains tend to be less and less active as the temperature becomes lower than the glass transition temperature, T_g. In other words, the relaxation times characteristic of such motions are apt to be longer and longer as the temperature becomes lower, and hence the α-dispersion becomes hardly observable at the temperatures far below T_g. Since the β-, and γ-dispersions are mainly observed at the temperatures below T_g, they seem to be attributed to the deformations of the types (2) and (3).

The first example for the deformations of the type (2) would be the rotational motions of the chain end dipoles in the amorphous part. Reddish[4] attributed the dielectric β-dispersion of the polyethylenetelephthalate to such rotational motions of the —OH groups in the chain ends. The magnitude of the β-dispersion due to the mechanism may have a remarkable dependence on the degree of polymerization and, further, it would be fairly small because the number of the chain end dipoles is quite small. The detailed experimental work with respect to these points[5] shows us, however, that the magnitude of β-dispersion seems to have rather weak dependence on the degree of polymerization, and hence the β-dispersion due to such a mechanism seems to have not yet been found out at the present stage.

The second instance of the type (2) would be the deformations due to the rotational motions of the long flexible side dipoles such as, for example, ester groups of PMMA. Since these motions do not need so large apparent activation energy, they would be also active at the temperatures below T_g. The β-dispersions of a series of linear high polymers such as polymethylmethacrylate (PMMA), polyethylmethacrylate (PEMA), poly-α-chloroacrylate, and so on, may be attributed to this mechanism.[6][16]

Besides the above polymers whose dipoles are long and flexible, there are another kind of polymers whose dipoles are short and rigidly attached to the main chains. Polyvinylchloride (PVC), polyvinylbromide (PVBr) and polymonochlorotrifluoroethylene (PCFE) are the examples of this kind of polymers. Since the β-dispersions are mainly observed in the temperatures far below T_g and the rotational and translational motions of the main chains are frozen in this temperature range, most of the β-dispersions for these linear high polymers would be due to the deformations of the type (3), that is, the deformations accompanied with rather small changes of the directions or locations of the dipoles. Here, the term "dipoles" means the composite dipoles of those of a monomer unit or of a structural unit like the monomer. One may consider several "models" describing such small motions of the dipoles. The first is as follows:

(a) Each dipole bound temporarily to one of the directions of the local equilibria is performing a small vibration in the vicinity of the local equilibrium. The β-dispersion is the superposition of the resonance absorptions by these oscillators.

The properties of the dispersion due to the above mechanism have already been investigated.[7] However, the limiting condition in which the dispersion due to the above mechanism can occur depends upon the fact that whether the oscillators could keep up their stationary characters during a period of the applied electric field or not. In the viscous media, such as we are now considering, the life times during which oscillators stay in one of the vibrational normal modes are expected to be much shorter than the period of the electric field, $10\sim10^{-7}$ sec. Thus, the possibility of the appearance of the dispersion due to the above mechanism seems to be little at least for the dispersion in the radio frequency range.

The second is the theoretical approach from the liquid-like model.** Because the rotational and translational motions of the main chains are frozen at the temperatures far below T_g, each dipole is bound in the vicinity of a local equilibrium direction during the time far longer than the period of the electric field, $10\sim10^{-7}$ sec. Thus, the

---

** A theory based on a view point of the liquid-like model has been developed by Okano[8] independently of us. His calculation is an application of Kirkwood's formulations to the β-dispersion.

small motions of the dipoles in the vicinity of the local equilibrium directions could be approximately described as those in the high visco-elastic liquid:

(b) Since the dipoles are bound high visco-elastically to one of the local equilibrium directions, they follow the change of the direction of the local electric field with a little delay on account of both the restoring and frictional forces. The β-dispersion is due to such a delaying phenomenon.

The third is the approach from the side of the crystalline solid:

(c) Each dipole performs the transition from one of the local equilibrium directions to another by the thermal agitations. If the transition probabilities for such transitions can be divided into two or three groups distinctly, the dispersions can also be divided into two or three groups accordingly.

Since the above mentioned model, (b), lies between the site model, (c), and the continuous rotating model in the viscous liquid, we may call it the "quasi-liquid" model. In this paper, the β-dispersions due to the deformations of the type (3) are investigated with the aid of the model (b). However, the site model is also useful in many points and will be discussed in the following paper.[13)]

In § 2, a phenomenological simple calculation is done in deriving an expression for the dielectric β-dispersion of the type (3), especially for PVC. The orders of the magnitudes of some quantities which appear in our theory are estimated from the observed values obtained from the mechanical β-dispersion. In § 3, the calculated results in § 2 are compared with the observations in the following three points: (A) the magnitude and the temperature dependence of the static dielectric constant, (B) the magnitude and the temperature dependence of the frequency of the maximum absorption, and (C) the shape of the absorption curve and its temperature dependence. Finally, the dielectric β-dispersions in other second group polymers such as PCFE are discussed in § 4.

§ 2. Phenomenological Theory

In this section we shall derive an expression for the dielectric β-dispersion curve due to the small deformations of the chains based on the model (b). First, we shall discuss the case of the linear chain polymers which have a single rigid dipole per monomer such as PVC. The extension of the theory to the case in which there are two or more dipoles per monomer such as PCFE will be discussed in § 4. Since, in the present case, we are not interested in the intra-monomer deformations of polymer molecules, the motions of dipoles can be approximately regarded as same as those of monomer units.

According to the molecular theoretical interpretation of the relaxation phenomenon, the dielectric dispersion is to be caused by an energy transfer from the rotational degree of freedom of dipoles to some other degrees of freedom, and the activation energy of dispersion is related, in some way or others, to the energy of coupling between the rotational degree of freedom and the remaining degrees of freedom of the molecular motion. Since the activation energy of the β-dispersion is fairly large, the interactions among monomers pertaining to the β-dispersion would be rather strong, though they are not so strong as in the case of α-dispersion. Then, it is to be expected that the small rotations around the quasi-stable positions affect those of many neighboring monomers and bring about the coupled motions of these monomers. For simplicity, however, we shall assume that all the dipoles in the system are divided into many groups each of which contains only the dipoles of several monomers rotating in the same way as a whole, and that each group of dipoles is moving independently of the other groups in a high elastic medium under the influence of both restoring and frictional forces. A slightly more extended consideration which takes into account the coupled motions among groups explicitly will be discussed in Appendix. In the following we shall call the j-th group of dipoles simply the j-th dipole but will represent a group of dipoles.

We shall put the "local" polar axis in the direction of the chain having its origine in the vicinity of the j-th dipole. Further, we shall treat the three dimensional motions of dipoles approximately by assuming that it is confined in the plane perpendicular to the local direction of the chain and denote the rotational angle of the j-th dipole by φ_j measured from its equilibrium directions in the absence of the external electric field. Then, the phenomenological equation of motion of the j-th dipole is expressed as follows.

$$I_j\frac{d^2\varphi_j}{dt^2}+\zeta_j\frac{d\varphi_j}{dt}+\gamma_j\varphi_j=\mu_j\sin\theta_i{}^0\sin(\varphi_j{}^0-\varphi_j)E_r\,, \tag{2.1}$$

where I_j, ζ_j, γ_j, and μ_j are the moment of inertia in the vicinity of the quasi-stable positions, the rotational friction constant, elastic restoring force constant of small rotation and the dipole moment of the j-th dipole, respectively, and E_r is Onsager's directing field which is in the direction ($\theta_j{}^0$, $\varphi_j{}^0$). Because the dipoles are rotating in a high elastic medium, we can easily prove that the first term in Eq. (2.1) is negligible. Then, the solution of Eq. (2.1) leads to a superposition of the dielectric dispersions of Debye type for the periodic external field of angular frequency ω:

$$\varepsilon(i\omega)-\varepsilon_\infty=\frac{4\pi}{3}\frac{E_r}{E}\sum_{j\ 1}^{N'}\frac{\mu_j{}^2}{\gamma_j}\frac{1}{1+i\omega\tau_j}\,, \tag{2.2}$$

where

$$\tau_j=\frac{\zeta_j}{\gamma_j}\,. \tag{2.3}$$

The static dielectric constant for β-dispersion is at once derived from Eq. (2.2), and is given by

$$\varepsilon_0-\varepsilon_\infty=\frac{4\pi}{3}\frac{E_r}{E}\sum_{j=1}^{N'}\frac{\mu_j{}^2}{\gamma_j}\,. \tag{2.4}$$

In Eqs. (2.2) and (2.4), N$'$ is the number of the groups of dipoles per unit volume. Since γ_j and ζ_j are, respectively, distributed in a certain range with some shape in general, the summations in Eqs. (2.2) and (2.4) are replaced by the integrals in which the summands are multiplied by the distribution functions. The shape of the distribution function of the relaxation times will be investigated in Appendix.

One of the important differences between our equation of dispersion and that of the phenomenological theory of α-dispersion or Debye's equation in liquid is in the definition of the relaxation time. While the relaxation time of Debye's is given by $\tau_D=\zeta_D/kT$, where k is the Boltzmann constant and T is the absolute temperature, ours is expressed as $\tau=\zeta/\gamma$. Although the similar mechanism to ours had been proposed with respect to the dielectric losses in the dipolar liquids, [9] the order of the magnitude of the relaxation time did not agree with observed values in liquids. In the glass state of the polymer, however, the medium is so high visco-elastic that our mechanism becomes meaningful as we shall discuss in § 3.

We shall now consider about γ_j and ζ_j. The detailed knowledge of these quantities is, of course, obtained by the molecular theoretical consideration. Our request in this paper is, however, not to find a detailed quantitative agreement between the theory and the observation, but only to know whether Eq. (2.2) based on our mechanism would give the correct order of the magnitudes and the correct qualitative tendencies of the observed data or not. It is, therefore, enough for our purpose to know only the approximate magnitudes and qualitative tendencies of γ_j and ζ_j. We shall, then, evaluate the approximate magnitudes of γ_j and ζ_j from the observed values for the β-dispersion of the dynamic rigidity.

The rotational friction constant of the dipole, ζ_j, is proportional to its shear viscosity, η_j', which is expressed by Stokes' law as

$$\zeta_j=8\pi a_j'^3\eta_j'\,, \tag{2.5}$$

where a_j' is the effective radius of the dipole when we replace it by a sphere. We shall assume that the average value of η_j' is approximately given from the observed value for the β-dispersion of the dynamic rigidity by

$$\eta'\cong G''(\omega_m)/\omega_m\,, \tag{2.6}$$

and similarly, for γ_j,

$$\gamma\cong G'(\omega_m)a'N'^{-2/3}\,. \qquad (2.7)^{***}$$

In Eqs. (2.6) and (2.7), ω_m is the maximum frequency of the absorption and G' and G'' are, respectively, the real and imaginary parts of the dynamic rigidity. In deriving Eq. (2.7), we used the facts that the shear elastic force may be most effective to the small rotations of composite dipoles and that only the nearest neighbors are remarkably dragged in such motions.

Although the condition under which the external force acts on the monomers is, of

---

*** Strictly speaking, $G'(\omega_0)$ should be used in place of $G'(\omega_m)$ in Eq. (2.7) where ω_0 is such an angular frequency that $\omega_{m,\beta}\gg\omega_0\gg\omega_{m,\alpha}$. However, the change of G' with angular frequencies is so small for the β-dispersions that it would be admissible to use $G'(\omega_m)$ instead of $G'(\omega_0)$.

course, different between the mechanical and the dielectric measurements, the replacements in Eqs. (2.6) and (2.7) are seen to be enough to evaluate the magnitudes and the temperature dependences of γ_j's and ζ_j's approximately. One may, however, have an objection that it is not reasonable to substitute the macroscopic quantities for the microscopic ones. Although this objection may be valid in principle, it happens to be unsuitable for our case. The detailed consideration in this respect will be given in § 3.

§ 3. Comparison with Observations

Since the equation of the dielectric β-dispersion due to small deformations of the chains, Eq. (2.2), is derived in a much simplified semi-phenomenological way, it is not reasonable to expect the detailed quantitative agreements between the theory and the observations. However, Eq. (2.2) should give not only the qualitative tendencies of the observations correctly but also the magnitudes of the observed quantities approximately so long as our mechanism is valid. In this section, we shall discuss this subject.

(3/1). The Static Dielectric Constant

The static dielectric constant for the β-dispersion in our case is given by Eq. (2.4). Evaluating the approximate magnitude of the static dielectric constant from this equation, we shall make further simplifications that we ignore the distributions of μ_j's and γ_j's and replace the quantities of composite dipoles by those of individual monomers. These replacements may bring about only the factors of the order of unity, which gives no serious effect to our purpose. Then, eq. (2.4) becomes

$$(\varepsilon_0-\varepsilon_\infty)_\beta \simeq \frac{4\pi}{3}\frac{E_r}{E}\frac{N\langle\mu^2\rangle}{G'aN^{-2/3}}, \qquad (3.1)$$

where N is the number of monomers per unit volume and a is the effective Stokes' radius for a monomer. The suffix β on the left hand side represents that the quantity is the static dielectric constant for β-dispersion. If we substitute the appropriate values on the right hand side of Eq. (3.1), for instance in the case of *PVC*, $N \sim 1.4\times10^{22}$ per cm³, $\langle\mu^2\rangle^{1/2} \sim 1.7\times10^{-18}$ esu, $a \sim 4\times10^{-8}$ cm, $G' \sim 1.5\times10^{10}$ dyne/cm² (−20°C)[1] and $E_r/E \sim 2.3$ the magnitude of the β-dispersion, $(\varepsilon_0-\varepsilon_\infty)_\beta$, in *PVC* becomes 4×10^{-1} (−20°C). Since Onsager's directing field may be replaced by $E_r=[3\varepsilon_s(\varepsilon_\infty+2)^2/9(2\varepsilon_s+\varepsilon_\infty)]E$, the value of the ratio E_r/E is calculated from the observed data. The order of magnitude of this value agrees fairly well with the observed data. (See Fig. 1.)

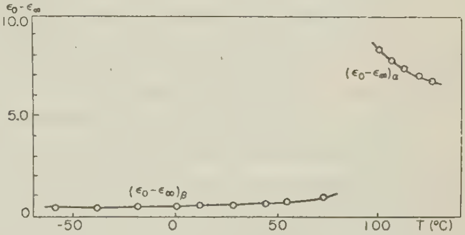

Fig. 1. The static dielectric constants for the α- and β- dispersions in PVC.[10]

As was mentioned above, there may be some objection to replace the microscopic quantities by the macroscopic ones. Although such a replacement leads to the correct results qualitatively in the usual case, it often yields wrong values in the order of the magnitude. However, such an objection would be unsuitable as far as the relaxation time, τ, is concerned because τ is given by the ratio ζ/γ and, further, we are interested in only the logarithm of τ. Then the possible errors for ζ and γ, if exist, would cancel each other. As for the elastic restoring force constant of small rotation γ, the value calculated from Eq. (2.7) is nearly the same as the value obtained from the more detailed molecular theoretical calculation in Appendix. In fact, the former is given by 5×10^{-13} while the latter is 8×10^{-13} in the case of *PVC*. Moreover, the value of γ estimated from the apparent activation energy for the β-dispersion in *PVC* (∼10 kcal/mol) is also 6×10^{-13}, showing the expected agreement for the order of magnitude. Thus we may conclude the objection that such a replacement would lead to a wrong order of magnitude for τ and γ seems to be unsuitable for our case.

For comparing the static dielectric constant corresponding to β-dispersion with the observations, it is more convenient to consider the ratio of the static dielectric constant for β-dispersion to that for α-one, because the uncertain factors, such as the mean square of the dipole moment, Onsager's directing field, etc., are eliminated by this procedure.

Since the static dielectric constant for α-dispersion at the temperatures far above T_g is given by

$$(\varepsilon_0-\varepsilon_\infty)_\alpha=\frac{4\pi}{3}\frac{E_r}{E}\frac{N\langle\mu^2\rangle}{kT}, \qquad (3.2)$$

its ratio to Eq. (3.1) yields

$$\frac{\varDelta\varepsilon_\beta}{\varDelta\varepsilon_\alpha}=\frac{(\varepsilon_0-\varepsilon_\infty)_\beta}{(\varepsilon_0-\varepsilon_\infty)_\alpha}=\frac{kT_\alpha}{G'(T_\beta)aN^{-2/3}}, \qquad (3.3)$$

where T_α and T_β are the temperatures at which α- and β-dispersions are observed, respectively. In Table I, the theoretical values of $\varDelta\varepsilon_\beta/\varDelta\varepsilon_\alpha$ are compared with the observed values of $\varDelta\varepsilon_\beta/\varDelta\varepsilon_\alpha$ for a few polymers appropriate for our theory. Though the values of a may be different for various kinds of polymers, we shall choose it as $a\sim4\times10^{-8}$ cm for convenience. The observed values in Table I are corrected for the degree of crystallization. The agreements between the theoretical and observed values are satisfactory.

Table I. Comparison of theoretical and observed values of the static dielectric constants for β-dispersions to α-ones in polyvinylchloride (PVC), polyvinylbromide (PVBr) and polyvinylacetate (PVAc).[10,13]

polymers	$\left(\frac{\varDelta\varepsilon_\beta}{\varDelta\varepsilon_\alpha}\right)_{\text{obs.}}$	$\left(\frac{\varDelta\varepsilon_\beta}{\varDelta\varepsilon_\alpha}\right)_{\text{theo.}}$	compared temperature
PVC	0.06	0.07	$\frac{0^\circ\mathrm{C}(\beta)}{100^\circ\mathrm{C}(\alpha)}$
PVBr	0.05	0.06	$\frac{10^\circ\mathrm{C}(\beta)}{85^\circ\mathrm{C}(\alpha)}$
PVAc	0.03	0.03	$\frac{-15^\circ\mathrm{C}(\beta)}{52^\circ\mathrm{C}(\alpha)}$

In our equation of the static dielectric constant for β-dispersion, only the real part of the rigidity, G', is the temperature dependent factor. Since G' decreases as the temperature becomes higher, the static dielectric constant for β-dispersion is expected to increase with temperature. Although the observed values of the latter quantity for *PVC* actually increased by some twice during the temperature range 0°C∼60°C (Cf. Fig. 1.), it can be explained from the temperature increase of G'. Besides, since the temperature change of G' is rather slow at lower temperatures, it is expected that the static dielectric constant will also change slowly with temperature. This agrees with the tendencies of the observed data, too. At higher temperatures, such as near T_g, the relaxation times characteristic of α- and β-dispersions become, however, comparable in the orders of magnitudes. Then the treatment such that of § 2 begins to lose its validity. Therefore, we cannot predict the behavior of $(\varepsilon_0-\varepsilon_\infty)_\beta$ near and at higher temperatures than T_g. However, since the number of dipoles pertaining to the β-dispersion due to the small deformations of the chains is, roughly speaking, the order of $N(1-\exp(-\tau_\alpha/\tau_\beta))$, it is inferred that the increment of $(\varepsilon_0-\varepsilon_\infty)_\beta$ becomes low at temperatures near T_g and, finally, it will begin to saturate and decrease.

(3/2). The Frequency of the Maximum Absorption

Now we shall consider the frequency of the maximum absorption. In the case of *PVC*, the value of τ evaluated from the data due to Schmieder and Wolf[1] and from the relations Eqs. (2.3), (2.5) and (2.6) gives $\tau\sim 9.4\times10^{-2}$. Then we obtain the logarithm of the frequency of the maximum absorption, $\log f_m$, as

$$\begin{aligned}\log_{10}(f_m)&=\log_{10}(\omega_m/2\pi)\\&=\log_{10}(1/2\pi\tau)\sim0.2 \text{ (at } -30^\circ\text{C)}.\end{aligned}$$

This is of nearly the same order of magnitude as the observed value. (Cf. Fig. 2.)

The similar situations are realized for other

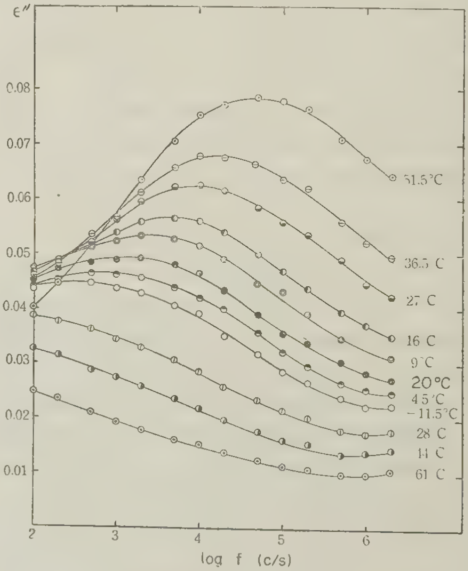

Fig. 2. The $\varepsilon''-\log f$ curve for the β-dispersion in PVC.[10]

polymers. In our theory, the temperature dependence of f_m is due to that of η' as well as that of G'. Since the activation energy of dynamic viscosity is nearly the same as that of the dielectric dispersion, the temperature dependence of f_m in our theory should bring about the coincidence with the observed values approximately. The correct temperature dependence should, of cource, be obtained from the more detailed molecular considerations based on our mechanism. As was mentioned above, G' is also a temperature dependent factor in f_m. It gives a little decrease of the transferring velocity of f_m to higher frequencies with increasing temperature.

(3/3). The Shape of the Absorption Curve

The marked broadness of the observed absorption curves are understood to be a consequence of the superposition of the many Debye absorption curves each of which has a single relaxation time τ. The relaxation time spectrum for the dielectric β-dispersion, $L_\varepsilon(\tau)$, seems to have following two characteristic features[3]: (1) the spectrum is rather symmetrical in $\log L_\varepsilon(\tau)-\log\tau$ curve compared with the mechanical retardation spectrum; (2) the Cole's parameter, $\bar{\beta}$, has the values nearly equal to 0.3 at the temperatures far below T_g both in the cases of the amorphous and the crystalline high polymers. This is in marked contrast to the α-dispersion for which the values of $\bar{\beta}$ lie between 0.3 for the crystalline polymers and 0.7~0.9 for the amorphous polymers.

The simple calculation in § 2 gives us no information about the detailed shape of the absorption curve and hence we must attempt some extension whose details are given in Appendix. However, the above characteristic features are not so satisfactorily explained by the calculations in Appendix. The theory of the relaxation time spectrum for the dielectric β-dispersion will be the next subject of investigation.

§ 4. Dielectric β-Dispersion in PCFE

In § 2 we discussed the case of the polymers which have only a single rigid dipole per monomer unit such as PVC. Here, we shall extend the discussion in § 2 to the case of two or more dipoles per monomer unit. Polymonochlorotrifluoroethylene (PCFE), polyethylenetelephthalate (PET), etc. are the examples of such polymers. Although the dielectric β-dispersions of these polymers are very similar to those of the linear vinylpolymers, the magnitudes of the α-dispersions for these polymers are much smaller than those of the linear vinyl-polymers. (Cf. Table II.)

Table II. The magnitudes of the dispersions for PCFE and PET.[12] (Data for PVC[10] is added for comparison.)

polymer	$(\varepsilon_0-\varepsilon_\infty)_{\alpha,\mathrm{obs.}}$	$(\varepsilon_0-\varepsilon_\infty)_{\beta,\mathrm{obs.}}$	$(\varepsilon_0-\varepsilon_\infty)_{\beta,\mathrm{theo.}}$
PCFE	0.24 (100°C)	1.2 (0°C)	1.9 (0°C)
PET	1.8 (82°C)	0.54 (30°C)	0.4 (30°C)
PVC	8.4 (100°C)	0.5 (30°C)	0.5 (30°C)

First, we shall consider the case of PCFE, which has three C-F dipoles and a C-Cl dipole per monomer unit. Suppose the angle between C-Cl and C-F dipoles is of the regular tetrahedron exactly, the dipole moment per monomer unit decreases to 0.2 Debye unit or so by the cancellation among the dipole moments of a C-Cl dipole and three C-F dipoles. Since PCFE has, however, the spiral structure including 14 monomers in a period[11] and, moreover, we are considering about the amorphous part, the cancellation among these dipole moments may be rather incomplete. Taking into account the fact that the root mean square of the dipole moment of $CClF_3$ is 0.46 Debye unit, the root mean square of the dipole moment per monomer unit would be expected to be approximately 0.4~0.5 Debye unit. Substituting the following appropriate values,

$$N_{\mathrm{PVC}}\sim 1.4\times 10^{22}\ \text{per cm}^3,$$
$$N_{\mathrm{PCFE}}\sim 1.0\times 10^{22}\ \text{per cm}^3,$$
$$(\langle\mu^2\rangle_{\mathrm{PVC}})^{1/2}\sim 2.0\times 10^{-18}\ \text{esu},$$
$$(\langle\mu^2\rangle_{\mathrm{PCFE}})^{1/2}\sim 0.5\times 10^{-18}\ \text{esu},$$
$$\text{and } (E_r/E)_{\mathrm{PVC}}\sim 3,\ (E_r/E)_{\mathrm{PCEF}}\sim 2,$$

into Eq. (3.2), the ratio the dielectric constant of the α-dispersion for PVC to that for PCFE becomes

$$\frac{(\varepsilon_0-\varepsilon_\infty)_{\alpha,\mathrm{PVC}}}{(\varepsilon_0-\varepsilon_\infty)_{\alpha,\mathrm{PCFE}}}\sim 34\ ,$$

which is approximately of the same value with the observed value 35 calculated from the Table II. This means that the monomer can be regarded as the nearly rigid motional unit in the case of α-dispersion.

On the other hand, the monomer cannot be regarded as a rigid motional unit in the case of the β-dispersion. For, in this case, the motion of the dipole is the small "diffusional" rotation near the minimum point of the potential, and hence the external electric field forces to attract the dipole pairs CCl-CF and CF-CF in the opposite directions to each other. Then, it may be possible to occur such a motion in which the pairs CCl-CF and CF-CF perform the small "diffusion" rotations partially independently under the effect of the periodic electric field. Therefore, we must substitute the root mean square of the dipole moment for CCl-CF or CF-CF pair into in Eq. (3.1). Substituting the appropriate values,

$$N \sim N_{\mathrm{CCl\text{-}CF}} + N_{\mathrm{CF\text{-}CF}} \sim 2 \times 10^{22} \text{ per cm}^3,$$
$$\langle \mu^2 \rangle^{1/2} \sim 1.7 \times 10^{-18} \text{ esu},$$
$$G' \sim 8 \times 10^9 \text{ dyne/cm}^2 \text{ (at 0°C)},^{1)}$$
$$a \sim 4 \times 10^{-8} \text{ cm and } E_r/E \sim 2 \text{ },$$

into the right hand side of Eq. (3.1), $(\varepsilon_0 - \varepsilon_\infty)_\beta$ for PCFE becomes 1.9 (at 0°C). If we take into account the fact that the small diffusion rotations of CF-CCl and CF-CF pairs are not "completely" but "partially" independent, the value of N should be decreased and hence the value 1.9 also should be decreased. At any rate, this is of the same order of magnitude with the observed data. (See Table II.)

The similar situation is also realized in the case of PET. (See also Table II.) However, it seems to be somewhat doubtful whether the cause of the small magnitude for the $(\varepsilon_0 - \varepsilon_\infty)_\alpha$ in such a high crystallized polymer as PET can be attributed only to the small resultant dipole moment per monomer caused by the spiral structure of the chain or not.

§ 5. Conclusion

Our theory based on the mechanism proposed in this paper with respect to the dielectric β-dispersions for the linear vinylpolymers such as polyvinylchloride agrees with observations qualitatively as well as semi-quantitatively. Our calculation is, however, based on the semi-phenomenological ground so that we cannot proceed more in details of the agreements with the observations. Furthermore, the discussion in § 2 was done under the assumption that the relaxation times characteristic of α-dispersion are far longer than those of β-one. Of course, this assumption begins to loose its validity in the temperatures such that the α- and β-dispersions appear at nearly the same frequencies. To improve these situations, it is necessary to build up a general theory which is based on the molecular theory and which involves both the cases of the α- and β-dispersions.

In this paper, the discussions are limited to the case of the β-dispersion due to the small deformations of the chains. As was mentioned in § 1, there are also the β-dispersions due to the micro-Brownian motions of the long flexible dipoles, which are hardly treated by our present model. In this case, and as for the possibility of simultaneous discussions about the α- and β-dispersions, the site model seems to be useful in some points. The discussions with the aid of the site model will be published in the near future.[13]

The author would like to express his sincere thanks to Professor Tamoyasu Tanaka for his stimulating suggestion of the problem and for helpful discussions. It is also his pleasure to thank Professor Yôichi Ishida (Department of Applied Chemistry) for his kind informations about the unpublished data and for valuable discussions.

Appendix

We shall try to extend the calculation in § 2 to a more detailed molecular theoretical way and obtain some information about the shape of the absorption curve for the β-dispersion.

At the temperatures far below T_g, the segmental rotations and translations of the main chains are not active and only the small deformations of the chains would be active. The segmental motions of the main chains are interpreted as the cooperative micro-Brownian motions of the segments each of which includes 10~50 monomers in it. Then the "small deformation of the chain" could be interpreted as the small deformations within each segment in which at least both ends of the segment are fixed. In other words, only the small rotational or translational motions of a few monomers could be active at the temperatures far below T_g and these motions could bring about the small deformations of the other monomers at most within the segment and not others. Therefore, it is enough for the β-dispersion to consider only the motions of the monomers within each segment and the interactions among the nearest neighbor chains.

Then, if we consider the case of the linear chain polymers which have a single rigid dipole per monomer such as PVC, the diffusion equation for the configurational distribution function f of these dipoles can be written as

$$\frac{\partial f}{\partial t}=\frac{kT}{\zeta}\sum_{l,m,n}\left[\frac{\partial^2 f}{\partial\varphi^2_{l,m,n}}-\frac{1}{kT}\frac{\partial}{\partial\varphi_{l,m,n}}\left\{f\left(\frac{\partial V}{\partial\varphi_{l,m,n}}\right)\right\}\right], \tag{A.1}$$

where ζ is the rotational frictional constant concerning the micro-Brownian motion of a monomer, k the Boltzmann constant, T the temperature. In Eq. (A.1), we assume that the dipoles are arranged nearly simple cubical way and l denotes a number of the concerning dipole along the chain from the fixed end and m, n denote a number of this dipole in the two perpendicular directions to the chain, respectively. We again, for simplicity, confines the three dimentional motions of the dipoles to the two dimensional rotational ones in the plane perpendicular to the local direction of the chain and denote the rotational angle of the l, m, n,-th dipole by $\varphi_{l,m,n}$ measured from its equilibrium direction in the absence of the external electric field.

The total potential energy V is given by

$$V=V_0+V_e\,, \tag{A.2}$$

where

$$\begin{aligned}V_0=&\frac{1}{2}\sum_{l,m,n}A_{l,m,n}(\varphi_{l,m,n}-\varphi_{l-1,m,n})^2+\frac{1}{2}\sum_{l,m,n}B_{l,m,n}(\varphi_{l,m,n}-\varphi_{l,m-1,n})^2\\&+\frac{1}{2}\sum_{l,m,n}B'_{l,m,n}(\varphi_{l,m,n}-\varphi_{l,m,n-1})^2+\frac{1}{2}\sum_{l,m,n}C_{l,m,n}\varphi^2_{l,m,n}\,,\end{aligned} \tag{A.3}$$

and

$$V_e=-\sum_{l,m,n}\mu_{l,m,n}\sin\theta^0_{l,m,n}\cos(\varphi^0_{l,m,n}-\varphi_{l,m,n})E_r\exp(i\omega t). \tag{A.4}$$

In Eq. (A.3), A's and B's, B''s are the elastic restoring force constants among the neighbor dipoles along and perpendicular to the chain, respectively. The last term of Eq. (A.3) may be necessary because each dipole tends to stay in its own equilibrium position. The E_r, θ^0's, and φ^0's in Eq. (A.4) are defined in § 2.

Instead of solving Eq. (A.1), we may derive the following average value equation:

$$\begin{aligned}\zeta\langle\dot\varphi\rangle_{l,m,n}&+A_{l,m,n}(2\langle\varphi\rangle_{l,m,n}-\langle\varphi\rangle_{l-1,m,n}-\langle\varphi\rangle_{l+1,m,n})\\&+B_{l,m,n}(2\langle\varphi\rangle_{l,m,n}-\langle\varphi\rangle_{l,m-1,n}-\langle\varphi\rangle_{l,m+1,n})\\&+B'_{l,m,n}(2\langle\varphi\rangle_{l,m,n}-\langle\varphi\rangle_{l,m,n-1}-\langle\varphi\rangle_{l,m,n+1})\\&+C_{l,m,n}\langle\varphi\rangle_{l,m,n}=F_{l,m,n}\exp(i\omega t)\,,\end{aligned} \tag{A.5}$$

where

$$F_{l,m,n}\equiv\mu_{l,m,n}\sin\theta^\circ_{l,m,n}\sin(\varphi^\circ_{l,m,n}-\varphi_{l,m,n})E_r\,. \tag{A.5$'$}$$

While the boundary conditions along the chains should be the rigid boundaries, it would bring about any serious effect if we choose any boundary conditions in the two perpendicular directions. Hence we may choose also the rigid boundaries in these two directions.

First, we shall consider the simple case in which each of all the $A_{l,m,n}$'s equals to A, $B_{l,m,n}$'s to B, $B'_{l,m,n}$'s to B', $C_{l,m,n}$'s to C and $\mu^2_{l,m,n}$'s to $\langle\mu^2\rangle$. Then with the aid of

$$u_{j_\rho k_\rho}\equiv\sqrt{\frac{2}{N_\rho}}\sin\left(\frac{j_\rho k_\rho}{N_\rho}\pi\right),\quad \sum_{k_\rho\ 1}^{N}u_{j_\rho k_\rho}u_{j'_\rho k_\rho}=\delta_{j_\rho j'_\rho}\,, \tag{A.6}$$

$\rho=1, 2, 3$, we obtain

$$\varepsilon(i\omega)-\varepsilon_\infty=\frac{4\pi N\langle\mu^2\rangle}{3\gamma}\cdot\frac{\Xi(i\omega)}{\Xi(0)}, \qquad N=N_1N_2N_3, \tag{A.7}$$

where

$$\frac{\Xi(i\omega)}{\Xi(0)}=\sum_{k_1k_2k_3}\frac{1}{N_1N_2N_3}\frac{\gamma}{i\omega\zeta+4A\sin^2(k_1/N_1)\pi+4B\sin^2(k_2/N_2)\pi+4B'\sin^2(k_3/N_3)\pi+C}, \tag{A.8}$$

and

$$\gamma^{-1}\equiv\Xi(0)=\sum_{k_1k_2k_3}\frac{1}{N_1N_2N_3}\frac{1}{4A\sin^2(k_1/N_1)\pi+4B\sin^2(k_2/N_2)\pi+4B'\sin^2(k_3/N_3)\pi+C}. \tag{A.9}$$

Comparing Eq. (A. 7) with Eq. (2.2), it is clear that γ in Eq. (A.9) acts just the same role as the phenomenological rotating elastic force constant defined by Eq. (2.1). Since the intra-chain interactions are much larger than the inter-chain ones in general, we may assume $A, C\gg B, B'$. Then, Eq. (A.9) may be estimated approximately as

$$\gamma^{-1}\cong\sum_{k_1}\frac{1}{N_1}\frac{1}{4A\sin^2(k^1/N_1)\pi+C}=\frac{1}{\sqrt{C(4A+C)}}, \tag{A.10}$$

Since, from its definition, A is the energy required to twist the chain and hence is the same order of magnitude as the energy of the chemical bond and C is the energy required per monomer in order to turn the untwisted chain by an angle $\pi/2$, we may take the values of A and C as[14)]

$$2A=5 \text{ e.v.} \qquad \text{and } C=1/30 \text{ e.v.}\ .$$

Then γ becomes approximately as

$$\gamma\cong[C(4A+C)]^{1/2}\cong(1/3)^{1/2} \text{ e.v.} \cong 8\times10^{-13}\text{ erg},$$

which is the same order of magnitude as the value of the phenomenological rotating elastic constant calculated by Eq. (2.7). (See § 3.) Since this value of γ leads to the correct order for the magnitude of the β-dispersion, we may conclude that the β-dispersion can be attributed to the small deformations of the monomers and dipoles within the segment.

The function $\Xi(i\omega)$ in Eq. (A.8) is a familiar function appearing in the cases of the lattice vibrations or the impurity bands, and the much complicated calculations are necessary for estimating it. However, the above condition among the force constants, $A, C\gg B, B'$, make the estimation of $\Xi(i\omega)$ a little easier. We may expand the summand of the right hand side in Eq. (A.8) by means of the powers of B/A or B'/A. Then Eq. (A.8) becomes as

$$\Xi(i\omega)=\sum_{s=0}^{\infty}\Xi^{(s)}(i\omega), \tag{A.11}$$

where

$$\Xi^{(s)}(i\omega)\equiv\sum_{k_1k_2k_3}\frac{(-1)^s}{N_1N_2N_3}\frac{(4B\sin^2(k_2/N_2)\pi+4B'\sin^2(k_3/N_3)\pi)^s}{(i\omega\zeta+C+4A\sin^2(k_1/N_1)\pi)^{s+1}}. \tag{A.12}$$

If we approximately replace the summation by integral, the first few terms of $\Xi^{(s)}(i\omega)$'s are estimated as

$$\begin{aligned}
\Xi^{(0)}(i\omega)&=\frac{1}{\sqrt{(i\omega\zeta+C)(i\omega\zeta+C+4A)}},\\
\Xi^{(1)}(i\omega)&=\frac{-2(B+B')(i\omega\zeta-C+2A)}{\sqrt{(i\omega\zeta+C)^3(i\omega\zeta+C+4A)^3}},\\
\Xi^{(2)}(i\omega)&=\frac{(3B^2+8BB'+3B'^2)[4A^2+5(i\omega\zeta+C+2A)^2]}{\sqrt{(i\omega\zeta+C)^5(i\omega\zeta+C+4A)^5}},\\
&\cdots\cdots\cdots\cdots\cdots\cdots
\end{aligned} \tag{A.13}$$

Since the dielectric relaxation time spectrum $L_\varepsilon(\tau)$ is defined by

$$\frac{\varepsilon(i\omega)-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty}=\int_{-\infty}^{\infty}\frac{L_\varepsilon(\tau)}{1+i\omega\tau}d\log\tau\,, \tag{A.14}$$

it can be estimated by an inverse transformation of the above Stieltjes-Hilbert transformation as

$$L_\varepsilon(\tau)=\frac{1}{\pi}\text{ Imaginary part of }\left[\frac{\varepsilon(-1/\tau)-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty}\right]. \tag{A.15}$$

With the aid of the following relation derived from Eq. (A.7),

$$\frac{\varepsilon(i\omega)-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty}=\frac{\Xi(i\omega)}{\Xi(0)}$$

and

$$\Xi(0)\equiv\gamma^{-1}\simeq\sqrt{C(4A+C)}\,,$$

we obtain

$$L_\varepsilon(\tau)=\sum_{S=0}^{\infty}L_\varepsilon^{(S)}(\tau) \tag{A.16}$$

and

$$\begin{aligned}
L_\varepsilon^{(0)}(\tau)&=\frac{1}{\pi}\frac{\tau}{\sqrt{(\tau-\tau_1)(\tau_2-\tau)}}\,,\\
L_\varepsilon^{(1)}(\tau)&=\frac{1}{\pi}\frac{2(2A+C)(B+B')}{C(4A+C)}\frac{\tau^2(\tau-\tau_3)}{\sqrt{(\tau-\tau_1)^3(\tau_2-\tau)^3}}\,,\\
L_\varepsilon^{(2)}(\tau)&=\frac{1}{\pi}\frac{(2A+C)^2(3B^2+8BB'+3B'^2)}{C^2(4A+C)^2}\times\frac{5\tau^3(\tau-\tau_3)^2+4\tau^5A^2/(C+2A)^2}{\sqrt{(\tau-\tau_1)^5(\tau_2-\tau)^5}}\,.
\end{aligned} \tag{A.17}$$

if $\tau_1<\tau<\tau_2$ and 0 if $\tau<\tau_1$ and $\tau_2<\tau$, where

$$\tau_1\equiv\zeta/(C+4A)\,,\qquad \tau_2\equiv\zeta/C\,,\qquad \tau_3\equiv\zeta/(C+2A)\,. \tag{A.18}$$

The leading term in Eq. (A.17) is, of course, essentially the "wedge type" spectrum characteristic of the linear Rouse chain, which has the gradient 1/2 in log-log scale. Since $\tau_3\ll\sqrt{\tau_1\tau_2}$, the first correction term has the gradient 3/2 near $\log\tau=(\log\tau_1+\log\tau_2)/2$, the second correction term 5/2.

Our calculation in this Appendix is essentially the same as the three dimensional Rouse model. The relaxation time spectrum for the Rouse model is very similar to the lattice vibrational spectrum.[3] In fact, the retardation time spectrum for the linear Rouse model, $L(\tau)=\pi^{-1}\tau_\alpha^{-1/2}(\tau-\tau_\alpha)^{-1/2}$, is just the same as the lattice vibrational spectrum for the perfect linear lattice, $G_1(\omega^2)=\pi^{-1}\omega^{-1}(\omega_L^2-\omega^2)^{-1/2}$, in which ω^2 is replaced by $-1/\tau$. Therefore, our relaxation time spectrum is very similar to the three dimentional lattice vibrational spectrum, $G_3(\omega^2)$, in the case of $A\gg B, B'$ in which ω^2 is replaced by $-1/\tau$,

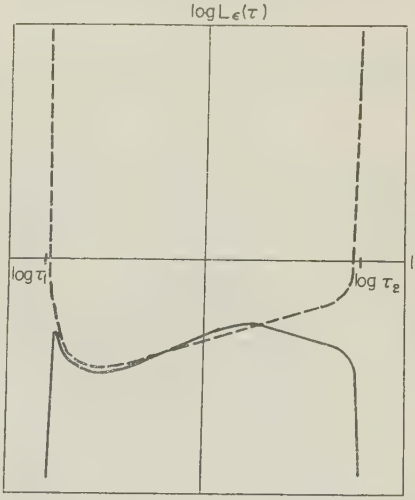

Fig. 3. The schematic graph for the relaxation time spectrum of the dielectric β-dispersion derived in Appendix. The dotted line is the leading term in Eq. (A.16).

which is schematically plotted in Fig. 3.

Although it can be easily shown that the gradient of the broader curve in Fig. 3 is possible to be smaller if we choose the ratios A to B and B' appropriately, the Rouse model seems to have a fault that it has unsymmetrical shape in log-log scale because $G(\omega^2)$ has symmetrical shape in ω^2-scale with respect to $\omega_L{}^2/2$ in general. The effect of the distributions of the force constants can be investigated by iteration method. However, these distributions also do not cause to the above characteristic features so seriously change so long as the width of the distribution is small. Then establishing the convincing theory of the relaxation time spectrum for the dielectric β-dispersion which has two characteristic features mentioned in § 3 will be the future subject of investigation.

Hyperfine Structure of the Spectra of Pr I and Pr II

By Kiyoshi MURAKAWA

Aeronautical Research Institute, University of Tokyo,
Komaba-machi, Meguro-ku, Tokyo

(Received August 17, 1960)

In the spectrum of Pr I three lines were classified and the hfs was measured, from which the interval factor of the level $4f^36s^2\,{}^4I_{11/2}$ was determined. From this and the known interval factor of $4f^36s^2\,{}^4I_{9/2}$ it was concluded that the value of a_{4f} determined from the hfs of Pr II is also appropriate for Pr I. The configuration $4f^3({}^4I)6s$ of Pr II was treated as of intermediate coupling, and the hfs lead to a reasonable value of a_{4f} and $a(6s)$. From the value of $a(6s)$ the magnetic moment of Pr^{141} was calculated to be 4.0 ± 0.2 n.m.

§ 1. Introduction

Some years ago Suwa and the author[1] measured the hyperfine structure (hfs) of the spectrum of Pr II; from the hfs of the term $4f^3({}^4I)6s$ it was concluded that $a(6s)=0.426\,\mathrm{cm}^{-1}$ and $a_{4f}=0.0227\,\mathrm{cm}^{-1}$, in which the relativity correction of the $4f$ electron was neglected and it was put

$$a'=\frac{16}{21}a_f\,,\quad a''=\frac{48}{35}a_f\,,\ \text{and}\ a'''=-\frac{1}{14}a_f\,.$$

From the value of $a(6s)$ the magnetic moment of Pr^{141} was deduced to be $\mu=+4.0\pm0.1$ n.m.

At about the same time Lew[2] measured the hfs of the level $4f^3 6s^2\ {}^4I_{9/2}$ of Pr I, and obtained $a_{4f}=706.2$ Mc/sec$=0.02356$ cm^{-1}.

It is natural to expect that the value of a_{4f} deduced from Pr I is equal to or slightly smaller than that deduced from Pr II, but Lew's value is somewhat larger than our expectation. It is the purpose of the present paper to clarify this point.

For that purpose it would be desirable to measure the hfs of all the levels belonging to $4f^3 6s^2\ {}^4I$ (Pr I); but no classification of Pr I is available at present, so in the present work only the hfs of ${}^4I_{11/2}$ and ${}^4I_{9/2}$ could be studied.

§ 2. Experimental Arrangement

As a light source a liquid air cooled hollow cathode discharge tube was used. The hfs was resolved by means of a silvered or dielectric multilayer coated Fabry-Pérot etalon. In order to test which lines were self-reversed, a hot hollow cathode carrying strong discharge current was also used.

§ 3. Hyperfine Structure of the Spectrum of Pr I

It was found that the first line which shows self-reversal is λ4951.4; this is the strongest line in the visible region. From the hfs it was concluded that this line represents the transition $4f^3 6s^2\ {}^4I_{9/2}-20_{9/2}$, the hfs being shown schematically in Fig. 1. The hfs of the final level is known from the work of Lew[2]. The hfs intervals measured by Lew are indicated by stars; they were originally expressed in units of Mc/sec, but now they are converted in units of cm^{-1}.

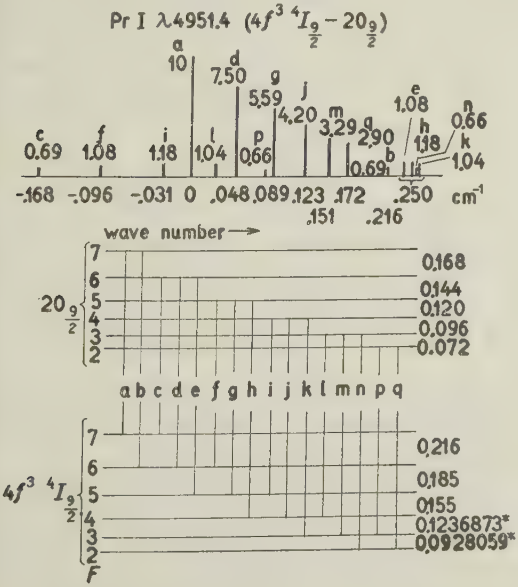

Fig. 1. Hfs of the line Pr I λ4951.4.

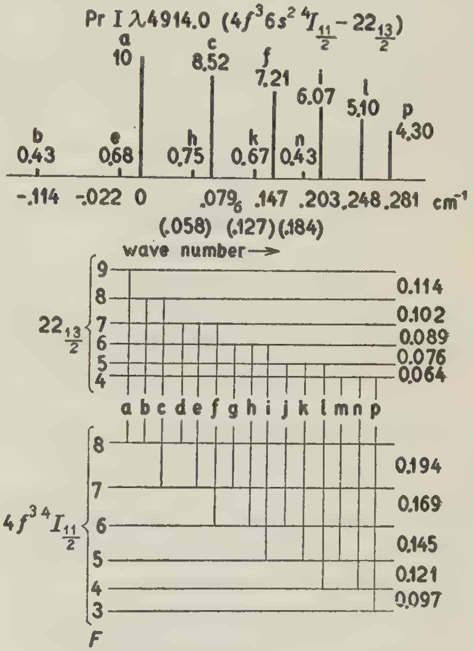

Fig. 2. Hfs of the line Pr I λ4914.0.

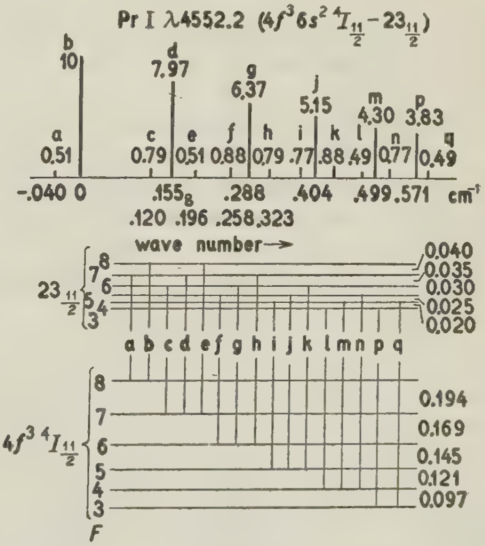

Fig. 3. Hfs of the line Pr I λ4552.2.

In addition to λ4951.4, two lines λλ4914.0 and 4552.2 could be classified, the hfs being shown in Figs. 2 and 3. Numbers in parentheses were calculated. From the hfs, we get the interval factor of the level $4f^36s^2\ {}^4I_{11/2}$: $A({}^4I_{11/2})=0.02425\ \mathrm{cm}^{-1}$. For the level $4f^36s^2\ {}^4I_{9/2}$, Lew obtained $A({}^5I_{9/2})=926.02\ \mathrm{Mc/sec}=0.0308891\ \mathrm{cm}^{-1}$.

Since the spin-orbit coupling parameter of the $4f$ electron ($\zeta=682.6$) of Pr I is small, we can assume that the configuration $4f^3$ is of LS-coupling.

If the $4f^36s^2$-configuration of Pr I were pure, we could calculate a_{4f} according to the usual formula

$$A(f^3\ {}^4I_{15/2})=\frac{176}{225}a_f\ ,$$

$$A(f^3\ {}^4I_{13/2})=\frac{2612}{2925}a_f\ ,$$

$$A(f^3\ {}^4I_{11/2})=\frac{14920}{14157}a_f\ ,$$

$$A(f^3\ {}^4I_{9/2})=\frac{476}{363}a_f\ .$$

Under this assumption, we get $a_{4f}=0.0230\ \mathrm{cm}^{-1}$ from ${}^4I_{11/2}$ and $a_{4f}=0.02356\ \mathrm{cm}^{-1}$ from ${}^4I_{9/2}$.

This discrepancy can be interpreted by assuming that the term $4f^36s^2\ {}^4I$ is mixed with $4f^36s7s\ {}^4I$, etc. We can put

$$\begin{aligned}4f^36s^2\ {}^4I'_{9/2}=K_1 4f^36s^2\ {}^4I_{9/2}&+K_2 4\overrightarrow{f}^3\overleftarrow{6}s\overrightarrow{7}s\ {}^4I_{9/2}\\ &+K_3 4\overrightarrow{f}^3\overrightarrow{6}s\overleftarrow{7}s\ {}^4I_{9/2}+\cdots\ ,\\ K_1\approx 1\ .&\end{aligned}$$

As a first approximation we may cut off the series at K_3 and assume

$$A({}^4I'_{9/2})=K_1^2\frac{476}{363}a_{4f}+\frac{3}{11}X(a(6s),\ a(7s),\ K_2,\ K_3)\ .$$

Putting $A=0.03089\ \mathrm{cm}^{-1}$, $a_{4f}=0.0227\ \mathrm{cm}^{-1}$ (this value was obtained from Pr II), $K_1=1$ in this expression, we get $X=0.0041$.

As a rough approximation we can assume

$$A({}^4I'_{11/2})=K_1^2\frac{14920}{14157}a_{4f}+\frac{5}{143}Y\ .$$

Putting $A=0.02425\ \mathrm{cm}^{-1}$, $a_{4f}=0.0227\ \mathrm{cm}^{-1}$, $K_1=1$ in this expression, we get $Y=0.009$.

X and Y have the same sign and are of the same order of magnitude. We may therefore consider $a_{4f}=0.0227\ \mathrm{cm}^{-1}$ to be appropriate for the hfs of Pr I.

§ 4. Hyperfine Structure of Pr II

In the previous work[1] hfs of some levels of the configuration $4f^36s$ was measured. In the present work no extension was made, except that the hfs of the line λ4189.5 ($4f^36s\ {}^5I_7-z^5I_7$)[3] was measured. The interval factor of the lower level was found to be $0.0441\ \mathrm{cm}^{-1}$. This is not so accurate, however, owing to the existence of close lying line.

As before, let us assume that the group of electrons $4f^3$ is of LS-coupling, to which the $6s$ electron is combined via intermediate coupling. Then the energy matrix is as given in Table I.

Table I. Energy matrix of $f^3s\ {}^{5,3}I$ in LS-coupling ($\zeta\equiv\zeta_f$).

$J=8$,	${}^5I$	$-3G+3\zeta$	
$J=7$,	${}^5I$	$-3G+\zeta$	$-\zeta$
	${}^3I$	$-\zeta$	$G+\frac{5}{2}\zeta$
$J=6$,	${}^5I$	$-3G-\frac{3}{4}\zeta$	$-\frac{1}{4}\sqrt{\frac{55}{3}}\zeta$
	${}^3I$	$-\frac{1}{4}\sqrt{\frac{55}{3}}\zeta$	$G-\frac{5}{12}\zeta$
$J=5$,	${}^5I$	$-3G-\frac{9}{4}\zeta$	$-\frac{1}{4}\sqrt{\frac{35}{3}}\zeta$
	${}^3I$	$-\frac{1}{4}\sqrt{\frac{35}{3}}\zeta$	$G-\frac{35}{12}\zeta$
$J=4$,	${}^5I$	$-3G-\frac{7}{2}\zeta$	

Fitting the observed levels to the energy matrix, the parameter values $\zeta=682.6$ and $G=243$ were obtained. Then the compositions of the levels were determined by the usual method; the result of the calculations follows.

$$\psi_J=K_1\ {}^5I_J+K_2\ {}^3I_J\ .$$

$$\left\{\begin{array}{lll}{}^5I_7': & K_1=0.955\ , & K_2=0.295\ ,\\ {}^3I_7': & K_1=-0.295\ , & K_2=0.955\ .\end{array}\right.$$

$$\left\{\begin{array}{lll}{}^5I_6': & K_1=0.903_5\ , & K_2=0.428_5\ ,\\ {}^3I_6': & K_1=-0.428_5\ , & K_2=0.903_5\ .\end{array}\right.$$

$$\left\{\begin{array}{lll}{}^5I_5': & K_1=0.839\ , & K_2=0.544_5\ ,\\ {}^3I_5': & K_1=-0.544_5, & K_2=0.839\ .\end{array}\right.$$

Let us first assume that there is no configuration mixing. Then the hfs interval factor for $J=7, 6, 5$ is given by

$$A_J=K_1^2A({}^5I_J)+2K_1K_2A({}^{3,5}I_J)+K_2^2A({}^3I_J)\ .$$

The expression for $A(I_J)$ follows.

$$A({}^5I_8)=\frac{11}{15}a_f+\frac{1}{16}a(s)\ ,$$

$$A({}^5I_7)=\frac{86}{105}a_f+\frac{5}{112}a(s)\ ,$$

$$A({}^{3,5}I_7)=\frac{1}{140}a_f+\frac{3}{56}a(s)\ ,$$

$$A({}^3I_7)=\frac{53}{63}a_f-\frac{1}{28}a(s)\ ,$$

$$A({}^5I_6)=\frac{4343}{4620}a_f+\frac{1}{56}a(s)\ ,$$

$$A({}^{3,5}I_6)=\frac{13}{126}\sqrt{\frac{1}{165}}a_f+\frac{\sqrt{165}}{168}a(s)\ ,$$

$$A({}^3I_6)=\frac{743}{756}a_f-\frac{1}{168}a(s)\ ,$$

$$A({}^5I_5)=\frac{743}{660}a_f-\frac{1}{40}a(s)\ ,$$

$$A({}^{3,5}I^5)=\frac{\sqrt{105}}{1485}a_f+\frac{\sqrt{105}}{120}a(s)\ ,$$

$$A({}^3I_5)=\frac{1421}{1188}a_f+\frac{1}{24}a(s)\ ,$$

$$A({}^5I_4)=\frac{476}{330}a_f-\frac{1}{10}a(s)\ .$$

Table II. Interval factor of $4f^36s\ {}^5I$ and ${}^3I$.

	obs.	calc.
$A({}^5I_8)$	0.0437	0.0433
$A({}^5I_7)$	~0.0441	0.0476
$A({}^3I_7)$	—	−0.0061
$A({}^5I_6)$	0.0536	0.0526
$A({}^3I_6)$	—	−0.0039
$A({}^5I_5)$	0.0622	0.0572
$A({}^3I_5)$	−0.0032	0.0026
$A({}^5I_4)$	−0.0100	(−0.0100)

Fitting the observed hfs to these formulas, we get, as before, the values $a_{4f}=0.0227\ \mathrm{cm}^{-1}$ and $a(6s)=0.426\ \mathrm{cm}^{-1}$, (Table II).

In reality the term $4f^36s^{5,3}I$ is mixed with $5s4f^36s^2\ {}^{5,3}I$, $5s4f^36s7s^{5,3}I$, etc.

If we cut off the series at $5s4f^36s^2\ {}^{5,3}I$, it can be seen that in the above-mentioned calculation for a_{4f}, the contribution from $5s$ and $6s$ almost vanishes, and the value $a_{4f}=0.0227\ \mathrm{cm}^{-1}$ seems to be accurate to about 1.5%. The expression for $a(6s)$, however, is now somewhat invalid and is slightly dependent on $a(5s)$. We may assume therefore that the value $a(6s)=0.426\ \mathrm{cm}^{-1}$ is in reality to be slightly modified, and the magnetic moment $\mu(\mathrm{Pr}^{141})=+4.0\pm0.1$ n.m. (that was given previously) suffers a slight change and is now

$$\mu(\mathrm{Pr}^{141})=+4.0\pm0.2\ \text{n.m.}\ .$$

This is in good agreement with $3.9_2\pm0.2$ n.m. obtained by Baker and Bleaney[4] by means of paramagnetic resonance experiment.

On the Viscosity of Irradiated Polymers. III. Effect of Branching

By Kanji KATSUURA*

Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received August 24, 1960)

The intrinsic viscosity of an irradiated polymetric substance is calculated with inclusion of the effect of branching. The contribution of a branched polymer to the intrinsic viscosity is evaluated according to Debye-Bueche's theory with some modifications. The distribution of molecular size and crosslink unit is obtained through an extention of the Saito's theory. Our results agree with experiment fairly well. The essential reason for the large discrepancy between Saito's calculation and experiment is shown to be his neglect of branching.

§ 1. Introduction

In a polymeric substance under irradiation, crosslinking between a pair of polymers and scission of a polymer take place simultaneously. This leads to a polymer with long branches and changed molecular size and results in changes in the distribution of molecular size and crosslink unit in the polymeric system. Among many properties which depend on the distribution, we are interested in the intrinsic viscosity.

In general, a theoretical treatment of properties of a branched polymeric substance confronts with two problems. Firstly, we must know the property of a branched molecule, and secondary, the distribution of molecular size and crosslink unit.

In connection with the first problem, Kirkwook-Riseman1) and Debye-Bueche2) gave different approaches to the contribution to the intrinsic viscosity of a polymer molecule. Here we will follow the Debye-Bueche's approach because of its mathematical simplicity.

Concerning the second problem, a theory of the molecular size and crosslink unit distribution was presented by Stockmayer3), but unfortunately his method is inconvenient for the calculation of the intrinsic viscosity. From a quite different point of view, Saito4)5) developed a more general and convenient theory of molecular size distribution in terms of an integro-differential equation. He could calculate the intrinsic viscosity according to simple Staudinger's rule neglecting the effect of branching.6) We will obtain the molecular size and crosslink unit distribution of an irradiated polymeric system according to Saito's method and evaluate the intrinsic viscosity taking the effect of branching into account. The closest parallel to our development will be found in the work of Kilb,7) who evaluated the intrinsic viscosity using Kirkwood-Riseman's theory and Stockmayer's distribution function.

In Section 2, the distribution function will be obtained. The contribution to the intrinsic viscosity of a branched polymer molecule will be evaluated in Section 3. In Section 4, the intrinsic viscosity of an irradiated polymeric substance will be obtained when the initial molecular distribution is Poisson-like. For more general initial molecular size distributions, the intrinsic viscosity will be derived for small radiation doses in Section 5. In Section 6, our theoretical results will be compared with experimental data.

§ 2. The Molecular Size and Crosslink Unit Distribution

Through our calculation we make the following assumptions: (1) the number of crosslinks or scissions is proportional to radiation dose: (2) crosslinks and scissions occur at random: (3) the number of crosslinks is small compared with the total number of monomer units: (4) the cyclization, a crosslink within a molecule, can be neglected.

A polymer molecule will be specified by the degree of polymerization p and the number of crosslink units n_c. For convenience, we will use one half of the number of chain ends $q=n_c+1$ instead of crosslink units. We define the molecular size and chain end distribution $n(p,q,R)\,dpdq$ of a polymeric system as the number of polymers whose degree of polymerization lies between p and $p+dp$, one half of the number of chain ends between q and $q+dq$ when the system has been irradiated up to radiation dose R.

---

* On leave from the Kurashiki Rayon Co., Ltd., Osaka, Japan.

To calculate $n(p,q,R)$, we will follow closely Saito's formulation[4)], though we make some necessary generalization.

a) The case when only crosslinks occur. When the radiation dose increases from R to $R+dR$, $n(p,q,R)$ loses $pn(p,q,R)2cdR$ and gains

$$\frac{1}{2N}\int_0^q ds\int_0^p dl(p-l)n(l,S,R)n(p-l,q-s,R)2cdR$$

according to Saito. Here N is the total number of monomers, and $2c$ is the probability that a monomer crosslinks with another monomer by irradiation of unit dose. $2c$ corresponds to Charlesby's α[8)]. Putting

$$cR=t,$$

$$n(p,q,R)/N=n(p,q,R) \text{ or } m(p,q,t),$$

we get

$$\frac{\partial m(p,q,t)}{\partial t}=-2pm(p,q,t)$$
$$+\int_0^q ds\int_0^p dll(p-l)m(l,s,t)m(p-l,q-s,t). \quad (1)$$

Hereafter we will call the normalized molecular size and chain end distribution function $m(p,q,R)$ simply the distribution function. The Laplace transform of $m(p,q,t)$, i. e.

$$f(z,x,t)=\int_0^\infty dq\int_0^\infty dpm(p,q,t)e^{-zp}e^{-xq} \quad (2)$$

satisfies the following equation:

$$\frac{\partial f}{\partial t}=2\frac{\partial f}{\partial z}+\left(\frac{\partial f}{\partial z}\right)^2. \quad (3)$$

The equation can be solved to give

$$\left.\begin{aligned}&f(z,x,t)=G(z_0,x)-\{G'(z_0,x)\}^2t,\\&z=z_0-2\{1-G'(z_0,x)\}t,\end{aligned}\right\} \quad (4)$$

where

$$G(z_0,x)=f(z_0,x,0), \text{ and } G'(z_0,x)=\partial G(z_0,x)/z_0$$

It should be noted that Eq. (3) has just the same form as Eq. (7) in Saito's paper I,[4)] so that the solution is also given by (4) which is similar to Eq. (8) in that paper. But, in our case f depends on x parametrically and this parametric dependence on x is essential in our following treatment.

b) The case when only scissions occur. We first note that, when only scissions occur, the distribution function for a system of linear molecules has the form

$$m(p,q,R)=\delta(q-1)m^\dagger(p,R),$$

because a scission of a linear molecule never gives a branched molecule. Saito has obtained the molecular size distribution $m^\dagger(p,R)$:

$$m^\dagger(p,R)=e^{-prR}\Big\{m^\dagger(p,0)+2rR\int_p^\infty m^\dagger(p,0)dp$$
$$+(rR)^2\int_p^\infty dp\int_p^\infty m^\dagger(p,0)dp\Big\}, \quad (5)$$

where r stands for the probability of scission per unit monomer per unit radiation dose, which Charlesby called β[8)].

c) The case when crosslinks and scissions simultaneously. Suppose we break virtually all the crosslinks in an irradiated polymeric system, then the distribution function will be given as in the case **b**, if the polymeric system had initially no crosslink units. Then we restore all the crosslinks. By this procedure we obtain the real distribution function corresponding to the irradiated system in terms of the Laplace transform, namely Eq. (4) solved under the initial condition $\delta(q-1)$ $m^\dagger(p,R)$ given by (5).

§ 3. The Contribution of a Branched Molecule to the Intrinsic Viscosity.

Following Debye-Bueche's theory, the contribution $\eta(p,q)$ to the intrinsic viscosity of a branched molecule can be expressed as

$$\eta(p,q)\propto p^\alpha g(q,p)^{2-\alpha}, \quad (6)$$

$$g(q)=\frac{R_e(p,q)^2}{R_e(p,o)^2}, \quad (7)$$

on the assumption that the proportionality of $R_e^2(p,q)$ to the degree of polymerization p. Here $R_e(p,q)$ represents the effective radius of the polymer molecule with the degree of polymerization p and the number of end points q. The exponent α of p in (6) corresponds to that of the Standinger's empirical law. We will regard it as constant for the present, though it should depend on p and q from a more rigorous viewpoint.

Consequently the effect of branching on the intrinsic viscosity only appears through the effective radius. So we should like to know $R_e(p,q)$ as a function of p and q, but it is beyond the scope of this theory to get the exact functional form of $R_e(p, q)$. Now we are forced to adopt the conventional assumption that R_e^2 is proportional to the mean square radius R^2 averaged over all the possible configurations.

The mean square radii of branched molecules have been calculated by Stockmayer[9] and more generally by Kataoka[10], on the assumption that the chains constituting polymer molecules obey random flight statistics. Kataoka obtained the following equation for R^2, when a polymer molecule contains merely branch units of equal functionality and no rings:

$$R^2=\frac{a^2p}{n_b(n_b+1)(n_b+2)}(n_b^2+\sum_{(k,l)}\nu_{kl}), \tag{8}$$

where a indicates the effective bond length, and n_b represents the number of branches in the molecule. A branch means a chain lying between a branch unit and an adjacent branch unit or chain end. ν_{kl} is the number of branches constituting a chain which connects two branches named k and l. Summation should be carried out over all the pairs of branches. Eq. (8) was derived by taking an average over all the molecules having same values of p, n_b and $\sum_{(k,l)}\nu_{kl}$. By (8) Kataoka could obtain g for crosslinked molecules of the normal form, one of which is shown in Fig. 1a.

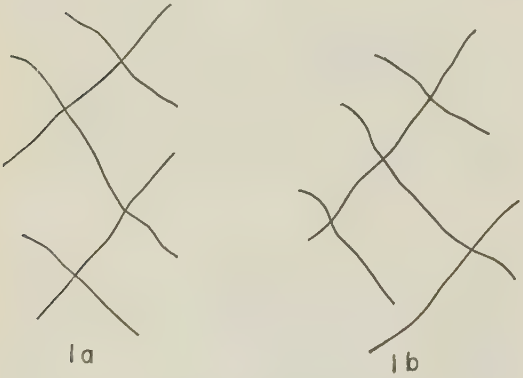

Fig. 1. Forms of crosslinked molecules.

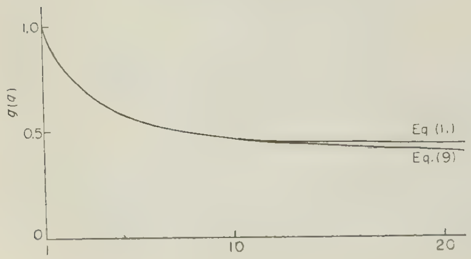

Fig. 2. Values of $g(q)$ plotted against q.

$$g(q)=\frac{3q^3+9q^2-18q+8}{q(3q-1)(3q-2)}. \tag{9}$$

We draw the curve of (9) in Fig. 2.

When the number of crosslink units is larger than four, polymer molecules of different forms, as shown in Fig. 1b, come into existence. These molecules have smaller R's than the molecule of the normal form with same p and n_b. We use, however, Eq. (9) because it may differ from the exact value only by ten percents at the largest. (See Appendix)

§ 4. The Intrinsic Viscosity. I. Poisson Distribution.

In this section we will evaluate effects of radiation on the intrinsic viscosity of a polymeric substance initially composed of linear molecules and having a Poisson-like molecular size distribution. With the aid of the result in the preceding Section, the intrinsic viscosity $[\eta]$ of the irradiated polymeric system can be expressed as

$$[\eta]=K\int_0^\infty dq\int_0^\infty dp p^\alpha g(q)^{2-\alpha} p m(p, q, R). \tag{10}$$

For mathematical simplicity, we approximate $g(q)^{2-\alpha}$ by a finite Dirichlet series.

$$g(q)^{2-\alpha}=Ae^{-aq}+Be^{-bq}+C. \tag{11}$$

The values of these coefficients are given in Table I, and the curve (11) is traced in Fig. 2 when $\alpha=1$.

Table I.

α	Ae^{-a}	Be^{-b}	C	e^{-a}	e^{-b}
1.0	0.466	0.102	0.431	0.737	0.243
0.9	0.484	0.119	0.397	0.735	0.250
0.8	0.498	0.137	0.365	0.733	0.256
0.7	0.509	0.155	0.336	0.731	0.261
0.6	0.518	0.173	0.309	0.278	0.264
0.5	0.524	0.192	0.284	0.726	0.266

First we suppose only crosslinks occur. Then

$$[\eta]=K\{AJ(a)+BJ(b)+CJ(0)\}, \tag{12}$$

where

$$J(a)=\int_0^\infty dq\int_0^\infty dp p^{\alpha+1}e^{-aq}m(p, q, t). \tag{13}$$

Making use of the equation obtained by Saito[6)],

$$\int_0^\infty p^{\alpha+1} m(p,q,t)dp=$$

$$\frac{e^{\alpha\pi i}\Gamma(\alpha+2)}{2\pi i}\int_c \frac{dz}{z^{\alpha+2}}\int_0^\infty m(p,q,t)e^{-zp}dp, \qquad (14)$$

we obtain

$$J(a)=\frac{e^{\alpha\pi i}\Gamma(\alpha+2)}{2\pi i}\int_c \frac{dz}{z^{\alpha+2}} f(Z,a,t). \qquad (15)$$

The integration should be performed along the contour C in Fig. 3. Substituting (4) into (15), we get

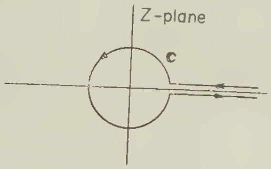

Fig. 3. Contour of integration.

$$J(a)=\frac{e^{\alpha\pi i}\Gamma(\alpha+2)}{2\pi i}\int_c \frac{dz}{z^{\alpha+2}}\{G(z_0,a)-G'(z_0,a)t\} \qquad (16)$$

$$=\frac{1}{\Gamma(1-\alpha)}\int_{\rho=0}^{\rho=\infty}\frac{G''(\rho_0,a)}{\rho^\alpha}d\rho_0, \qquad (17)$$

where

$$\rho=\rho_0-2\{1+G'(\rho_0,a)\}t. \qquad (18)$$

In the case $a=0$, Saito[6)] derived (17). This procedure could be easily extended to our case, $a \neq 0$.

The initial distribution function is now

$$m(p,q,0)=u^{-2}e^{-p/u}\delta(q-1), \qquad (19)$$

where u is the number average degree of polymerization.

$$G(\rho_0,a)=f(\rho_0,a,0)$$
$$=\int_0^\infty dp\int_0^\infty dq\, m(p,q,0)e^{-\rho_0 p}e^{-aq}$$
$$=u^{-1}(1+u\rho_0)^{-1}e^{-a}. \qquad (20)$$

Substitute (20) into (17) and put $(1+u\rho_0)^{-1}=y$. Then we get

$$J(a)=\frac{2u^\alpha e^{-a}}{\Gamma(1-\alpha)}\int_0^{y_0}\frac{y^{1+\alpha}}{\{1-y-2ut(1-e^{-\alpha}y^2)\}^\alpha}dy, \quad (21)$$

where y_0 is the root of the equation

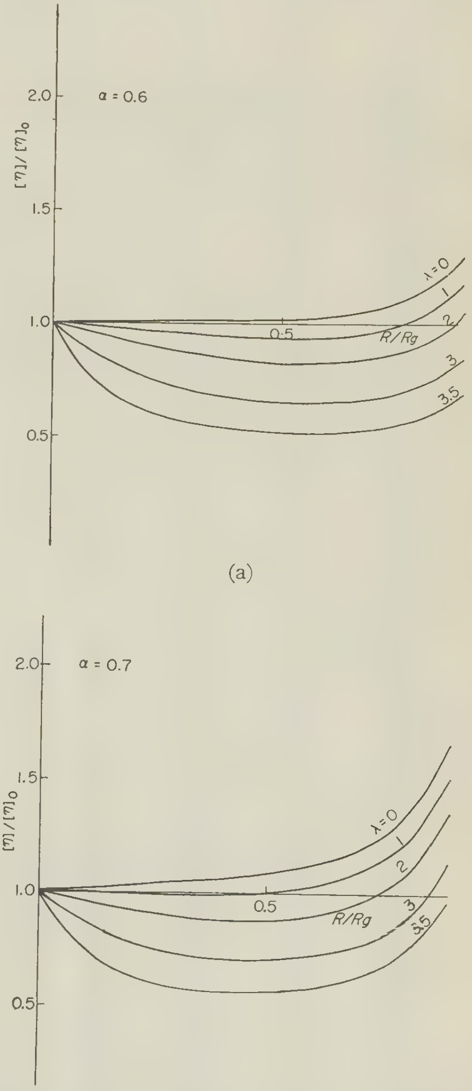
$$1-y-2uty(1-e^{-a}y^2)=0 \qquad (22)$$

that tends to unity when a tends to zero.

When scissions occur in addition to cross-linking, we should use the following distribution function as the initial distribution.

$$m(p,q,R)=(u/1+ruR)^{-2}$$
$$\exp[-p(u/1+ruR)^{-1}]\delta(q-1). \qquad (23)$$

This leads to $J(a)$ having $(u/1+ruR)$ instead of u. Numerical calculations were carried out using a high speed electronic computor, TAC. For various values of α and r/c, we obtained the ratio $[\eta]/[\eta]_0$, where $[\eta]_0$ indicates the intrinsic viscosity before irradiation. These results are given in Table II. In Fig. 4, we draw $[\eta]/[\eta]_0$ against R/R_g, where R_g is the dose at incipient gelation, which occurs when $4c>r$.



(a)

(b)

Fig. 4. The ration $[\eta]/[\eta]_0$ against R/R_g.

§ 5. The Intrinsic Viscosity. II. Small Radiation Doses.

In this Section, we will evaluate the effect of the initial molecular size distribution on the viscosity-dose curve at small radiation doses. To clarify the relationship between the initial molecular size distribution and the radiation-induced change of the intrinsic viscosity, Inokuti[11] has discussed the coefficient $A_1(\lambda, \alpha)$ in the following expansion:

$$[\eta]/[\eta]_0=1+A_1(\lambda, \alpha)R+A_2(\lambda, \alpha)R^2+\cdots. \quad (24)$$

Table II. The Values of $[\eta]/[\eta]_0$ when the initial molecular size distribution is Poisson-like.

He did not take the effect of branching into account, however. Considering the effect, we followed the method and could obtain A_1 for a system initially composed of linear molecules. By use of notations;

$$f_{\alpha+1}=\int_0^\infty p^{\alpha+1}m^\dagger(p, 0)dp, \quad (25)$$

$$I(\alpha)=\int_0^\infty dp\,p^{\alpha+1}\int_0^p dl\,l(p-l)m^\dagger(l,0)m^\dagger(p-l,0), \tag{26}$$

where $m^\dagger(p,0)$ indicates the initial molecular size distribution, A_1 can be expressed as follows:

$$A_1=-\frac{c\alpha}{\alpha+2}\cdot\frac{f_{\alpha+2}}{f_{\alpha+1}}(\lambda-\lambda_0), \tag{27}$$

where

$$\lambda_0=\frac{\alpha+2}{\alpha}\left\{g(2)^{2-\alpha}\frac{I(\alpha)}{f_{\alpha+2}}-2\right\}. \tag{28}$$

If we put $g(2)=1$, namely if we assume that a polymer molecules with one crosslink unit has the same R_e as the linear molecule with the same degree of polymerization, our result coincides with Inokuti's. The quantities $f_{\alpha+2}$ and $I(\alpha)$ have been calculated for several molecular size distributions by him[11)] and by him and the author.[12)]

For

$$m^\dagger(p,0)=\frac{b^{b+1}}{u^2\Gamma(b+1)}\left(\frac{p}{u}\right)^{b-1}e^{-bp/u}, \tag{29}^*$$

$f_{\alpha+1}$ and $I(\alpha)$ are given as follows:

$$f_{\alpha+2}=(u/b)^{\alpha+1}\Gamma(b+2+\alpha)/\Gamma(b+1), \tag{30}$$

$$I(\alpha)=(u/b)^{\alpha+1}\Gamma(2b+3+\alpha)/\Gamma(2b+2). \tag{31}$$

Then

$$A_1=-\frac{c\alpha u}{\alpha+2}\left(1+\frac{\alpha+1}{b}\right)(\lambda-\lambda_0), \tag{32}$$

where

$$\lambda_0=\frac{\alpha+2}{\alpha}\left\{g(2)^{2-\alpha}\frac{\Gamma(2b+3+\alpha)\Gamma(b+1)}{\Gamma(b+2+\alpha)\Gamma(2b+2)}-2\right\}. \tag{33}$$

If $\lambda<4$, namely $4c>r$, gelation occurs. The dose R_g at incipient gelation is

$$R_g=1/2cf_2=(2cu)^{-1}b/(b+1.) \tag{34}$$

We expand $[\eta]/[\eta]_0$ in powers of R/R_g.

$$[\eta]/[\eta]_0=1+a_1(R/R_g)+a_2(R/R_g)^2+\cdots. \tag{35}$$

$$a_1=A_1R_g=-\frac{\alpha}{2\alpha+4}\cdot\frac{b+1+\alpha}{b+1}(\lambda-\lambda_0). \tag{36}$$

We draw contours for constant a_1's on $\lambda-b$ plane for $\alpha=1$. (Fig. 5). Fig. 5 shows that a_1 increases with b and decreases with λ. The dependence of a_1 on b is strong when λ is near four.

§ 6. Comparison with Experiment.

Shultz et al[13)] measured the intrinsic viscosity of irradiated polystyrene in benzene. The experimental $[\eta]/[\eta]_0$ versus R/R_g are plotted in Fig. 6. The exponent α in the Staudinger's law is 0.74 for the benzene solution of polystyrene. The ratio $\lambda=r/c$ was obtained to be 0.74 by the measurement of the gel fraction according to Charlesby. Soito has shown, however, the Charlesby's method gave an overestimated value of λ because of the neglect of cyclization.[5)]

Kilb's measurement[7)] was made on dimethylsilicone oil. The data were plotted in

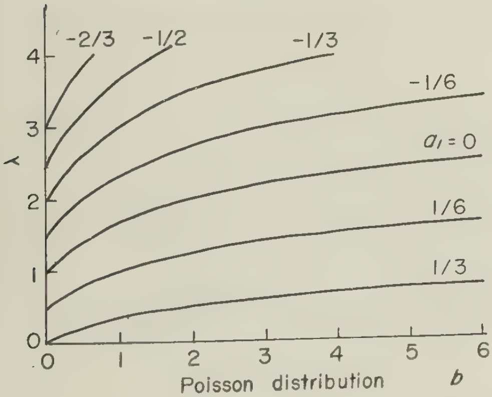

Fig. 5. Contours for constant a_1's on $\lambda-b$ plane.

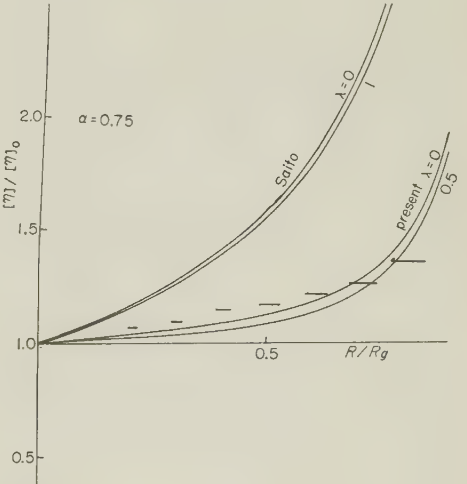

Fig. 6. The experimental $[\eta]/[\eta]_0$ of irradiated polystyrene in benzene, measured by Shultz, et al.

---

* We call (29) the generalized Poisson distribution. The parameter b is connected with the ratio of the weight average degree of polymerization P_w to the number average P_n in the following way:

$$P_w/P_n=1+1/b\,.$$

If $b=1$, (29) reduces to the Poisson distribution; and if $b=\infty$, to the uniform distribution.

Fig. 7. α is 0.79 for the toluene solution of the silicone polymer. The value of λ for this polymer is 0.1, which was obtatined by chemical techniques.

Our calculated $[\eta]/[\eta]_0$ coincides with these experiments fairly well as in Figs. 6 and 7. The effect of branching lowered Saito's curves* towards the observed values.

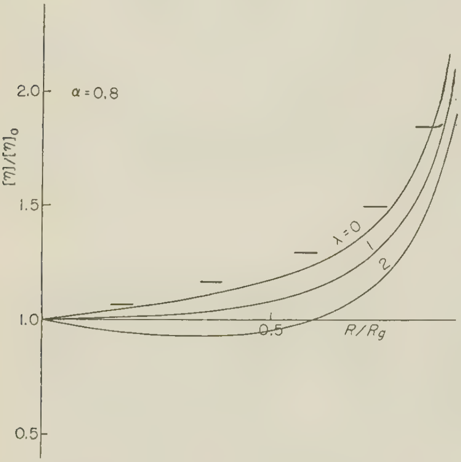

Fig. 7. The data of Kilb, of dimethylsilicone oil in toluene.

§ 7. Concluding Remarks.

We conclude that the large discrepancy between Saito's theory and experiment should be due to the neglect of the effect of branching. The present theory, however, is not yet satisfactory. It contains several ambiguous assumptions: (1) the proportionality of R_e^2 to R^2; (2) the neglect of cyclization; (3) the neglect of dependence of α on p and R_e.

Concerning (1) we note the recent work of Zimm and Kilb.[15] They proposed that the ratio of the intrinsic viscosity of branched molecule to that of a linear molecule of the same weight should be rather $\{R^2(q)/R^2(0)\}^{1/2}$ than $\{R^2(q)/R^2(0)\}^{2-\alpha}$, which we adopted. The other two assumptions (2) and (3) have never been examined quantitatively, but fortunately they should be valid at least for small radiation doses. This is one of the advantages of the theory at small radiation doses.

Besides, we can point out the following merits; firstly that the present theory at small radiation doses enables us to analyse experimental data of a polymeric substance whose initial distribution is not necessarily Poisson-like; secondly in the sense that it contains only $g(2)$, but not $g(q)(q \geqq 3)$, which is difficult to evaluate exactly.

In view of our conclusion, accurate measurements of the intrinsic viscosity at small doses are very desirable.

Acknowledgements

The author wishes to thank Professor A. Amemiya of the University of Tokyo and Professor O. Saito of the Chuo University for their helpful discussions and encouragements. Thanks are also due to Mr. M. Inokuti of the University of Tokyo for invaluable suggestions and advices during the work; to Dr. T. Watanabe of the Japan Atomic Energy Research Institute and Mr. Y. Hirano of the Kurashiki Rayon Co., Ltd. for their interest and valuable comments. Further, he is grateful to Dr. T. Murata and Dr. K. Nakazawa of the Electronic Computer Laboratory of the Faculty of Engineering, University of Tokyo for providing the author with opportunities for electronic computation.

Appendix: A Lower Limit of *g*

By (8) we get the following expression:

$$g=\frac{6}{n_b(n_b+1)(n_b+2)}\left(n_b^2+\sum_{(k,l)}\nu_{kl}\right). \qquad \text{(A1)}$$

We will estimate $\sum_{(k,l)}\nu_{kl}$ following a probability-theoretic argument. A molecule with n crosslink units has $2n+2$ chain ends, and each crosslink unit has four branches. So the probability P that one of the four branches attached to a crosslink unit does not reach a chain end but another crosslink unit is

$$\frac{4n-(2n+2)}{4n}=\frac{n-1}{2n}.$$

If the molecule has no ring structure, a crosslink unit C_i should be connected with another crosslink unit C_j through only one chain. We will obtain an average value of ν_{ij} the number of branches constituting the chain.

By use of P, we obtain the probability P_1 that one of the branches attached to C_i reaches directly C_j:

---

* In fact, Saito performed numerical evaluation of his expression (Eq. (10) in his paper III[6]) only for $\alpha=1/2$ and $\alpha=1$. For general values of α, numerical evaluation was made by the author.[14]

$$P_1=4{}_4C_4P^4\frac{1}{n-1}\cdot\frac{n-2}{n-1}\cdot\frac{n-3}{n-1}\cdot\frac{n-4}{n-1}$$
$$+3{}_4C_3P^3(1-P)\frac{1}{n-1}\cdot\frac{n-2}{n-1}\cdot\frac{n-3}{n-1}$$
$$+2{}_4C_2P^2(1-P)^2\frac{1}{n-1}\cdot\frac{n-2}{n-1}$$
$$+{}_4C_4P(1-P)^3\frac{1}{n-1}. \qquad \text{(A2)}$$

The first term represents the probability that one of the four branches reaches C_j and the other branches other crosslink units. The second stands for the probability that one reaches C_j, two other crosslink units, and the other a chain end. We should note that our approach leads to a finite probability that C_i does not connect with any other crosslink unit, namely that it is isolated. This is inconsistent with our starting point, since we have had a single molecular network in mind. But it is an inevitable failure of such a probability-theoretic approach as ours. It is clear, however, that our approach must give a lower limit to the exact value of $\sum_{(k,l)}\nu_{kl}$. Now we approximate $(n-2)/(n-1)$, $(n-3)/(n-1)$, and $(n-4)/(n-1)$ by unity in (A2) for simplicity. It will be easily seen that this approximation still assures the evaluation of a lower limit. With this approximation (A2) reduces to

$$P_1=4P\frac{1}{n-1}=\frac{2}{n}, \qquad \text{(A3)}$$

which permits a naive interpretation.

Similarly we can obtain P_2, the probability that $\nu_{ij}=2$.

$$P_2=4P\frac{n-2}{n-1}(4P-1)\frac{1}{n-1}=4P(4P-1)\frac{1}{n-1}. \qquad \text{(A4)}$$

Generally, the probability that $\nu_{ij}=k$ is given by

$$P_k=4P(4P-1)^{k\ \ 1}\frac{1}{n-1}. \qquad \text{(A5)}$$

Now the required quantity $\sum_{(k,l)}\nu_{kl}$ can be expressed as

$$\sum_{(k,l)}\nu_{kl}=9{}_nC_2\sum_{k=1}^{n\ \ 1}kP_k. \qquad \text{(A6)}$$

The factor 9 comes from the fact that a chain specified by crosslink units i, j should have weight 9 in the specification by means of branches k and l belonging to the crosslink units i and j, respectively. The summation yields

$$\sum_{(k,l)}\nu_{kl}=\frac{9n^2(n-1)}{4}\left\{1-\frac{3n-2}{n-2}\left(\frac{n-2}{n}\right)^n\right\}. \qquad \text{(A7)}$$

Substituting (A7) into (A1) and taking care of the relation $n_b=3n+1$, we obtain

$$\lim_{n\to\infty} g=\frac{1}{2}(1-3e^{-2})=0.297.$$

Ultrasonic Studies in Chemically Active Liquid Media
(1) Aqueous Solution of N_2O_4

By M. KRISHNAMURTHI

Director's Research Laboratories,
Indian Institute of Science, Bangalore (India)

and M. SURYANARAYANA

Department of Physics, Nizam College,
Hyderabad (India)

Using a pulse method the ultrasonic absorption has been studied in the frequency range of 2 to 10 Mc/s in dilute aqueous solutions of nitrogen tetroxide gas at room temperature. The absorption peaks ($\alpha\lambda$ vs frequency) observed in this study are attributed to the ionic dissociation reaction of the nitrous acid into its constituent ions. The rate constants of the forward and backward reactions are calculated using the theory of Tabuchi. The variation of the logarithm of the rate constant of the bimolecular ionic reaction, namely, $\log_{10} k_b$, with the square root of ionic strength qualitatively follows Brönsted's theory for ionic reactions in solutions.

§ 1. Introduction

The factors that contribute to the absorption of an ultrasonic wave as it propagates through a medium are, according to the classical theories, shear viscosity, thermal conduction and heat radiation in that order of importance. The coefficient of absorption α, due to viscosity and heat conduction increases as the square of the acoustic frequency f. In other words $\alpha\lambda$, the absorption per wavelength, increases almost linearly with frequency. During the past few years many liquids and solutions have been encountered where $\alpha\lambda$ instead of increasing linearly with frequency goes through a maximum at some frequency. At frequencies far away from this and on either side of it, α/f^2 remains constant as required by the classical theory. This behaviour is traced to the relaxation of the molecules of the liquid at that frequency. Various types of relaxation such as thermal relaxation and structural relaxation are envisaged. Besides these, it is now realized that the presence of a reversible chemical reaction in a liquid medium can also give rise to peaks in ultrasonic absorption. Theoretical considerations reveal that the frequency at which such a peak occurs is related to the rate of the reaction. In media where reversible chemical reactions are taking place, disturbances in the equilibrium between the various participants and products of the reaction may not be in phase with the changes in pressure produced by the sound wave, with the result that the absorption per wavelength $\alpha\lambda$ passes through a maximum near a characteristic frequency f_c. This is the case of a relaxation due to chemical reaction.

Einstein$^{1)}$ is probably the earliest to have interpreted the excess sound absorption in terms of relaxation due to a chemical reaction. Liebermann$^{2)}$ used the concept to explain the excess absorption in the aqueous solutions of magnesium sulphate. But, Freedman$^{3)}$ and independently, Manes$^{4)}$, have considered the absorption of sound in liquid media in general chemical equilibrium. In the development of the theory they made some simplifying assumptions. For example, Freedman assumed that the volume change due to chemical reaction is zero. Recently, Tabuchi$^{5)}$ developed a more generalized theory which connects the kinetics of chemical reaction with the dispersion and absorption of sound in liquids. He showed that if the necessary simplifying assumptions are made in his theory, the equations approximate to those derived by Freedman and Manes. Another interesting feature of Tabuchi's theory over that of Freedman and Manes is that it is extended to include the electrolyte solutions also.

The present work deals with the study of ultrasonic absorption in aqueous solutions of nitrogen tetroxide. The peaks of absorption observed in this study are attributed to the ionic dissociation of the nitrous acid. Tabuchi's theory is used to calculate the rate constants of the ionic reaction mentioned above. The essential equations of Tabuchi's theory used in these calculations will now be given briefly.

§ 2. Tabuchi's Theory

Let the molecules of the type $A, B, \cdots Q, R, \cdots$ be contained in a liquid whose volume is v and assumed to be in the chemical equilibrium

$$a \cdot A + b \cdot B + \cdots \rightleftharpoons q \cdot Q + r \cdot R + \qquad (1)$$

An arbitrary molecule is denoted by i and n_i represents the number of moles of the molecule i. When a sound wave passes through the liquid the total number of moles of each species changes periodically with time depending on the frequency. This is usually accompanied by change in volume as well as the internal energy. Taking into account these two factors, Tabuchi derives equations for the curves showing the variation of the velocity and absorption with the acoustic frequency. He also connects the equations for these curves with the relaxation time τ, the rate constants k_f and k_b of the chemical reaction and arrives at the equation

$$\chi(1+i\omega\tau)\frac{\Delta nq}{q} + \xi\frac{\Delta v}{v} - \left(\frac{E}{RT^2}\right)\Delta T = 0 \qquad (2)$$

where ω is the acoustic circular frequency and E is the reaction heat at constant volume of the chemical reaction and χ and ξ are defined as follows:

$$\chi = \sum_A \frac{a^2}{n_A} + \sum_Q \frac{q^2}{n_Q}, \qquad (3)$$

and

$$\xi = \sum_A a - \sum_Q q, \qquad (4)$$

also

$$\frac{1}{\tau} = r_f \cdot v \cdot \chi$$

$$= r_f \cdot v \cdot \sum_A \frac{a^2}{n_A} + r_b \cdot v \cdot \sum_Q \frac{q^2}{n_Q}, \qquad (5)$$

in which r_f and r_b are the forward and backward reaction rates. The forward and backward reaction rates are related to the corresponding rate constants k_f and k_b by the equations

$$r_f = k_f\left(\frac{n_A}{v}\right)^a \left(\frac{n_B}{v}\right)^b, \qquad (6)$$

$$r_b = k_b\left(\frac{n_Q}{v}\right)^q \left(\frac{n_R}{v}\right)^r. \qquad (7)$$

In the application of this theory to electrolyte solutions, the activity coefficients of the molecular species have to be used in the rate equations. This involves necessary changes in the equations given above.

Fur a uni-univalent electrolyte dissociating into two ions such as

$$A \rightleftharpoons B^+ + C^-,$$

where $a=1$; $b=1$; $c=1$; the valencies $Z_A=0$; $Z_B=1$; $Z_C=-1$ the general equations are reduced to

$$\chi = \left(\frac{1}{n_A} + \frac{1}{n_{B^+}} + \frac{1}{n_{C^-}}\right) - \log_e \frac{(f\pm)^2}{n_{B^+}+n_{C^-}}, \qquad (8)$$

and

$$\frac{1}{\tau} = k_f \cdot n_A \cdot \chi \qquad (9)$$

In equation (8) $f_\pm$ represents the mean activity coefficient of the ions B^+ and C^-.

Tabuchi further derives an equation for the complex velocity of sound in terms of the static isothermal compressibility, the density and the heat capacities $C_P{}^0$ and $C_V{}^0$ of the solution at zero frequency and C_P and C_V at infinite frequency of sound. The heat capacities are related by the equations

$$C_P{}^0 = \frac{W}{\chi} + C_P, \qquad (10)$$

$$C_V{}^0 = \frac{E^2}{RT^2\chi} + C_V, \qquad (11)$$

where W is a complicated function involving the partial molar volumes of the components of the reaction. He ultimately connects the characteristic values of the ultrasonic absorption curves (i.e. $\alpha\lambda$ vs ω curve) with the parameters defined previously. Thus he gets

$$\omega_{\max} = (C_P{}^0 C_V{}^0 / C_P C_V)^{\frac{1}{2}} / \tau, \qquad (12)$$

and

$$(\alpha\lambda)_{\max} = \pi/2 \frac{C_V{}^0 C_P - C_P{}^0 C_V}{(C_P{}^0 C_V{}^0 C_P C_V)^{\frac{1}{2}}}. \qquad (13)$$

§ 3. Experimental Technique

In this work, the pulse method of Pellam and Galt[6] is used with some modifications. Instead of a reflector on the receiving side another identical x-cut quartz crystal is used as a receiver of the traversed ultrasonic beam. The experiment is performed at four frequencies, namely 2.12, 3.23, 6.36 and 10.61

Mc/s. As observations are confined to the Fresnel region of the ultrasonic beam, frequencies below 2 Mc/s could not be employed.

A schematic diagram of the experimental arrangement is given in Fig. 1.

Nitrogen tetroxide gas is produced from dilute hydrochloric acid and sodium nitrite. The gas thus obtained is passed through distilled water. The strength of the solution is determined by titration using a standard potassium permanganate solution. The titration carried out before and after an ultrasonic observation does not differ by more than 2 percent. Only dilute solutions have been used in this work to ensure constancy of concentration during the observations and also to avoid bubbles of gas forming within the liquid under ultrasonic excitation. It is estimated that the error in the measurement of absorption is smaller than ±5 percent.

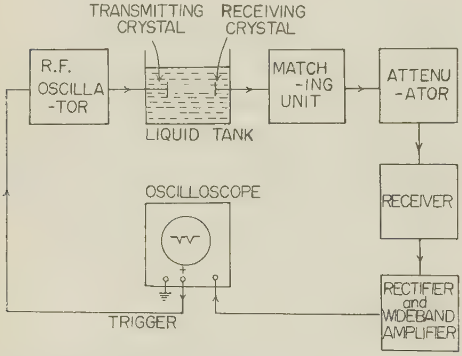

Fig. 1. Schematic diagram of the experimental arrangement.

§ 4. Results

The ultrasonic absorption α, is determined at various concentrations of the aqueous solutions of nitrogen tetroxide gas at 2.12, 3.23, 6.36 and 10.6 Mc/s and at a temperature close to 28°C. Curves connecting α/f^2 and concentration are drawn for each frequency. Values of α/f^2 are read out from these graphs for representative concentrations. For theoretical analysis of the results the excess absorption, (i.e., absorption over and above the classical contribution due to viscosity, heat conduction etc.) should be considered.

It is interesting to note that the ultrasonic velocity of the solution at any concentration is not significantly different from the velocity in the solvent even though the absorption is considerable. Fig. 2 shows the behaviour of $\alpha\lambda$ vs frequency at various concentrations. It is seen from this figure that the frequency of peak absorption increases with increasing concentration up to a limit after which it is independent of concentration. Preliminary results of this work have been reported earlier[7].

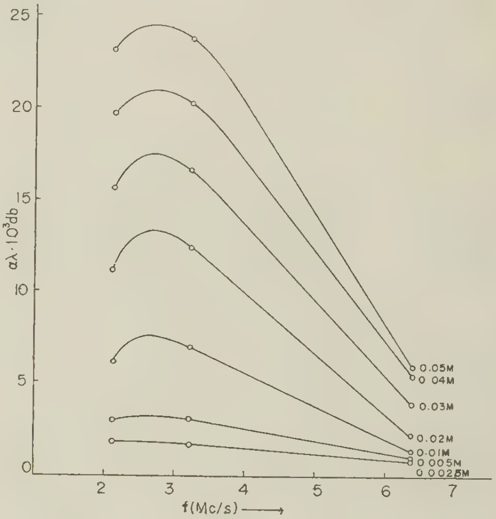

Fig. 2. Dependence of $\alpha\lambda$, the ultrasonic absorption per wavelength, on f, the frequency, in the aqueous solution of N_2O_4 at various concentrations (moles/litre).

§ 5. Discussion of the Results

Krishnamurthi[8] found a similar relaxation phenomenon in the case of aqueous solutions of sulphur dioxide near about 6 Mc/s. On the other hand, non-aqueous solutions of sulphur dioxide do not show such a relaxation thus excluding the possibility that the pure gas is causing the relaxation. The relaxation effect in the aqueous SO_2 solutions is, therefore, attributed to a dynamic chemical equilibrium between H_2SO_3 and H^+ and HSO_3^- ions.

Nitrogen tetroxide gas has been thoroughly studied by Richards and Reid[9),10)] and it is known to exhibit a frequency of peak absorption in the region of 400 Kc/s as compared to about 1 Mc/s for SO_2 gas. In aqueous solution, N_2O_4 undergoes a chemical change and a dynamic equilibrium[11] is set up as indicated by the equation II given below:

$$N_2O_4 + H_2O \rightarrow HNO_2 + HNO_3 \qquad \text{I}$$

$$HNO_2 \rightleftharpoons H^+ + NO_2^-. \qquad \text{II}$$

On an analogy with SO_2 solutions the aqueous solutions of N_2O_4 also must exhibit peaks of absorption. It is indeed the case (Fig. 2). Thus the relaxation effects observed in the case of the aqueous N_2O_4 solutions are attributed to the reversible chemical reaction II mentioned above.

As an additional check to show that the nitrite ion is causing the relaxation, the ultrasonic propagation in the aqueous solutions of sodium nitrite has been studied in the frequency range of 2 to 26 Mc/s. The results of this study are given in Table I. It is seen from this table that for any concentration of the aqueous solution of sodium nitrite, the absorption coefficient α/f^2 is not a constant for different frequencies in the range 2 to 10 Mc/s, thus indicating a relaxation effect in these solutions also in that frequency range.

Table I. Ultrasonic velocity and absorption in the aqueous solutions of sodium nitrite (29°C).

§ 6. Ultrasonics and Fast Reactions

The chemical reactions which take place between ions generally proceed very rapidly and are commonly called instantaneous reactions. The conventional chemical and physical methods of following the reactions are unsuitable in such cases. In addition, the usual methods of initiating a reaction by mixing becomes inadequate. One has to resort to indirect methods for measuring such fast reaction rates. One possibility is the use of ultrasonics for such a study.

When a chemical equilibrium exists in a solution, it can be disturbed by a rapid variation of pressure or temperature of the medium. The speed of the chemical reaction determines the extent to which it can keep up with this variation and observations can be made either directly or indirectly on the subsequent shifting of the equilibrium which proceeds with a finite time lag. This type of method (called the relaxation method) seems to be one of the most promising for investigating extremely fast reactions. Ultrasonic data have been used in the calculation of reaction rates of ionic reactions in aqueous solutions by some of the previous workers. The work done on the aqueous solutions of magnesium sulphate by Bies[12)], manganous sulphate by Kor and Verma[13)] and ammonia by Eigen and Schoen[14)] may be mentioned in this connection.

It is stated earlier that Tabuchi worked out the theory for determining the speed of a reversible chemical reaction from a study of the ultrasonic absorption and velocity. His theory is used here for finding the rate constants of the reaction II mentioned earlier. The method of arriving at the various parameters required in the evaluation of the rate constants will be given briefly.

The heat of reaction E for the ionic dissociation reaction is given in the international critical tables (Vol. V; p. 178, 1929). The degree of dissociation, δ can be calculated from the equilibrium constant K given in the International critical tables (Vol. VII; p. 239, 1929) by means of the relation

$$K=\frac{\delta^2\cdot c\cdot f^2{\pm}}{(1-\delta)},$$

where $f_\pm$ is the mean ionic activity coefficient. The mean ionic activity coefficient follows from the well-known Debye-Hückel's theory and is given by

$$-\log_{10}f_\pm=\frac{0.5\sqrt{\mu}}{1+\sqrt{\mu}}-0.1\mu,$$

where μ is the ionic strength of the solution being equal to $c(\delta+1)$ for a concentration of c moles per litre. Since K and $f_\pm$ both involves the degree of dissociation, we can calculate δ by the method of successive approximations. Since $f_\pm$ is nearly unity, a rough value of δ is determined from K by putting $f_\pm=1$. This value of δ is used to calculate $f_\pm$. The process is repeated till $f_\pm$ and δ remain constant. The values of n_A, n_B and n_C are obtained from the expressions $n_A=(1-\delta)c$ and $n_B=n_C=c\delta$.

The heat capacities $C_P{}^0$ and $C_V{}^0$ of the solutions at zero frequency are taken to be the same as those for water as we are dealing with dilute solutions. In these calculations $C_P{}^0$ and $C_V{}^0$ are expressed in heat capacities per mole of HNO_2.

The value of χ is calculated from equation (8) and is used in equation (11) for the evaluation of C_V, the heat capacity at constant volume for infinite frequency of sound.

Since the formula for C_P in equation (10) involves some uncertain parameters like the molar volumes of the ions taking part in the reaction, an indirect method of calculating C_P is adopted by the use of equation (13) where all the quantities are known except C_P. This equation uses $(\alpha\lambda)_{\max}$ in nepers while the curves (Fig. 2) give $\alpha\lambda$ in decibels and are to be converted to nepers.

From (12) the relaxation time of the chemical reaction is evaluated and finally used in the equation (9) to calculate the rate constant k_f of the forward reaction. The rate constant k_b of the reverse reaction can be calculated from the equilibrium constant $K=\frac{k_f}{k_b}$.

The following values are used in the calculations:

Heat of reaction	−3345 cal/mol
Formula weight (HNO_2)	47.02 g
Equilibrium constant	0.0005 mol/litre
$C_P{}^0$, Heat capacity per mole of HNO_2	46.96 cal/mol-deg.
$C_V{}^0$, Heat capacity per mole of HNO_2	46.35 cal/mol-deg.
Temperature	301°K

The various parameters used in the calculations and the rate constants are given in Table II.

The influence of the ionic strength μ on the velocity coefficient of a bimolecular reaction between charged particles in solutions is given by the equation (14) due to Brönsted[15)], namely,

$$\log_{10}\left(\frac{k_b}{k_0}\right)=q\cdot Z_A\cdot Z_B\cdot\sqrt{\mu}\,, \tag{14}$$

where k_0 is the velocity coefficient corresponding to zero ionic strength, Z_A and Z_B are the valencies of the reacting ions and q is a constant given explicitly by the theory of interionic attraction proposed by Debye and Hückel. For aqueous solutions at room temperature the value of q is nearly unity. In fact, at 29°C, q is equal to 1.025.

The theory thus implies that the logarithm

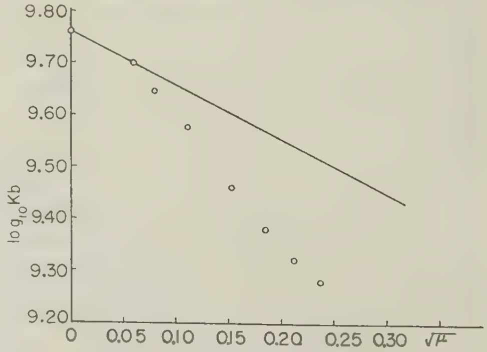

Fig. 3. Variation of $\log_{10} k_b$ with the square root of the ionic strength, μ, of the aqueous solutions of N_2O_4. The solid line is expected according to theory. The observed values are represented by (0).

of the velocity coefficient is a linear function of the square root of the ionic strength, the gradient being positive for reactions involving two ions of like sign and negative in the case of two ions of unlike sign. Further, the theory requires that the gradient should be nearly unity at room temperature when the reaction is between two univalent ions in aqueous solutions.

Fig. 3 represents the variation of $\log_{10} k_b$ with the square root of the ionic strength of the solutions studied in this work. It should be noted that in calculating the ionic strength of the solutions one should consider the valencies and concentrations of all the ionic species present in the solution. The chemical equation I given earlier shows that when N_2O_4 is dissolved in water both HNO_2 and HNO_3 are produced in equimolar quantities. While HNO_2 is weakly ionized, HNO_3 is completely ionized. These factors are taken into consideration in calculating the ionic strength of the solutions given in Table II.

The decrease of $\log_{10} k_b$ (Fig. 3) with the increase of the ionic strength indicates that the reaction involves two ions of opposite sign. The solid line represents the theoretically expected line according to equation (14). The value of k_0 of this equation is found by the extrapolation of the graph between k_b and the concentration of HNO_2. It can be seen from the graph that the experimental values show near agreement with the theory only at very low dilutions. In some cases of slow ionic reactions, it has been observed that the variation of $\log_{10} k_b$ with the ionic strength at low dilutions can be represented (reference 15 p. 110) to within ±20 per cent by Bronsted's equation (14). The study of fast ionic reactions is a subject of recent origin and until more experimental data accumulate it is not possible to compare the experimental results with the existing theory. However, it may be concluded that the variation of the reaction rate of fast ionic reactions qualitatively follows the predictions of the theory.

This work was carried out at the Physical Laboratories, Osmania University, Hyderabed. The authors thank Professor S. Bhagavantam for suggesting the problem and for his encouragement during the progress of this work.

Volume Viscoelasticity of Polymers and Other Highly Dissipative Materials

By Yasaku WADA, Hidenori HIROSE, Hiromichi UMEBAYASHI
and Motoharu OTOMO

Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received August 30, 1960)

A new method for determining the real and imaginary parts of bulk modulus of polymers and other solid materials is represented. The method, as is called "suspension method", consists of measurements of sound velocity and attenuation in a suspension of powders and is superior in experimental accuracy to the existing method which essentially consists of the comparison of longitudinal and shear wave measurements. The new method has also a merit in the applicability to the sample in powdery state.

The results are given for styrene-butadiene rubber, natural rubber, polyethylene, polypropylene, polytrifluoromonochloroethylene, paraffin and yeast cell, among which styrene-butadiene rubber is most fully investigated. From these results, the followings are concluded: In the primary dispersion of amorphous polymers, the relaxation strength is of the same order of magnitude for bulk and shear moduli, and moreover, relaxation times, their distribution and temperature dependence have no appreciable discrepancy between two moduli. In the case of crystalline polymers, the mechanical dispersions are quite different between the power samples which have undergone no treatment after polymerization and the ones moulded from the powder.

Nomenclature

K', K'':	Real and imaginary parts of complex bulk modulus of a solid, respectively.
G', G'':	Real and imaginary parts of complex shear modulus of a solid, respectively.
K_1:	Real part of bulk modulus of a liquid.
ρ, ρ_1:	Density of solid and liquid respectively.
η_1:	Shear viscosity of a liquid.
V, V_1:	Sound velocity in suspension and liquid, respectively.
α, α_1:	Attenuation coefficient of sound in suspension and liquid, respectively.
c:	Volume fraction of solid particles in a suspension.
a:	Average radius of particles.
f:	Frequency of sound. $\omega=2\pi f$.
λ:	Wave length of sound.
V_l, V_s:	Longitudinal and shear wave velocities in a solid, respectively.
α_l, α_s:	Longitudinal and shear wave attenuation coefficients in a solid, respectively.

§ 1. Introduction

The fact that there is a viscous energy-dissipating mechanism associated with pure volume deformation for many gases and liquids has been firmly established recently. In the case of polymers the information on this subject is not so extensive and rather contradictory. For the primary dispersion region of amorphous polymers, there exist three kinds of opinion about the relaxation of bulk modulus. Marvin et al.[1] have found the relaxation phenomena of bulk modulus to be of comparable order of magnitude with shear modulus in both relaxation strength and relaxation time, whereas Nolle and Sieck,[2] Cunningham and Ivey[3] have found that the relaxation strength of bulk modulus is much smaller than that of shear. Recently Kono[4] said that the relaxation strength is of the same order of magnitude for both moduli, but the relaxation time and its temperature dependence are quite different and accordingly different molecular mechanisms should be associated with volume and shear deformations. A recent theory by Nakada[5] supports the results by Marvin on the whole, though Nakada has pointed out a small difference in the relaxation mechanism between bulk and shear moduli.

There is a basic experimental problem involved in obtaining these data of complex bulk modulus. All the informations abovementioned come from a comparison of the velocity and attenuation of shear waves (governed by the shear modulus, G) and longitudinal waves (governed by both the shear and bulk moduli, $K+4G/3$). Since the attenuation of shear waves in polymers is generally very large, the observed values of velocity and attenuation are likely to include appreciable errors. When combined with longitudinal wave measurement, therefore, the calculated imaginary part of bulk modulus very probably has a large scatter.

For example, a set of values—$V_l=1945\ m/s$, $\alpha_e=0.94$ nepers/cm, $\rho=1.00$g/cc, $f=100$Mc/s—results in $K'=3.0\times10^{10}$, $G'=0.6\times10^{10}$, $K''=1.0\times10^{9}$, $G''=0.9\times10^{9}$ dyn/cm², when combined with $V_s=775$m/s and $\alpha_s=6.1$ nepers/cm. On the contrary, the same values give $K'=2.8\times10^{10}$, $G'=0.8\times10^{10}$, $K''=0$ and $G''=1.6\times10^{9}$ dyn/cm², when combined with $V_s=880$m/s and $\alpha_s=7.5$ nepers/cm. In fact, a scatter of this order of magnitude in the shear wave data is very probable to occur and yet the conclusions about K'' are quite contradictory: $K''\fallingdotseq G''$ from the former data and $K''\ll G''$ from the latter.

From this reason, in order to deduce any reliable conclusion, it is necessary to measure directly the real and imaginary parts of bulk modulus of a sample. A few attempts to this purpose have been made, using a transient technique[6] and a dynamic one.[7,8] But, up to this time at least, the published results are rather scanty. The present paper represents a new method (which we call the "suspension method") for the direct determination of complex bulk modulus of polymers and other solid materials, with some results for rubbers, crystalline polymers, paraffin and yeast cell in its living state.

§ 2. Suspension Method

The new method described here is based on the fact that, when sound waves propagate through a suspension, suspended particles undergo only volume deformation on account of the lack of shear elasticity in a liquid.

Urick[9] has shown a simple theory on the sound velocity in a suspension of finely divided solid particles whose density is similar to the suspending liquid. According to him, when the radius of particle is much smaller than the wave length, the velocity becomes

$$V=\left[\{\rho_1(1-c)+\rho c\}\left\{\frac{(1-c)}{K_1}+\frac{c}{K'}\right\}\right]^{-\frac{1}{2}} . \qquad (1)$$

When c is small, the above equation can be

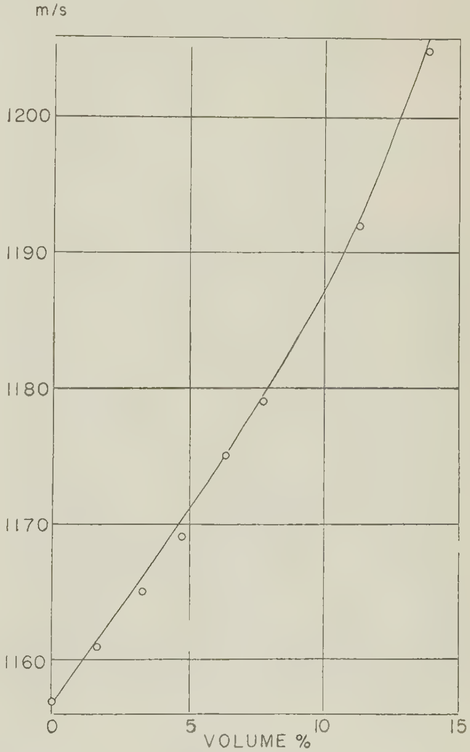

Fig. 1. Sound velocity at 1 Mc/s in polymethyl methacrylate suspension in methyl alcohol (10°C). Particles are perfectly spherical with average radius of 40μ. Solid line represents calculated values from Eq. (3), in which K' is estimated from longitudinal and shear wave velocity in a moulded plate of the polymer.

expanded as

$$V=V_1\left[1+\frac{1}{2}\left(\frac{K'-K_1}{K'}-\frac{\rho-\rho_1}{\rho_1}\right)c\right], \qquad (2)$$

where $V_1=(K_1/\rho_1)^{1/2}$.

Urick and Ament[10] have extended the theory to a more general case, where the particle and liquid are different in density and accordingly they oscillate in a sound field in different phase and amplitude. Assuming particles to be spherical, the velocity is given by

$$V=V_1\frac{1-\frac{1}{8}\left(\frac{vc}{1+uc}\right)^2}{\left[1-\frac{K'-K_1}{K'}c\right]^{\frac{1}{2}}[1+uc]^{\frac{1}{2}}}, \qquad (3)$$

where u and v are functions of ρ/ρ_1 and βa ($\beta=\sqrt{\omega\rho_1/2\eta_1}$) and graphically given in the original paper.

Eq. (3) is experimentally verified by the present authors as illustrated in Fig. 1.

For a dilute suspension, Eq. (3) can be approximated as

$$V=V_1\left[1+\frac{1}{2}\left(\frac{K'-K_1}{K'}-u\right)c\right]. \qquad (4)$$

Using Eq. (4) we can obtain the real part of bulk modulus of the particle from the measurement of sound velocity in a suspension.

Our primary concern, however, is with the imaginary part of bulk modulus. One of the present authors[11] has pointed out in an investigation of the attenuation of ultrasonic waves in a suspension of viscoelastic spheres that some parts of the attenuation should be attributed to the dynamic loss associated with volume deformation of particles, while the other parts are due to the well-known effects: the scattering of sound by particles and the viscous drag effect. The expression of attenuation coefficient due to the dynamic loss of particles, α_k, can easily be obtained as follows: When K' and V^{-1} in Eq. (2) are substituted by complex quantities, $K'+iK''$ and $V^{-1}-i\alpha_k/\omega$ respectively, it follows under the assumption $K''\ll K'$

$$\alpha_k=\left(\frac{\omega}{2V}\right)\frac{K_1K''}{K'^2}c\,. \qquad (5)$$

Eq. (5) is of course only valid under the same assumptions as for Eq. (2). A more general theory by Okano[12], however, has revealed that the same formula applies also to the case where ρ and ρ_1 are not similar.

Taking into consideration all the origins of attenuation, the total attenuation coefficient of a suspension can be written as

$$\alpha=\alpha_1+\alpha_s+\alpha_v+\alpha_k, \qquad (6)$$

where α_s and α_v are contributions from scattering and viscous drag effect respectively. Since α_s and α_v can be evaluated under some reasonable assumptions from the following equations respectively;[13 14]

$$\alpha_s=\left(\frac{\omega}{2V}\right)\left(\frac{\omega a}{V}\right)^3\left\{\frac{1}{3}\left(\frac{K'-K_1}{K'}\right)^2+\left(\frac{\rho-\rho_1}{2\rho+\rho_1}\right)^2\right\}c \quad (7)$$

and

$$\alpha_v=\left(\frac{\omega}{2V}\right)\frac{\frac{9}{4\beta a}\left(1+\frac{1}{\beta a}\right)\left(\frac{\rho-\rho_1}{\rho_1}\right)^2}{\left\{\frac{9}{4\beta a}\left(1+\frac{1}{\beta a}\right)\right\}^2+\left\{\frac{2\rho+\rho_1}{2\rho_1}+\frac{9}{4\beta a}\right\}^2}c, \quad (8)$$

we can obtain α_k, and hence K'', from observed value of α.

If the shear viscosity of the liquid medium is much smaller than the volume viscosity of the particle K''/ω, α_v becomes a negligible fraction of α. Furthermore, if the frequency of sound is so low that a/λ is small enough compared with unity, α_s also can be neglected. Under these conditions α_k becomes nearly equal to $(\alpha-\alpha_1)$. In fact this is the case with a suspension of polymer particles in water or alcohol measured by the sound whose wave length is more than twenty times the particle radius.

For Eqs. (4) and (5) to be a good approximation, the following conditions are required:

(1) The wave-length of sound waves must be large enough compared with the particle radius. Though a theoretical criterion is not attained here, experiments show the condition $a/\lambda\leqq 0.05$ to be satisfactory to the above requirement. For particles of radius 1μ, for example, the upper limit of frequency is about 50 Mc/s. The lower limit of frequency depends on the available quantity of the suspension. If only one litre of a suspension is available, the frequency perhaps cannot be extended to lower than several hundreds kilocycles per second. In the low frequency range, the standing wave tube technique may probably be useful.

(2) The shape of particle must be spherical or nearly spherical, so that the particle may undergo uniform dilatation and compression in a sound field. The irregularity of the surface of particle might prevent sound

pressure from applying in equal phase and intensity to the whole surface. This unfavorable effect of surface irregularity is depressed at low sound frequencies.

(3) The concentration of the suspension must be so small that the linear relation of both velocity and attenuation against concentration may hold. Within this restriction, however, concentration as large as possible is desirable for the precise determination of $(V-V_1)/c$ and $(\alpha-\alpha_1)/c$. One must make, therefore, a preliminary test as to the concentration dependence of velocity and attenuation and decide the most appropriate concentration.

(4) The liquid medium must have a good affinity to the particle. If not, microbubles of air on the particle-liquid interface and coagulation of particles might cause an appreciable error. Of course, dissolution or swelling of particles by the liquid is also undesirable.

The suspension method described here affords a new method for measuring dynamic mechanical properties of powder materials, whether polymeric substances or not. No technique for this purpose has been developed as yet, according to the authors, before this work.

§ 3. Experimental Technique

A pulsed compressional wave was generated and received in a suspension by a pair of X-cut quartz transducers. A schematic diagram of the apparatus is illustrated in Fig. 2. The receiving crystal was moved by a calibrated screw drive so that the change in distance between the transducers could be read within 1/100 mm. The crystals used were of sufficient cross section to insure a well collimated plane wave and no correction for the divergence of beam was necessary.

The wave velocity was determined from the amount of displacement of the receiving crystal which gave a shift of ten microseconds to the received signal on the oscilloscope. In purpose of obtaining an accuracy within 0.1%, the time axis of the oscilloscope was exactly synchronized by a 100kc/s quartz oscillator and the carrier wave of the received pulse, not the envelope of the pulse, was displayed on the oscilloscope screen. The change in relative distance between the crystals results in a change in the received pulse height. By compensating this change by use of a calibrated attenuator, the attenuation coefficient in a suspension was obtained.

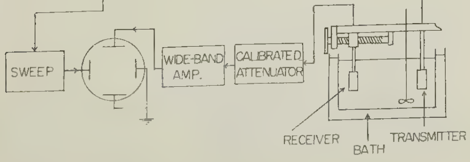

Fig. 2. Block diagram of apparatus.

Measurements were made at 1/3, 1 and 3 Mc/s, in the temperatures above 0°C for water suspensions and above −70°C for alcohol suspensions. The temperature of suspension was controlled by a liquid bath surrounding the sample vessel. As a bath liquid, water and alcohol-dry ice mixture were used above and below the room temperature, respectively. A continuous stirring of the suspension was necessary not only to insure a temperature uniformity throughout the suspension, but also to avoid settling under gravity.

In order to calculate K' and K'' from the sound velocity and attenuation in a suspension, the values of K_1, α_1, ρ and ρ_1 at each temperature are also required. K_1 and α_1 were determined from the sound velocity and attenuation in a suspending liquid, measured following the same procedures as a suspension. The density of particle and liquid was measured at 20°C by the pycnometer method, and the thermal expansion coefficient was determined by a dilatometer, the details of procedures having been described elsewhere.[15] The shape and average radius of particles were examined from microscopic observation.

In the case of styrene-butadiene rubber, polyethylene and polytrifluoromonochloroethylene, the measurement of sound propagation was also made for a plate-shaped sample moulded from particles. This experiment was performed using the same apparatus as the suspension method, by inserting the plate in the path of the sound beam. Details are seen in a literature.[4] From the velocity and attenuation in a plate, the modulus and loss factor were calculated by the well-known equations:

$$K'+\frac{4}{3}G'=\rho V_l^2\frac{1-\left(\dfrac{\alpha_l V_l}{\omega}\right)^2}{\left\{1+\left(\dfrac{\alpha_l V_l}{\omega}\right)^2\right\}^2}, \tag{9}$$

$$\frac{K''+\dfrac{4}{3}G''}{K'+\dfrac{4}{3}G'}=\frac{2\left(\dfrac{\alpha_l V_l}{\omega}\right)}{1-\left(\dfrac{\alpha_l V_l}{\omega}\right)^2}, \tag{10}$$

$$G'=\rho V_s^2\frac{1-\left(\dfrac{\alpha_s V_s}{\omega}\right)^2}{\left\{1+\left(\dfrac{\alpha_s V_s}{\omega}\right)^2\right\}^2}, \tag{11}$$

$$\frac{G''}{G'}=\frac{2\left(\dfrac{\alpha_s V_s}{\omega}\right)}{1-\left(\dfrac{\alpha_s V_s}{\omega}\right)^2}. \tag{12}$$

§ 4. Styrene-butadiene Rubber

The original form of styrene-butadiene rubber sample used in this study was a latex of 50% concentration. The concentration was determined by perfectly drying the latex at 80°C, 1 cm Hg. The radius of particles is less than 1 micron. Diluting the latex by distilled water, the concentration dependence of sound velocity and attenuation was measured. The result showed that both velocity and attenuation have a linear relation to concentration below 20%. A suspension of 11.1% volume fraction was therefore used as a sample.

The temperature dependence of velocity and attenuation of the suspension is illustrated in Figs. 3 and 4. From the smoothed curves in Figs. 3 and 4, K' and K'' are calculated using Eqs. (4) & (5) respectively, as shown in Fig. 5.

The broken lines in Fig. 5 show for comparison Cunningham and Ivey's data[3] of K', G' and G'' at 1 Mc/s for GR-S which is a

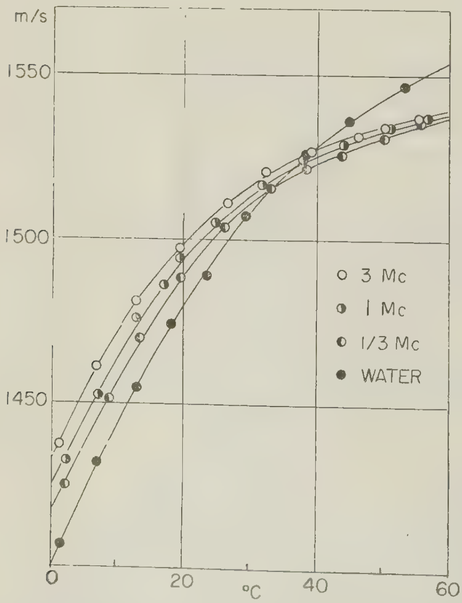

Fig. 3. Sound velocity *versus* temperature in aqueous suspension of styrene-butadiene rubber (c=11.1%).

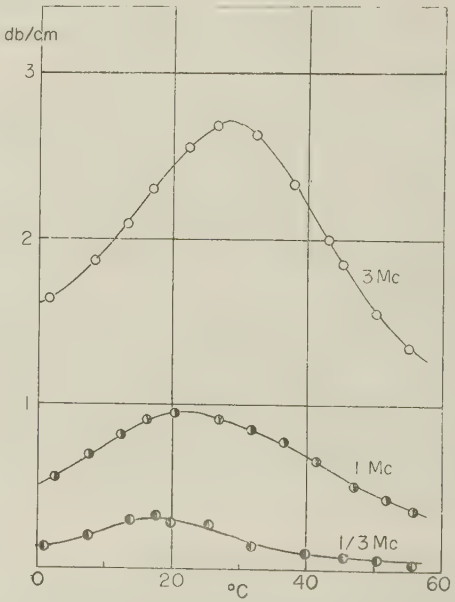

Fig. 4. Attenuation of sound in aqueous suspension of styrene-butadiene rubber (c=11.1%). Attenuation in water is negligibly small.

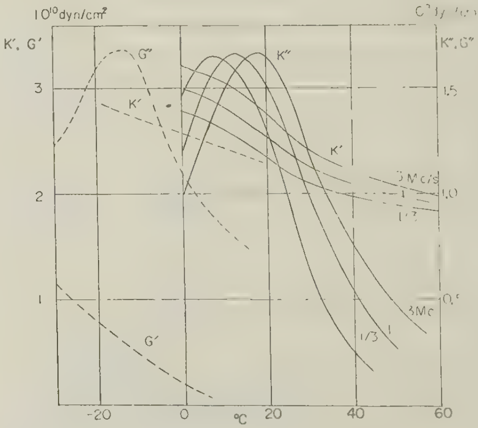

Fig. 5. Real and imaginary parts of bulk modulus of styrene-butadiene rubber. Broken lines show Cunningham-Ivey's data for GR-S at 1 Mc/s.

sort of styrene-butadiene rubber. Comparing K'' of the present study with G'', it is evidently seen that the relaxation strength is of the same order of magnitude for volume and shear deformation. On the other hand, the peak temperature seems at first sight to be quite different for K'' and G''; the peak of K'' at 1 Mc/s is higher than that of G'' by 27° at the same frequency. This discrepancy, however, should be attributed to the difference in styrene content between GR-S and the present sample. The glass transition temperature T_g is $-61°$ C for GR-S,[16] whereas T_g of the present sample determined from volume dilatometry is $-27°$C, being 34° higher. The higher peak temperature of K'' accordingly might be due to the higher styrene content of our sample.

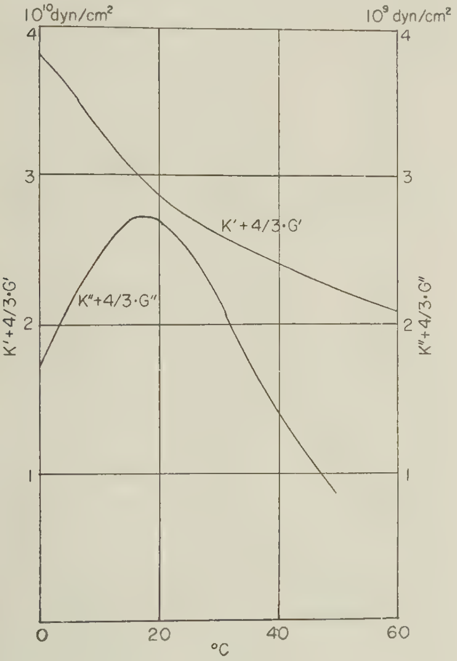

Fig. 6. Real and imaginary parts of $K+4G/3$ of styrene-butadiene rubber at 1 Mc/s.

The validity of this prediction can be verified from the following experiment. Fig. 6 shows the real and imaginary parts of $K+4G/3$ at 1 Mc/s obtained from the longitudinal wave propagation in the rubber plate made of the latex used in the present investigation. The peak temperature of $K''+4G''/3$ is 13°C in agreement with K'' in Fig. 5. The peak value of $K''+4G''/3$ is about twice larger than K'', hence K'' and G'' are of nearly the

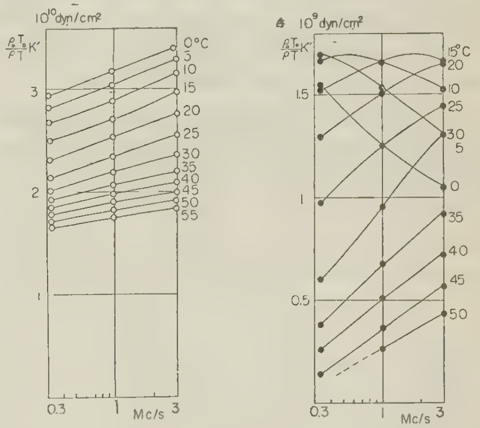

Fig. 7. Real and imaginary parts of bulk modulus of styrene-butadiene rubber multiplied by vertical shift factor plotted against frequency in logarithmic scale.

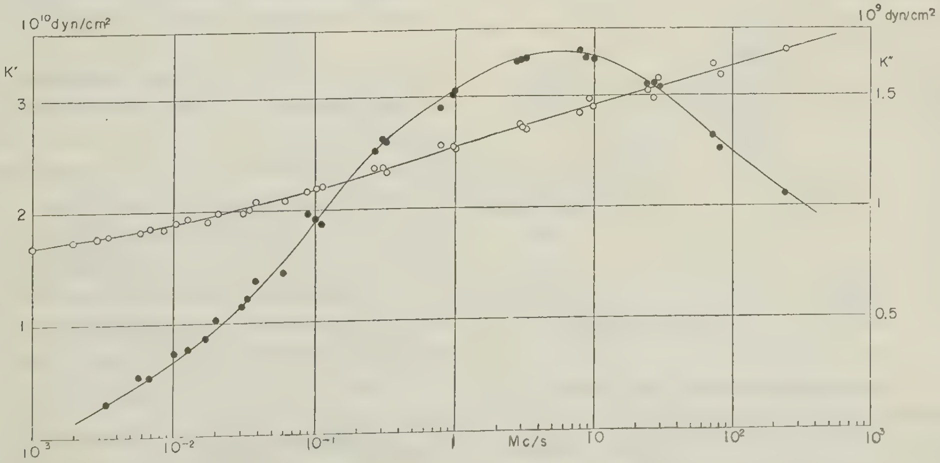

Fig. 8. Reduced curves of K' and K'' of styrenebutadiene rubber ($T_0=20°$C).

same magnitude at their maxima. It may now be quite safely concluded, therefore, that the transition region lies at the same temperatures for bulk and shear moduli.

Now we shall apply the well-known reduction scheme of Ferry17) to the present results. Fig. 7 shows K' and K'' multiplied by the vertical shift factor $\rho_0 T_0/\rho T$, plotted against frequency in logarithmic scale. The reduced curves at 20°C are obtained in Fig. 8 by the horizontal shift, in which the same reduction factor was employed for K' and K''.

The frequency range of the reduced curves is not broad enough to allow a precise conclusion as to the relaxation spectrum. But it may be noted here that, in the low frequency side of the K'' curve, K'' is proportional to square root of the frequency. This behavior should result in a wedge-type relaxation spectrum of slope 1/2, as is widely observed in shear deformation of rubber.18)

The reduction factor a_T is plotted against temperature in Fig. 9. The curve is best fitted by Williams-Landel-Ferry's equation:19)

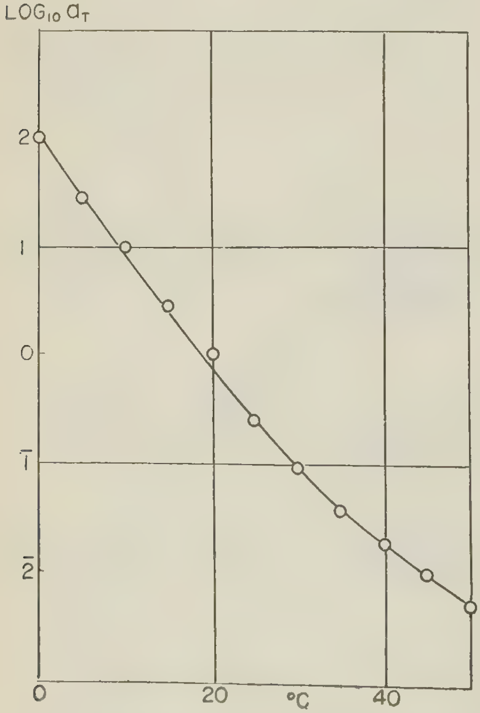

Fig. 9. Reduction factor a_T for bulk modulus of styrene-butadiene rubber plotted against temperature ($T_0=20$°C). Solid line represents Williams-Landel-Ferry's equation ($T_s=20$°C).

$$\log_{10} a_T = -\frac{8.86(T-T_S)}{101.6+(T-T_S)}, \qquad (13)$$

when T_S is chosen as 20°C. This T_S value is 47° higher than T_g. The factor a_T may be differentiated to give the apparent activation energy $H=Rd(\log a_T)/d(1/T)$. H is 34 kcal/mol in this case.

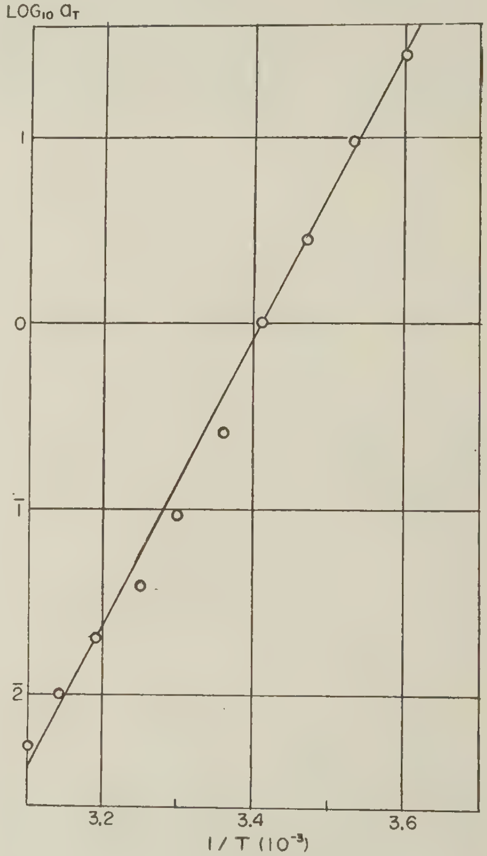

Fig. 10. Reduction factor for bulk modulus of styrene-butadiene rubber plotted against reciprocal of absolute temperature ($T_0=20$°C).

All the above-mentioned behaviors about the bulk modulus, i.e. the relaxation strength, relaxation times, their distribution and temperature dependence, are quite similar also in the case of the shear modulus. Within the precision and frequency range available in this work, there is no appreciable discrepancy between the relaxation mechanisms of volume and shear deformation, hence the molecular mechanisms involved also should be of nearly the same character.

§ 5. Natural Rubber

The original form of natural rubber suspension used in this study was a latex of 50% concentration, the particle radius being 1 micron or less. The latex was diluted by distilled water to 10% volume fraction. Since the transition region of natural rubber, when measured even at megacycles range, lies below 0°C, the result is rather incomplete as is illustrated in Fig. 11.

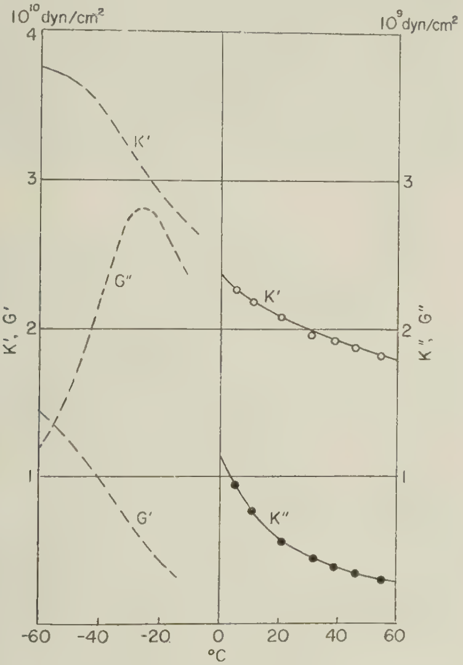

Fig. 11. Real and imaginary parts of bulk modulus of natural rubber at 1 Mc/s. Broken lines indicate Cunningham and Ivey's data[3)] of natural rubber at 1 Mc/s.

It may be safely said, however, that the prediction by Cunningham and Ivey,[3)] $K'' \ll G''$ at transition region, might not be the case. The present result rather suggests that K'' is of the same order of magnitude as G'', as is the case with styrene-butadiene rubber.

§ 6. Polyethylene

Many of the crystalline polymers, such as Ziegler polyethylene, polypropylene, fluorine-containing polymers etc., are originally polymerized into a shape of fine powders. The suspension method described in this paper can well be applied to the determination of viscoelastic properties of these materials.

Ziegler polyethylene powders, sifted from coarse grains by a 100 mesh sieve, were suspended in methyl alcohol, volume concentration being 6.5%. Particles are nearly spherical in shape and the average radius is about 30 microns. The values obtained are illustrated in Fig. 12. One sees that K''/K' has a remarkable maximum at -35°C.

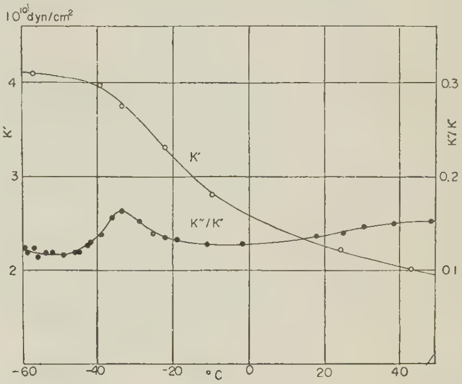

Fig. 12. Real part and loss factor of bulk modulus of Ziegler polyethylene powder at 1 Mc/s.

Many investigations have so far been performed on the dynamic mechanical properties of polyethylene.[20)] It is a well established fact that polyethylene exhibits three dispersion regions, labeled as α, β and γ descending from higher temperatures. When measured at 1 Mc/s, three peaks of the loss factor are expected to appear in the vicinity of 80°, 20° and -65°C, respectively. In case of Ziegler polyethylene, the β peak is very slight, often undetectable because of its high crystallinity. Of course these date have been obtained for moulded samples and mostly for shear deformation.

The dispersion phenomena of polyethylene powder in Fig. 12 is quite unexpected from these previous data. In the present case the β and γ peaks completely disappear and instead a new one reveals itself in the vicinity of -35°C. This variation cannot be considered to come from the peculiarity of the present sample, nor from the different mechanisms involved in volume and shear deformations. The reason is in what follows. When our powder was moulded into a plate and the longitudinal and shear wave propagations in the plate were measured, the γ peak clearly appeared both for $(K''+4G''/3)/(K'+4G'/3)$ and G''/G' at -65°C (see Fig. 13).

From these results, we may conclude that the virgin powders of polyethylene which have not undergone any treatment after polymerization is quite different from the moulded block in mechanical behaviors and accordingly in molecular arrangement. In this connection the studies of other types of behavior of the powder, such as dielectric, thermal, nuclear-magnetic and the like, is very desirable.

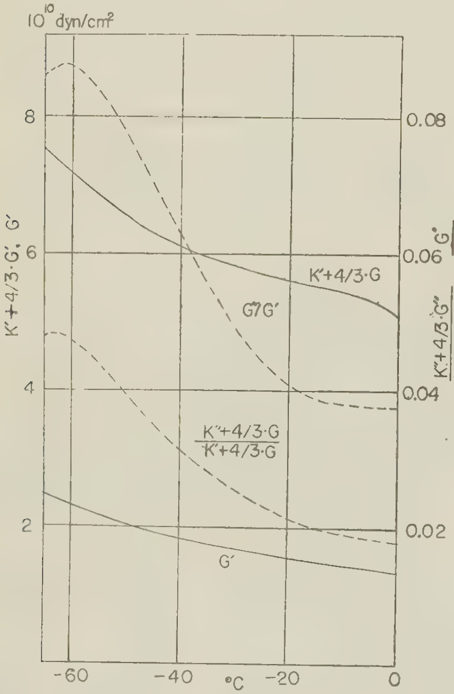

Fig. 13. Moduli and loss factors in moulded plate Ziegler polyethylene at 1 Mc/s.

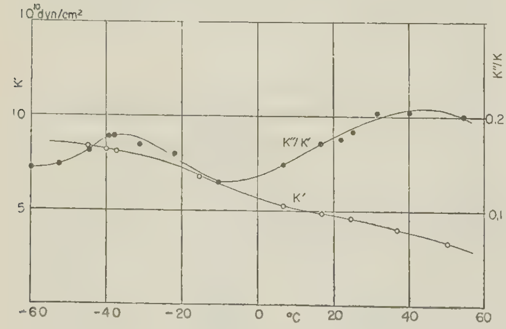

Fig. 14. Real part and loss factor of bulk modulus for polypropylene at 1 Mc/s.

§ 7. Polypropylene

Polypropylene powders (Moplen-2) used is about 10 microns in radius. The velocity and attenuation of sound at 1 Mc/s were measured for 8.7% suspension in methyl alcohol. The calculated values of K' and K''/K' are shown in Fig. 14.

The data available about the mechanical properties of this polymer is at this time so scanty, therefore no discussion will be given here.

§ 8. Polytrifluoromonochloroethylene

Polytrifluoromonochloroethylene powders used in our experiment is about 25 microns in average radius, being not spherical in shape. The powders, after separated from coarse grains by a 100 mesh sieve, was suspended in methyl alcohol at volume fraction of 3.0%. The results are given in Fig. 15.

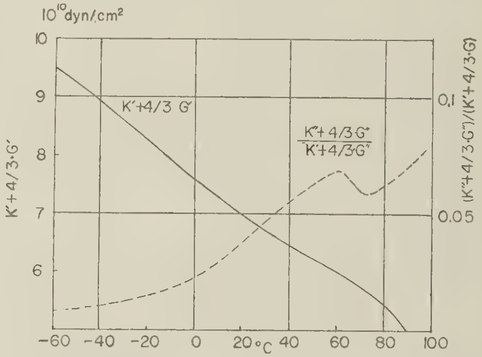

Fig. 15. Real part and loss factor of bulk modulus of polytrifluoromonochloroethylene powder at 1 Mc/s.

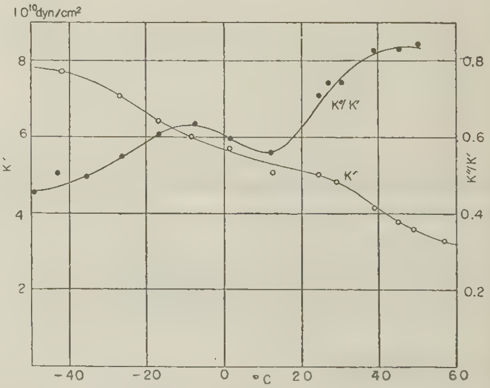

Fig. 16. Real part and loss factor of longitudinal wave modulus of moulded polytrifluoromonochloroethylene at 1 Mc/s.

For comparison, a longitudinal wave measurement at 1 Mc/s was performed for the plate moulded from these powders, the results being represented in Fig. 16. The dispersion region is quite different between the powder and plate as is the case with polyethylene.

§ 9. Paraffin

Fine spherical powders of engineering paraffin was prepared as follows: Paraffin is emulsified by violent stirring in hot water plus emulsifier and slowly cooled down below freezing point under continuous stirring. The powders thus yielded are filtered and dried. The average radius of powders depends on the velocity of stirring, being 15 microns in our case. A suspension of 6.1% in methyl alcohol was used. The observed values of K' and K''/K' are given in Fig. 17.

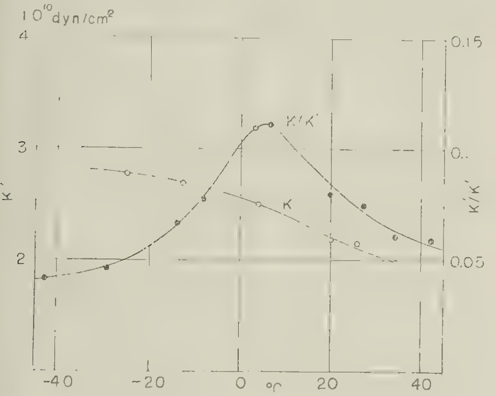

Fig. 17. Real part and loss factor of bulk modulus of engineering paraffin (M.P.=54°C) at 1 Mc/s.

There exists an evident peak of K''/K' at 6°C. This is very reasonable when compared with the data by Mikhailov and Soloview,[21] in which the loss factor at 100 kc/s associated with Young's modulus is found to become maximum at −12°C. The molecular mechanism of this dispersion may persumably be associated with the premelting phenomena in paraffin.

§ 10. Yeast Cell

Using the techniques described in this paper, we can obtain some informations about the mechanical properties of micro-organism in its living state from the velocity and attenuation of sound in an aqueous suspension of the organism.

As a preliminary study, yeast cells (Saccharomyces cerevisiae) which are nearly spherical with radius of 2.8 microns were suspended in water in a concentration of 10% and measured by ultrasonic waves at 1 Mc/s. The temperature range of observation was restricted in the upper side by the death of organism and, below 20°C, the organism falled into "sleep."

The obtained results are represented in Fig. 18. Since a yeast cell is not in a single phase, but surrounded with a thin cell wall, the physical meanings of K' and K''/K' shown in Fig. 18 are somewhat complicated. If the influence of the cell wall is neglected for simplicity, the values should be associated with protoplasm in the cell. K' in Fig. 18 is nearly independent of temperature. This type of behavior is known to be characteristic to some aqueous solutions of organic substance, because K' increases with temperature for water, but decreases for organic substance. The protoplasm in the cell is an aqueous solution of proteins and fits this case.

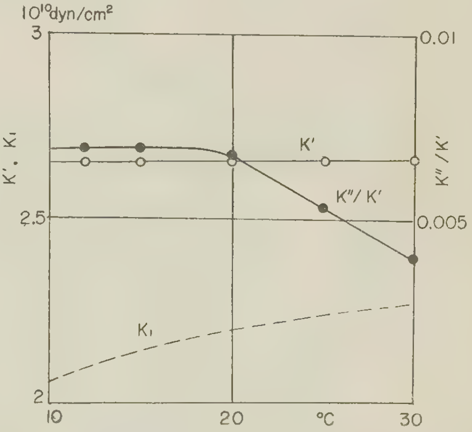

Fig. 18. Real part and loss factor of bulk modulus of yeast cell at 1 Mc/s. Broken line represents real part of bulk modulus of pure water for comparison.

§ 11. Acknowledgements

The authors are deeply indebted to Dr. S. Koga for his help in study of the yeast cell and to Assist. Prof. S. Fukutomi for his aid in obtaining part of the data presented in this report. They also wish to thank Mr. K. Okano for his helpful comments on the theoretical basis of this study.

Optical Properties of KCl : Tl in the Extreme Ultraviolet Region

By Kiyoshi AOYAGI and Goro KUWABARA

Department of Physics, Faculty of Science,
University of Tokyo

(Received August 4, 1960)

The optical properties of KCl : Tl in the vacuum ultraviolet range were studied between room and liquid nitrogen temperatures. A new band was observed in both the absorption and excitation spectra on the long wave length tail of the exciton band, i.e. 7.19 ev at −180°C. From the measurements of the temperature dependence and the emission spectrum the band is supposed to be associated with a transition in Cl ions in the neighborhood of a Tl ion.

Excitation and emission spectra of fluorescence by the light in the fundamental band region, as well as thermal glow and optical stimulation curves of phosphorescence were also measured. The process of this luminescence is discussed.

§1. Introduction

Alkali-halide phosphors activated with thallium have been extensively studied both experimentally and theoretically. Three prominent absorption bands, denoted as A, B, and C band, were found and assigned as transitions from the ground state $^1S_0$ to the excited levels of a thallium ion such as $^3P_1$ and $^1P_1$.

Recently, however, detailed experimental studies(1) revealed that these bands have more complex structures than expected from the simple assignment, and in order to explain complex behaviors the mixing of electron transfer states with those of thallium ions has been proposed,(2) but definite conclusions have not yet been attained.

Some of the bands corresponding to transfers of an electron from the neighboring chlorine ion to the thallium or the transitions to the perturbed exciton states may be expected to appear in the long wave length side of the exciton band of pure alkali-halides, and Yuster and Delbecq(3) have observed one band for KI : Tl.

In order to see the effects of the configuration mixing, it may be valuable to study also some other alkali-halides, especially of various anions, which have the spin-orbit interaction of different magnitude. Moreover, if the bands assigned to the perturbed or localized exciton states are clearly observed, it may be interesting to study the mechanism of excitation of thallium ions with lights in those bands.

On the other hand, it is well known that those phosphors luminesce by excitation with high energy particles, X-ray or with light in the fundamental absorption band. This phenomenon is common for most of practical phosphors, and in this case an activator excited not directly by incident particles or photons but indirectly by free carriers and excitons produced simultaneously by radiation. Alkali-halides phosphors activated with thallium are most suited for elucidating the detailed mechanism of energy transfer through the crystal, because in these phosphors the optical transitions corresponding to direct excitation and those producing free carriers and excitons are well separated with each other.

Several experiments, especially intended for the study of the behavior of excitons, have been reported on alkali-iodides.(4) In these crystals, however, the fundamental band has a complex structure probably because of the large spin-orbit interaction and moreover the *C* band lies so closely to the exciton band that it seems rather difficult to distinguish the effects of direct and indirect excitation of thallium ions.

In these respects potassium chloride, in which the spin-orbit interaction is small and both bands are separated as much as 1.3 ev, is suited also for this purpose.

§ 2. Experimental Procedures

Measurements of excitation and absorption spectra were performed with a vacuum monochromator constructed in our laboratory, which is equipped with a concave grating working at nearly normal incidence as shown in Fig. 1a. The grating is of Bausch & Lomb Optical Co. with 40 cm concave radius and 600 lines per mm. The light source is a hydrogen discharge lamp with a hot-cathode operated at several hundred watts. For the purpose of excitation and photoconductivity measurement this spectrometer is intended to give high intensity rather than resolution. The optical arrangements in the detector chamber were changed according to the purposes of measurements. The intensity of light below 250 mμ was measured by means of 1P28 photomultiplier tube with a fluorescent screen of sodium salicylate which is reported to have a constant efficiency below 300 mμ. The slit width was about 3 mμ in wave length for the measurements of excitation spectra and about 1 mμ for absorption spectra. For the measurements at low temperatures the crystal holder was attached to a double Dewar vessel shown in Fig. 1b. To prevent some vapors to adhere to the surface of the specimen at low temperatures, liquid nitrogen was poured into the outer shell of the double Dewar vessel at first. The crystal holder was warmed with a heater to about room temperature and then after half an hour the

specimen cooled down by filling the inner vessel with liquid nitrogen.

Single crystals of KCl : Tl were grown by the Kyropoulos method from the melts containing 0.001∼10 mole per cent of thallium and annealed for several hours. Concentrations of thallium in the crystals were estimated from the absorption intensity in the A band assuming the oscillator strength of this band to be 0.1 at room temperature, and were found to be of the order of 10^{-2} of those in the melts.

The emission spectra were photographed with a small quartz spectrograph from the same side of the crystal as the exciting light to prevent reabsorption of the emission, and Neopan-SSS photographic films of Fuji Photo Film Co. were used.

§ 3. Results and Discussions

(1) *D-band*

The excitation spectra of KCl : Tl single crystals at 12 and −180°C for equal number of incident photons are shown in Fig. 2. The well-known three bands, namely A, B and C band, are observed in these spectra. On the higher energy side of the C band another band was found, to which somewhat similar band had been reported by Eby and Teegarden[2]. However, it is probably different from ours, as will be seen in the following details. The peak of the new excitation band lies at about 7.01 ev at room temperature, and shifts towards higher energy side with decrease of temperature.

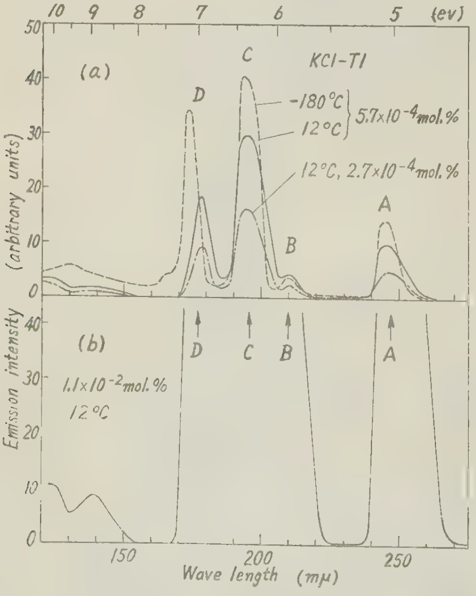

Fig. 2. Excitation spectra of KCl : Tl crystals with different thallium concentrations.

Curve (a) in Fig. 3 shows the absorption spectrum at liquid nitrogen temperature of one of the KCl : Tl crystals quoted in Fig. 2, and (b) shows that of an undoped crystal* grown from the same reagent grade KCl. When we plotted the differences of these two absorption curves, near the tail of the fundamental band there appeared one absorption band which precisely coincides with the band found in the excitation spectra. Curve (d) is the absorption spectrum of this band at room temperature obtained by the same way.

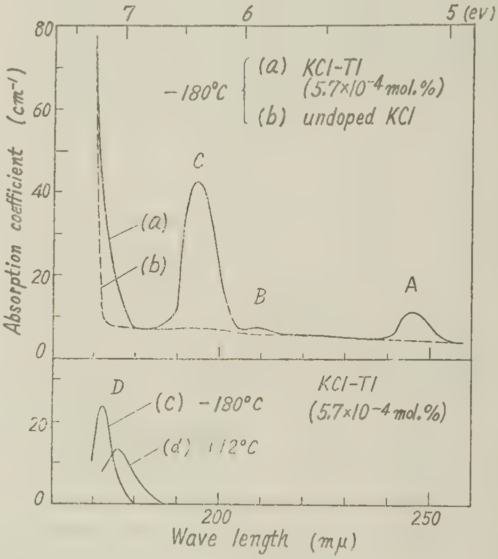

Fig. 3. Absorption spectra of a KCl crystal containing 5.7×10^{-4} mole per cent thallium (a) and of undoped KCl crystal (b) at liquid nitrogen temperature. Curve (c) is the absorption spectrum of the D band obtained by subatacting (b) from (a), and curve (d) is for room temperature.

The new band, which is found both in the absorption and excitation spectra is denoted as D band in this paper. As shown in Fig. 4 the absorption intensity of the D band increases almost linearly with the increase of thallium concentration within the range of the present experiment, i.e. from 2.7×10^{-4} to 1.1×10^{-2} mole per cent.

---

* The undoped KCl crystals prepared in our laboratory has an absorption coefficient ca. 65 cm^{-1} at 175 mμ at room temperature, which is somewhat larger than that reported by Kobayashi *et al.*[5] This may be due to a presence of bromine impurities as they suggested.

Fig. 5 shows the temperature dependence of the absorption hand. The peak lies at 7.01 ev (177 mμ) and 7.19 ev (172 mμ) at 12 and −180°C respectively, and the rate of the shift was -9.4×10^{-4} ev/deg between these temperatures, which is nearly equal to that of the exciton band.⁽⁶⁾

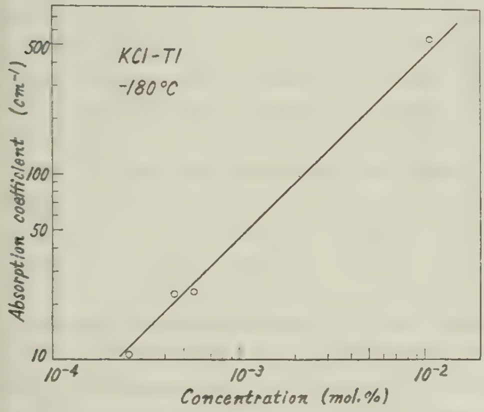

Fig. 4. Concentration dependence of the maximum absorption coefficient of the D band at liquid nitrogen temperature.

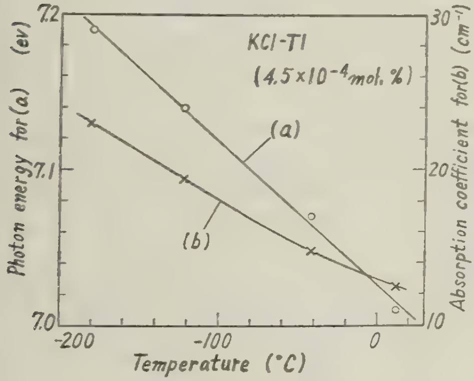

Fig. 5. Temperature dependences of the peak position and the absorption coefficient of the D band.

The shape of the absorption band could not be determined precisely because of the exciton band tail, but it appears to be simple and intermediate between the Gaussian and the Lorentzian. The width of half maximum of the D band was 0.29 ev at 12°C and 0.21 ev at −180°C. The absorption intensity, i.e. the product of the maximum height and the half width, is nearly five times as large as that of the A band, but it increases slightly with the decrease of temperature. Taking into consideration the difference of the refractive index, the oscillator strength of the D band was estimated to be 2.7 times of the A band at −180°C for a crystal containing 4.5×10^{-4} mole per cent of Tl.

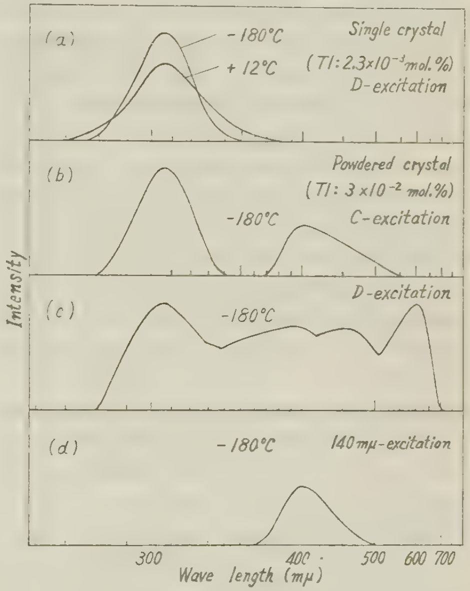

Fig. 6. Microphotometer curves of the emission spectra. (a) of KCl-1.3×10^{-3} more % Tl single crystal excited by the D light at 12 and −180°C; (b), (c) and (d) of KCl-3×10^{-2} mole % Tl powdered crystal at −180°C excited by the C, D and 140 mμ light, respectively. The corrections for the slit width and the sensitivity of films are not made.

Fig. 6a is the microphotometer curve of the emission of a KCl : Tl single crystal excited by the D band light. The ordinate is the absorbance of the photographic films. The emission spectrum was consisted of only the 305 mμ emission band characteristic of thallium ion. Taking into consideration the overlap of the D band with the tail of the fundamental absorption, i.e. subtracting the amount of light absorbed in the tail of the exciton band, the quantum efficiency of the emission by light absorbed in the D band was estimated to be about 1.5 times of that of the emission excited by light in the A band, and it remained nearly constant within the temperature range of the present experiment. According to Bünger,⁽⁷⁾ the quantum efficiency of the emission by the A light is ca. 0.5. Therefore it is concluded that the light in the D band causes luminescence due to thallium with a quantum efficiency of nearly unity. The details of the emission spectrum will be described at the end of this section.

From these results on the D band, it is supposed that the band may be due to an excitation of perturbed chlorine ions neighboring to a thallium ion, i.e. the D band corresponds to the β band of the F center. A similar absorption band has been reported for KI : Tl.(3)

If we take the above assignment for the D band, the oscillator strength may be reasonable but the fine structure due to a spin-orbit interaction is expected. According to Knox,(2) the spin-orbit splittings on the transfer spectra will be the combination of those for Cl and Tl atoms, which are about 0.1 ev and 0.97 ev respectively.

No structures, however, was observed in the D band, even though the pass band was 0.03 ev in this region and sufficient for resolving.

If we take the large value for the separations, the other members of the transfer spectra may lie in the A, B and C band regions or in the exciton band. At present, it can not be decided which of the above assumptions is correct. However, it is noted that no structure have yet been reported even for the β band of KCl or NaCl.(8)

The excitation of Tl ions by the D band light may be caused by an auto-excitation process. However, the high quantum efficiency of the D band, such as ca. 1.5 times of the A band, is difficult to understand from a simple picture, and for explanation we must assume that the light of the exciton band tail overlapping with the D band somewhat contributes to the excitation of Tl or that the A band is composed of two bands, one of which is not associated with the luminescence.

It has been reported that KCl : Tl has three emission bands. In our experiment, however, in the case of single crystals only the 305 mμ band was observed by excitation with light in the A, B, C or D band and neither 475 mμ

nor 247 mμ band could be detected both at 12° and at −180°C. Taking the characteristics of the photographic films and the spectrograph into consideration, the intensities of these emission bands were estimated, if they existed, to be less than one twenteith of that of the 305 mμ band in all cases for crystals prepared in our laboratory. This result appears to somewhat contradict the generally accepted view that all the emission bands are due to the same single Tl center, but we will not touch these problems in this paper.

However, in order to see the effects of form of a specimen or mechanical treatment, the powder specimens were prepared by grinding the single crystals, and emission spectra under the excitation with lights in the various bands at room and liquid nitrogen temperature were examined. The results including those for single crystals are summarized in Table I.

In the case of single crystals all of the emission, or at least most part of the emission was the 305 mμ band irrespective of the exciting lights or the temperature, while in the case of powdered specimens other emission bands, except the 247 mμ band, appeared at low temperatures under the excitation with lights in the C, D or fundamental band. The microphotometer curves of these emission bands are shown in (b), (c) and (d) of Fig. 6. The band peaked at about 400 mμ was observed also for the powdered specimen of undoped KCl under the excitation with the fundamental band light at low temperatures. This fact will be discussed in the later section. The appearance of various emission bands in the case of powdered crystals may be explained that new centers or excitation bands due to the lattice defects were produced by grinding.

(2) *Fluorescence and Phosphorescence by Light in the Fundamental Band Region*

Let us first consider the luminescence at room temperature. On the higher energy side of the D band in the excitation spectra of Fig. 2, almost no luminescence is observed with the exciton band and as the photon energy is increased above the higher energy side of this band, the intensity of the luminescence rises gradually, which is the 305 mμ emission band at room temperature as shown in Table I.

The dip at 130 mμ coincides with the peak of the 2nd fundamental absorption band, and can be interpreted to be mainly caused by rise of reflection loss. The same reason, however, can not explain the deep minimum at the exciton band completely, rather it is supposed that the exciton causes little luminescence at least at room temperature.

Strictly speaking the luminescent intensity for light in the fundamental band range varied with the irradiation time, that is, under the excitation with the 2nd fundamental band light, the luminescence was hardly observed at first for a freshly prepared KCl : Tl crystal and gradually increases with irradiation, saturating at some intensity. The saturation value or the efficiency of the luminescence depends on the intensity of exciting light as well as on the concentration of Tl, but does not vary linearly with them and the luminescence efficiency of the crystal containing 1.1×10^{-2} mole % of Tl for the 140 mμ light was estimated to be about one fifth of that for the A band at light intensity of ca. 10^{13} photons/cm^2 sec.

The irradiation of light in the 2nd fundamental band makes the crystal phosphorescent as well as fluorescent. As the irradiation proceeds, the phosphorescent intensity also increases and attains the saturation value, which depends upon the intensity of exciting light and upon the Tl concentration as in the case of fluorescence. But the incident photon numbers necessary for saturation are different for fluorescence and phosphorescence.

The emisson band of the phosphorescence at room temperature was found to be composed of the 305 mμ band characteristic of Tl ions. The decay of the phosphorescence, the half life of which is ca. 110 sec at 20°C, can not be strictly expressed by a simple exponential curve.

The excitation spectrum of the phosphorescence of a crystal with 1.6×10^{-3} mole % Tl for exciting light of equal intensity (ca. 10^{13} photons/cm^2 sec) is given in Fig. 7. This curve was obtained by repeating the following procedures; the intensity of the phosphorescence saturated by excitation with a monochromatic light was measured and the crystal was restored to the initial state by heating to 100°C for about ten minutes and then excited again with another monochromatic light.

From this figure it is concluded that the phosphorescence of the 305 mμ band appears by irradiation with lights in the 2nd fundamental band as well as the B, C and D band due to Tl, but not by those in the A and the exciton band, and that the spectral distribution in the fundamental band region is similar to that of the fluorescence.

The luminescent behaviors of KCl : Tl crystals at low temperatures were rather different from those at room temperature. In the excitation spectrum shown as dashed curve in Fig. 2 a small hump is observed at the low energy tail of the exciton band. The efficiency, decreasing once at the peak of exciton band, increases again with the increase of photon energy and shows a peak at the 2nd fundamental band i.e. 130 mμ.

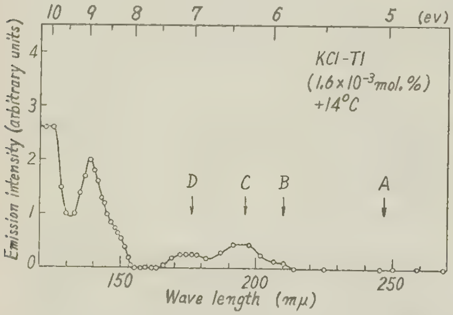

Fig. 7. Excitation spectrum of the phosphorescence at room temperature.

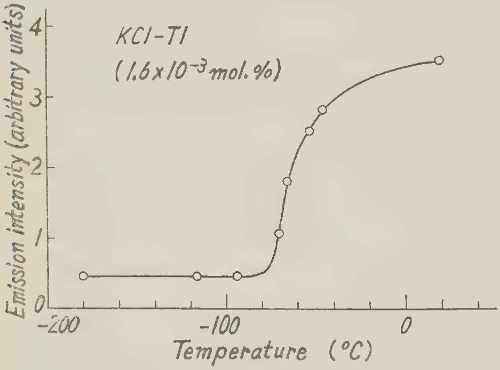

Fig. 8. Temperature dependence of the fluorescence excited with 140 mμ light.

The fluorescent spectrum of a single crystal at −180°C by the 140 mμ light is composed of almost only one band with a peak at ca. 400 mμ.

In Fig. 8 the luminescent intensity of a crystal with high Tl concentration under irradiation with the 140 mμ light is shown as a function of temperature. The intensity abruptly changes near −70°C, below which the fluorescence is mainly composed of the 400 mμ band. While a crystal containing small amount of Tl behaved differently, i.e. the fluorescent intensity rather increased at low temperatures.

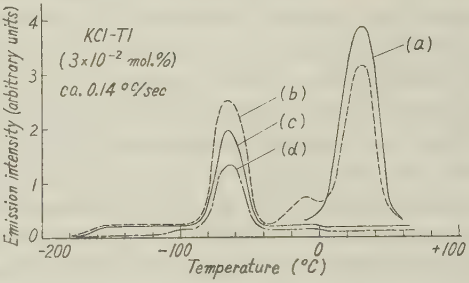

Fig. 9. Thermal glow curves of a KCl : Tl crystal excited with light of 140 mμ at −16 or −180°C. Curve (a) and (b) are total emission; (c) and (d) are visible emission measured with a filter transparent above ca. 380 or 430 mμ, respectively.

In order to study the mechanism of phosphorescence the thermal glow experiment was performed. Curves (a) and (b) in Fig. 9 are the results for a crystal excited with the 140 mμ light at −16° and −180°C, respectively. Three prominent peaks were observed at −65°, −10° and 32°C, conforming with the results obtained by previous authors. The spectral composition of the emission was examined by inserting a filter, which transmits the light longer than 380 or 430 mμ. The emission associated with the peak at 32°C was entirely cut off by either of two filters, and is supposed to be the 305 mμ band, while most or the greater part of the emission associated with the peak at −65°C transmits these filters, showing that the emission is composed of lights above 360 mμ, probably the 400 mμ band. This result is different from that reported by Johnson and Williams,(9) and will be discussed in the later section.

The KCl : Tl crystal, which became phosphorescent, shows a burst of luminescence by stimulation with selective visible light. The spectral distribution of the efficiency of stimulating light measured at room temperature has a peak near 570 mμ. A part of the stimulated emission transmits a filter transparent from 300 to 400 mμ and is supposed to be the 305 mμ band. The effects of various stimulating lights on the thermal glow curve were also studied. The crystals excited with the 140 mμ light at −180°C were irradiated at this temperature with the 546,435 or 365 mμ light from a mercury lamp. All of the thermal glow peaks entirely disappeared simultaneously by irradiation with the 546 mμ light of ca. 10^{18} photons/cm², and the lights 435 and 365 mμ affected slightly.

The effects of the fundamental band light on KCl : Tl single crystals are summarized as follows:

At room temperature (1) the exciton band light causes scarcely any fluorescence or phosphorescence, (2) the crystal shows long lasting phosphorescence as well as fluorescence by irradiation with light which has been supposed to create free electrons and holes in the crystal, (3) the excitation spectra for fluorescence and phosphorescence are similar with each other, (4) in all cases the emission is the 305 mμ band, which is characteristic of Tl ions, (5) the phosphorescence can be stimulated thermally as well as optically;

At low temperatures below about −60°C (6) the emission is mainly the 400 mμ band, (7) the fluorescence can be excited by light which can be absorbed strongly in the surface layer more effectively than at room temperature.

These characteristics may indicate that the fluorescence and the phosphorescence occur by a similar mechanism and that free charge carriers created by light play a dominant role in the transfer of energy absorbed by the host crystal to the emitting centers.

The 305 mμ emission at room temperature is supposed to occur by the following mechanism. Either of an electron or a hole is captured near a Tl ion and when another kind of carriers happens to approach, they recombine with each other giving the energy to the Tl ion by auto-excitation or by dipole transfer. We tentatively assume that a Tl ion itself acts as an electron-trap.

The difference between the fluorescence and the phosphorescence lies in that in the former the electrons trapped by Tl ions recombine with holes produced directly by photons, and in the latter with those holes which have been once captured by some hole-traps and then released again by lattice vibrations. The rises of the fluorescent and phosphorescent intensities with irradiation are interpreted as processes of filling up of carrier traps.

Delbecq *et al*(10) have observed the spin resonance signal due to holes for X-rayed KCl crystals doped with Tl, which disappears at −65°C simultaneously with an absorption band at 350 mμ, and ascribed it to the self-trapped holes.

The present experiment seems to be closely related to these phenomena, i.e. the glow peak of the 400 mμ band or the abrupt change of fluorescence intensity at −65°C corresponds to the temperature above which the self-trapped holes become unstable.

Accordingly, the luminescence at low temperatures is explained by assuming an emitting center other than TI. This center emits the 400 mμ band and may be a kind of lattice defects intrinsic to KCl crystals, which acts as a recombination center as well as an electron-trap much more effectively than Tl at low temperatures, since the faint 400 mμ band is observed also in the undoped crystals. It is supposed that these defects increase by doping as well as by mechanical treatment, and moreover that they are distributed near the surface of the crystal, because the 400 mμ band is effectively excited with light at the peak of the fundamental band, which is strongly absorbed in the surface layer.

At low temperatures most of the recombinations occur at or near the recombination centers and consequently the 400 mμ band is mainly observed.

When the crystal irradiated at liquid nitrogen temperature is gradually warmed up, the self-trapped hole begin to move at −65°C and some of them will recombine with electrons trapped by the recombination centers emitting the 400 mμ band, while the rest will be trapped by hole-traps near the Tl and as the temperature is raised they recombine with electrons which have been trapped by Tl emitting the 305 mμ band.

In the above explanation we have assumed two kinds of traps each for electrons and holes including self-trapping. Some of them may correspond to color centers already reported,(11) but could not be detected by optical absorption measurement, probably because they were too small in numbers. The optical stimulation of the phosphorescence is supposed to be associated with the ionization of electron-traps, probably Tl atoms, which corresponds to the thermal glow peak at 32°C.

Above speculations for the behaviors of free carriers may be checked by the photoconductivity measurement, which is now in progress.

As for excitons it is concluded that they are ineffective as an energy carrier to Tl ions at room temperature even in the highly doped crystal (3×10^{-2} mole % Tl). The difference between the exciton and the second band light for luminescence may be due to some kind of lattice defects densely populated in the surface layer, which annihilate excitons but are inactive for free carriers.

However, the small humps between the exciton and the D band peak observed in the excitation spectra at low temperatures may correspond to the exciton-induced luminescence.

§ 4. Conclusions

The optical properties of KCl : Tl crystals, especially below 200 mμ were studied with a vacuum spectrometer.

A new single band was found on the exciton band tail in the absorption and excitation spectra. The intensity of the band is ca. five times of the A band and increases linearly with the Tl concentration. The absorption peak is situated at 7.01 ev at room temperature and shifts to the higher energy side with the decrease of temperature similarly to the exciton band. This band causes the 305 mμ emission band characteristic of Tl ion, and is assigned as the excitation of Cl ions neighboring to Tl ions.

The lights in the fundamental band region, except the exciton band, also causes phosphorescence as well as fluorescence. The emissions are mainly the 305 mμ and the 400 mμ band at room and low temperatures, respectively.

It is supposed that a Tl ion is excited by the recombination of free carriers, when it occurs in the neighborhood of the Tl, and that the 400 mμ band predominant below ca. −70°C is associated with the defects other than Tl, which are distributed near the surface, enhanced by doping or by mechanical treatment and act as recombination centers.

Effect of Oxygen upon Sintered Cadmium Sulphide Photoconducting Films

By Saburo KITAMURA

Central Research Laboratories, Matsushita Electric Industrial Co., Ltd., Osaka

(Received August 1, 1960)

The dark conductivity and decay time of sintered CdS films prepared by firing in nitrogen gas were higher than those of sintered CdS films prepared by firing in the mixture of nitrogen gas and hydrogen sulphide. Accordingly it was thought that the sintered CdS films prepared by firing in nitrogen gas have many sulphur vacancies acting as donors.

As a result of heat-treatment in oxygen of the sintered CdS films prepared by firing in nitrogen gas, the dark conductivity and decay time decreased. A new peak appeared at 680 mμ in spectral response of the photocurrent. The activation energy obtained by measuring the slope of the curve of logarithm of dark conductivity plotted against $1/T$(°K) increased, while the trap concentration obtained by measuring the thermally stimulated current decreased with the increase in temperature of heat-treatment in oxygen. The results of experiments supported the interpretation that sulphur vacancies acting as donors had been occupied by oxygen atoms, and then vanished. At the same time there were produced new exciting centers at about 1.8 eV below the bottom of the conduction band.

By electron-microscopic observations it was found that by heat treatment above 400°C in oxygen, CdO grains were produced on the surface or near the grain boundary of the sintered CdS film, and when the whole surface of the CdS film was coated by CdO layers, photoconductivity was not observed.

§ 1. Introduction

Sintered cadmium sulphide (CdS) photoconducting films have comparatively large photocurrent and are utilized in many electronic devices. However, the investigation of the properties of sintered CdS films is difficult, because there are many barriers interposed between different crystallites in the films and the properties of barriers are supposed to be different from those of the bulk of crystallites. The properties of CdS single crystals have been investigated by many workers, and it seems correct to claim that the properties of the bulk of crystallites in the films are similar to those of a single crystal.

The surface phenomena of CdS single crystals have also been investigated recently. The heat-treatment in vacuum, air, oxygen, hydrogen, hydrogen sulphide, cadmium vapour and sulphur vapour have been reported.[1,2,3,4] Especially, the phenomena in the case of heat-treatment in vacuum, hydrogen and cadmium vapour suggested that sulphur vacancies were produced near the surface of crystals by heat-treatment, and that the oxygen atoms perhaps occupied the sulphur vacancies.

By the investigations of CdS single crystals, it was ascertained that halogen or group III B metal impurities or sulphur vacancies act as donors, and group I B metal impurities or cadmium vacancies act as acceptors.[4,5] To obtain high photoconductivity the compensation of donors and acceptors may be necessary. If the sintered CdS films are prepared in inert gas, there seems to appear donor levels due to sulphur vacancies. In the present study, the author attempted to show how the effect of oxygen appears upon these sintered CdS films.

To prepare sintered CdS films, two different methods have been used. In one method cadmium halide was used as flux material,[6,7] while in the other activated CdS powder was sintered after having been spread or compressed.[8,9] The first method is rather easier to control the properties than the second. In the present paper some results obtained by heat-treatment in oxygen of sintered CdS films prepared by the first method are presented.

§ 2. Preparation of Sintered CdS Films

The sintered CdS photoconducting film was prepared by the flux method using $CdCl_2$ as flux material on a fused quartz plate. A formulation found to be particularly suitable for general application of sintered CdS film had the following composition[7]: 20g of high purity CdS powder, 2 g of $CdCl_2$, 100 cc of distilled water. The purity of CdS powder was found by chemical analysis to be 99.99% or more, and by spectroscopic analysis it was found that there were traces of Si and Zn. All components were blended and ground in a quartz mixer. To add Cu as the activator in sintered CdS film, 0.2 cc of 0.1 mol $CuCl_2$ solution (0.05 atom % of CdS) was added in the suspension. The suspension was then sprayed on the surface of 20×10 mm fused quartz plate by a spray gun made of quartz, and the sprayed layer was dried for 4 hours at 100°C in nitrogen gas. Next, the sprayed layer was fired for 15 minutes at 600°C in a furnace in which nitrogen gas purified by pyrogallol and liquid nitrogen was flowing, and was then cooled at a rate of about 10 deg per minute.

The process of firing was as follows: $CdCl_2$ was first melted by heating, CdS powder was dissolved in melted $CdCl_2$, and then dissolved CdS was recrystallized by the evaporation of melted $CdCl_2$. When all $CdCl_2$ had evaporated, sintered CdS film of thickness of about 10 μ was obtained on the fused quartz plate. As the result of electron-microscopic observation it was found that the sintered CdS film was consisted of many crystalline grains of about 1 μ. The electron-micrograph of the surface of sintered CdS film is presented in Fig. 12(a). The thickness of sintered CdS film can be varied by varying the quantity of the suspension to be sprayed.

In and Ga were usually used as the electrode material in order to make ohmic contact, but in the following experiments these metals could not be used, because the electrodes were to be heated above 600°C in oxygen together with sintered CdS films. The author used Au as the electrode material. Before spraying the suspension on the surface of fused quartz plate Au was evaporated on it. In this case the property of electrode contact was ohmic above 0.1 volts of applied voltage and nonohmic below 0.1 volts. In the following experiments all measurements were carried out above 0.1 volts of applied voltage. The interelectrode distance was 0.5 mm, and the length of electrodes was 10 mm. Fig. 1 shows a diagram of such a specimen.

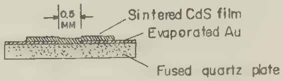

Fig. 1. Diagram of a specimen.

§ 3. Properties of Sintered CdS Films

The sintered CdS films prepared by firing in nitrogen gas using $CdCl_2$ as the flux material have some Cl impurities, and perhaps have many sulphur vacancies. The dark conductivity of sintered CdS films thus prepared was much larger than that of those prepared by firing in nitrogen gas plus hydrogen sulphide. The photoconducting properties of these CdS films are represented in Table I. The properties of sintered CdS films prepared by firing in nitrogen gas were extremely affected by oxygen, but there were little effects of oxygen upon those prepared by firing in nitrogen gas plus hydrogen sulphide. In the investigations of evaporated CdS films, Kuwabara[10] reported that the dark conductivity of CdS film evaporated in vacuum was varied by exposing to air. Also, in the investigations of CdS single crystal, it was reported that sulphur vacancies played as donors.[4] Hence, sintered CdS films prepared by firing in nitrogen gas should have some sulphur vacancies.

When Cu was added to sintered CdS films, the dark conductivity was decreased and the ratio of photocurrent to dark current was increased.

§ 4. Heat-treatment of Sintered CdS : Cl Films in Oxygen

Sintered CdS films added with Cl and having some sulphur vacancies were heated at fixed temperatures in the range of 100∼600°C for 10 minutes in a furnace through which oxygen is flowing. The properties of sintered CdS : Cl films heat-treated at various temperatures

Table I. Properties of sintered CdS films.

Photocurrent: Values obtained by deducting the dark current from the current at the illumination of 200 Lx and at applied voltage of D.C. 2 volts.
Dark current: Current flowing with the applied voltage of D.C. 2 volts in darkness.
Decay time: Time interval until the photocurrent decays to one-half its value for continuous white light illumination of 200 Lx.
*: Values measured with applied voltage of D.C. 20 volts.

were measured by electrical and optical methods.

(a) *Variation of Photocurrent and Dark Current*

One example of variations of photocurrent* and dark current* of sintered CdS films heat-treated in oxygen is shown in Fig. 2. By heat-treatment both photocurrent and dark current were decreased, and the degree of decrease of the dark current is larger than that of the photocurrent. When the sintered CdS films were heated at 650°C, the photocurrent was negligible, while dark current was very large.

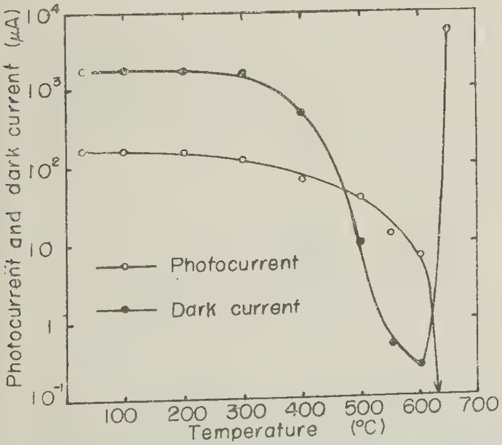

Fig. 2. Variations by heat-treatment in oxygen of photocurrent* and dark current* of sintered CdS:Cl film.

(b) *Spectral Response*

The spectral response of photocurrent of sintered CdS films heat-treated at various temperatures in oxygen was measured by a spectro-photometer of Beckmann type in the range of 400~900 mμ. Light source was an incandescent lamp of 30 watts. Spectral response curves are presented in Fig. 3. The

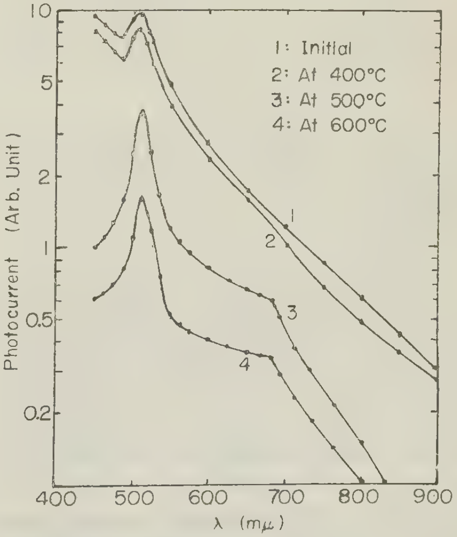

Fig. 3. Spectral response curves of sintered CdS:Cl films heat-treated in oxygen.

---

*: Values measured with applied voltage of D.C. 2 volts.

*: Values measured with applied voltage of D.C. 20 volts.

spectral response curves of sintered CdS : Cl films heat-treated in oxygen below 400°C were found to have only one broad peak at 520 mμ, and by treatment above 450°C a peak at 520 mμ became sharp and a new peak was produced at about 680 mμ.

(c) *Dark Conductivity as a Function of Temperature*

Variations of the dark conductivity as a function of temperature of three specimens, that is CdS : Cl films before heat-treatment, after treatments at 400°C, and at 500°C respectively are illustrated in Fig. 4. Below room temperature, the plot of logarithm of the conductivity against $1/T$(°K) gave a curve with linear portion below−100°C. The slopes of such linear portions for three films corresponded to energies of 0.01 eV, 0.015 eV and 0.02 eV respectively. Above−100°C, the slopes of curves increased with temperature rise.

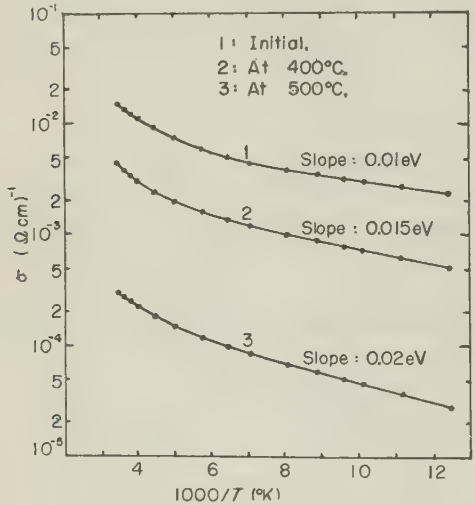

Fig. 4. Dark conductivity of sintered CdS:Cl films heat-treated in oxygen as a function of temperature.

(d) *Thermally Stimulated Current*

The thermally stimulated current is associated with the motion of electrons made free from traps by thermal energy. Measurements of thermally stimulated current were made in the following manner: The sintered CdS film was cooled to liquid nitrogen temperature, and exposed to illumination of white light for 30 sec. Then it was heated in the dark at a rate of about 1 deg per second with applied voltage of D. C. 1 volt. The difference between the current measured in this way and the normal dark current at the corresponding temperature is the thermally stimulated current.

Fig. 5 gives the curves of thermally stimlated current for the initial film and the film heat-treated at 500°C in oxygen. Both the initial film and the heat-treated film had a large broad rise of thermally stimulated current, with a peak at about −140°C. The initial film had fairly large current above 0°C, but the heat-treated film had a small current above 40°C and had an additional small peak at roomtemperature.

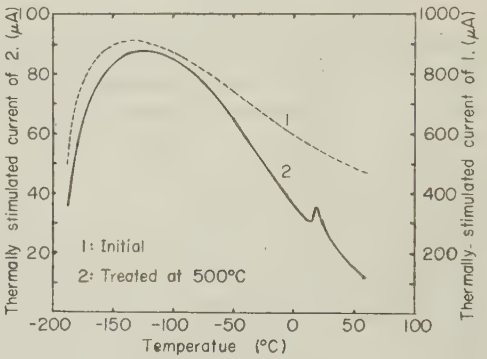

Fig. 5. Thermally stimulated current of sintered CdS : Cl films as a function of temperature: D.C. 1 volt applied, heating rate of about 1 deg/sec.

(e) *Decay Time of Photocurrent*

The decay time of the photocurrent relating to electron traps was as long as about 100∼200 m sec. It was found that the decay time of the photocurrent becomes short with heat-treatment in oxygen.

§ 5. Heat-treatment of Sintered CdS : Cl : Cu Films in Oxygen

The dark conductivity and decay time of sintered CdS : Cl film were very large, and the sintered CdS : Cl : Cu film in which Cu was added had fairly small dark conductivity and large ratio of the photocurrent to the dark current. It was seen that the concentrations of electron traps were decreased by added Cu. In the following experiments, the quantity of added Cu was 0.05 atom % of CdS. The effects of oxygen upon the sintered CdS : Cl : Cu films were remarkable. The method of heat-treatment in oxygen was the same as that in § 4.

(a) *Variation of Photocurrent and Dark Current*

The variations of photocurrent* and dark current* of sintered CdS : Cl : Cu films heat-treatment in oxygen are shown in Fig. 6. The dark conductivity was considerably decreased by heat-treatment in oxygen, so that the ratio of the photocurrent to the dark current became 10^4 or more by heat-treatment at 500∼600°C.

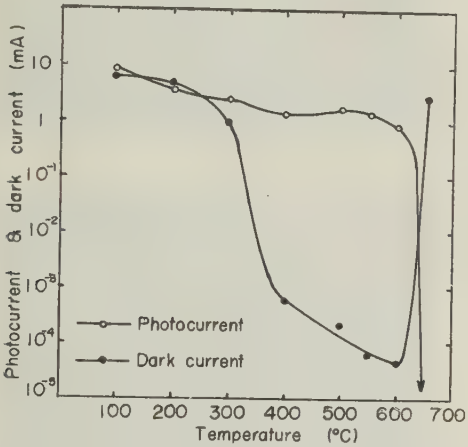

Fig. 6. Variation of photocurrent* and dark current* of sintered CdS:Cl:Cu films by heat-treatment in oxygen.

(b) *Spectral Response*

There were two peaks at about 520 mμ and 620 mμ in the spectral response curves of sintered CdS : Cl : Cu films as shown in Fig. 7. A peak at about 520 mμ corresponded to the absorption edge, and a broad peak at about 620 mμ was produced by added Cu. A broad peak at about 620 mμ became sharp and shifted to red region by the heat-treatment in oxygen. A peak at 520 mμ became sharp by the heat-treatment in oxygen and became low by heat-treatment at 600°C.

(c) *Dark Conductivity as a Function of Temperature*

The variations of dark conductivity of sintered CdS : Cl : Cu films heat-treated in oxygen are given in Fig. 8 as a function of temperature. The conductivity decreased with heat-treating temperature in oxygen, and the slope of the curve of logarithm of conductivity plotted against $1/T$(°K) was increased.

(d) *Rise and Decay Time of Photocurrent*

The rise and decay time were measured by an arrangement consisted of an electromagnetic oscillograph, an incandescent lamp and a shutter. The results are given in Fig. 9. Measurements of rise and decay time were made at applied voltage of D. C. 20 V, with illumination of 200 Lx, and at room temperature. The decay time of photocurrent was extremely decreased by heat-treatment at 200∼300°C in oxygen. The rise time of photocurrent varied very little by heat-treatment in oxygen.

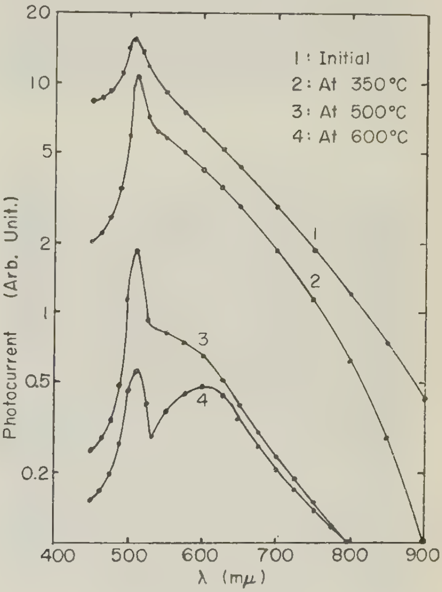

Fig. 7. Spectral response curves of sintered CdS : Cl : Cu films heat-treated in oxygen.

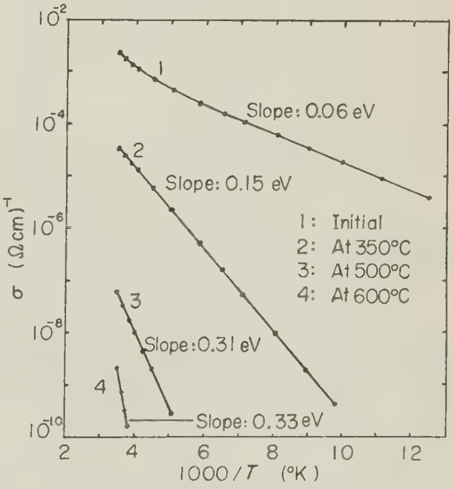

Fig. 8. Dark conductivity of sintered CdS:Cl:Cu films heat-treated in oxygen as a function of temperature.

(e) *Thermally Stimulated Current*

The thermally stimulated current of the sintered CdS : Cl : Cu films was measured by the same method as that in § 4. The results of measurements are shown in Fig. 10. The sintered CdS : Cl : Cu films at initial state had large number of traps, and by heat-treatment in oxygen the trap concentration was decreased, and a peak at about room temperature appeared by heat-treatment at 350∼500°C in oxygen. By heat-treatment at 600°C in oxygen the peak at about room temperature has almost vanished.

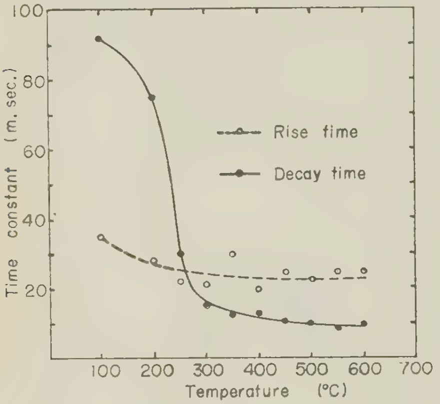

Fig. 9. Rise and decay time constants of sintered CdS : Cl : Cu film heat-treated in oxygen.

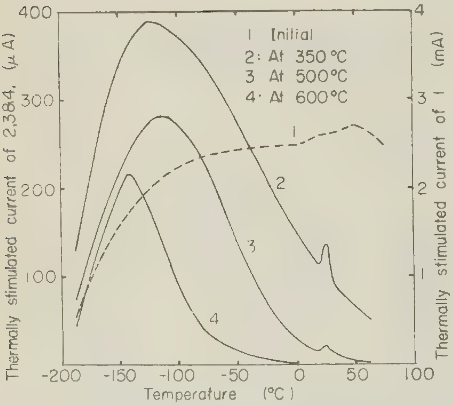

Fig. 10. Thermally stimulated current of the sintered CdS:Cl:Cu films heat-treated in oxygen as a function of temperature: D.C. 37 volts applied, heating rate of about 1 deg/sec.

§ 6. Observation of Produced CdO by an Electron-microscope

It was expected that CdO will be produced by heat-treatment of sintered CdS : Cl : Cu film in oxygen. The quantity of produced CdO in CdS : Cl : Cu films was measured by the method of X-ray diffraction. The results are illustrated in Fig. 11. It was found that CdO was produced by heat-treatment of sintered CdS : Cl : Cu films in oxygen above 400°C. By heat-treatment at 650°C, the quantity of produced CdO was found to be about 20% of CdS.

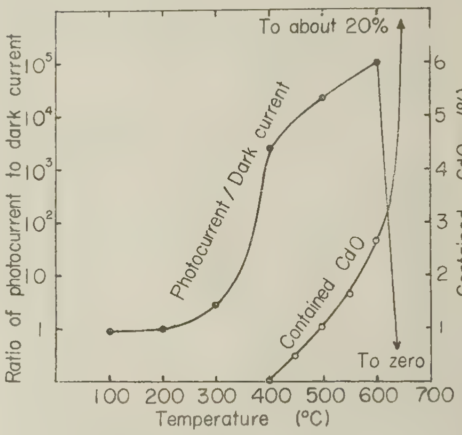

Fig. 11. The quantity of produced CdO in sintered CdS : Cl : Cu films and the ratio of the photocurrent to the dark current as a function of temperature in the case of heat-treatment in oxygen.

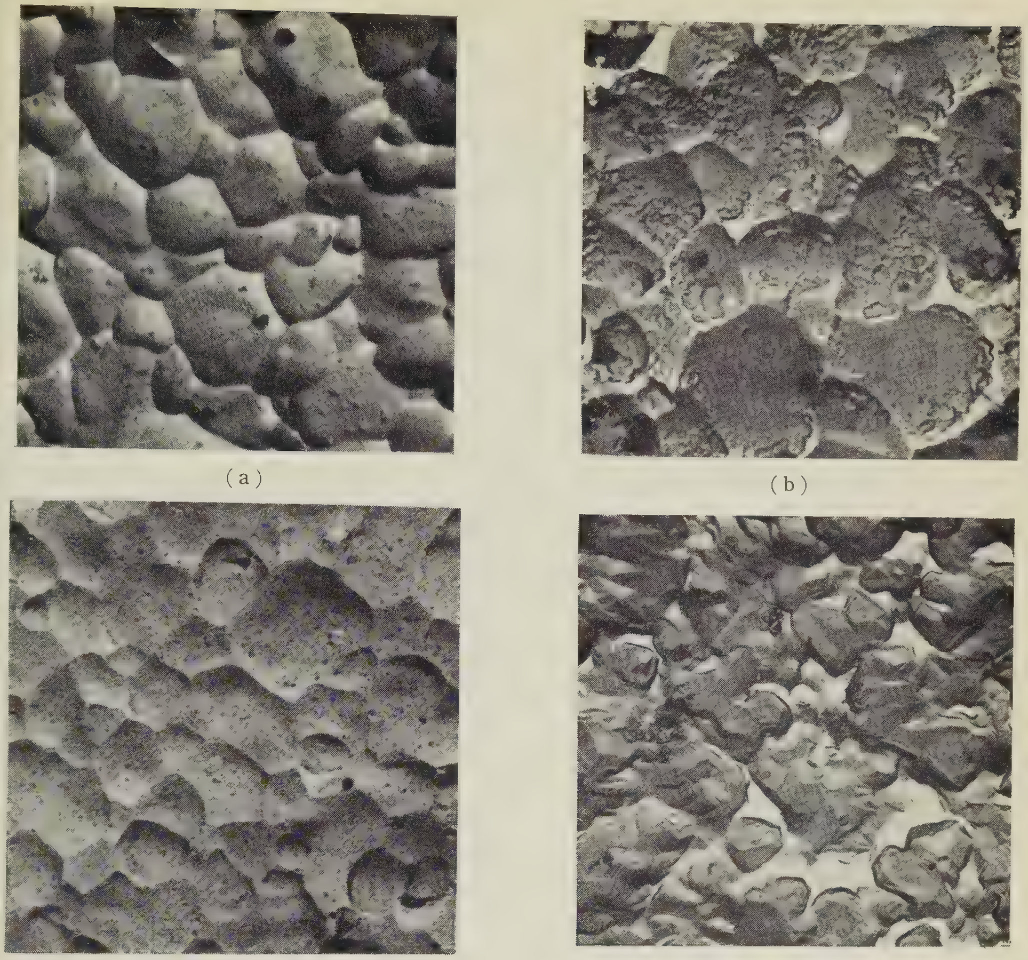
The variations of the surface of sintered CdS : Cl : Cu films by heating in oxygen were observed as shown in Fig. 12 by an electron-microscope with carbon replica method. At 300°C in oxygen, there were found some small particles on the surface, and at 500°C many particles, and at 600°C, these particles grew up and the whole surface of CdS : Cl : Cu films was covered by the grown particles. The shape of some of the grown particles on the surface of CdS : Cl : Cu film was cubic. By heating in oxygen at 650°C, it was seen that the produced CdO covered the whole surface of CdS : Cl : Cu film, so that the photoconductivity was negligible.

§ 7. Discussion

The sintered CdS films prepared by firing in nitrogen gas had large dark conductivity and long decay time, but the sintered CdS films prepared by firing in nitrogen gas plus hydrogen sulphide had small dark conductivity and short decay time. Both of the two sintered CdS films had many donors of Cl,



(a) (b)

(c) (d)

Fig. 12. Electron-micrographs of the surfaces of sintered CdS:Cl:Cu films heat-treated in oxygen. (×10000)

(a) Initial state; (b) Heat-treated at 300°C; (c) Heat-treated at 500°C; (d) Heat-treated at 650°C.

but the former should have many sulphur vacancies and by heat-treatment in oxygen these sulphur vacancies should have been occupied by oxygen atoms. By heat-treatment in oxygen at high temperature CdO has been produced on the surface and grain boundary of sintered CdS film.

(1) When sintered CdS films prepared by firing in nitrogen gas were heated in oxygen, the dark conductivity decreased. Below 300°C the degree of decrease was small, and above 300°C it was large. The dark conductivity was produced by thermally excited electrons from donors, so that it was thought that the concentration of donors was decreased by introducing oxygen. It seems that the sulphur vacancies were occupied by oxygen atoms so that the sulphur vacancies acting as donors had vanished.

(2) When sintered CdS : Cl films were heated in oxygen above 400°C, there was observed a new peak at 680 mμ in the spectral response curves. By this fact, it was found that an optical exciting centers were produced at 1.8 eV beneath the conduction band by introduced oxygen. In the case of CdS : Cl : Cu films, the peak at 620 mμ was slightly shifted to longer wavelength region, and the peak at 680 mμ did not appear.

(3) The activation energy corresponding to the slope of the curve of logarithm of conductivity plotted against the reciprocal of

Kelvin temperature increased with heat-treatment in oxygen. This fact shows that there was a new level below previous levels.

(4) By heat-treatment in oxygen, the decay time of photocurrent decreased, and it seems that the concentration of trap decreased. This fact supports the interpretation introduced in (1).

(5) The trap concentrations estimated by measuring thermally stimulated current are shown in Table II, where the trap concentration have decreased with heat-treatment in oxygen. When the CdS films were heated in oxygen, there resulted two peaks in thermally stimulated current curves at about −150°C and at room temperature, and by heat-treatment at 600°C a peak at room temperature in thermally stimulated current curves vanished. It was thought that there were many traps with the trap depth corresponding to energy of about room temperature of thermally stimulated current in the sintered CdS films at initial state, and these traps vanished by heating at 600°C in oxygen. But it is still unknown whether the peak at room temperature is produced by sulphur vacancies or by other defects.

Table II. Concentration of traps.

Specimen		Number of traps/cm³
CdS : Cl films	initial	about 5×10^{20}
〃	heat-treatment in oxygen at 500°C.	4×10^{19}
CdS : Cl : Cu films	initial	about 4×10^{19}
〃	heat-treatment in oxygen at 350°C.	4×10^{18}
〃	at 500°C.	2×10^{18}
〃	at 600°C.	1×10^{18}

(6) CdO was produced on the surface or grain boundaries of sintered CdS films by heat-treatment in oxygen, and finally the whole surfaces of CdS films were convered with CdO layers. Then the dark conductivity was very large and the photoconductivity was not observed as shown in Fig. 11. When there was little CdO in the sintered CdS films, the dark conductivity was fairly small, but it was unknown whether or not the photoconductivity of sintered CdS film was influenced by these CdO. While the dark conductivity of evaporated CdO film was higher than that of sintered CdS : Cl film, the photoconductivity of CdO film was very small. Therefore, the decreasing phenomena of dark conductivity would be due to the occupation of sulphur vacancies by oxygen atoms, but not directly due to CdO grains.

The mechanism that the introduced oxygen destroyed the sulphur vacancies as donor and produced a new exciting center at about 1.8 eV below conducting band, will be explained by detailed investigation on single crystals. And also, further experiments on grain boundaries will be necessary.

Acknowledgements

The author wishes to express his gratitude to Assistant Professor K. Fukuda of Kyoto University for his valuable suggestions rendered during the course of this work. The author is much indebted to Mr. T. Kubo, Mr. T. Yamashita and Mr. S. Matsuura in our laboratory for their interests and endeavors in measurements and preparations of specimens.

Possibility of Supervelocity of Glass Fracture

By Shin-ichi HYODO

Department of Applied Physics, Faculty of Engineering,
University of Tokyo

(Received August 1, 1960)

Extrapolating the Glathart-Preston equation for the variation of the glass strength with the loading time, it is assumed that, before a fracture is caused in soda-lime glass within the order of microseconds, the stress applied on it must have attained a value extraordinarily higher than the one for usual impacts—the difference in magnitude being nearly one order. From this assumption it is suggested that the local compression strain in soda-lime glass when subjected to impact by underwater sparks must surpass the ordinary linear elastic limit and accordingly that there may be a possibility of propagation of this fracture at a velocity higher than the normal limit.

Quite recently it has been reported by the writer[1)] that a glass fracture velocity remarkably higher than the usually accepted limiting one was observed when the fracture was initiated by underwater disruptive electric spark. In this paper are given some discussions concerning how a fracture in glass can propagates at such a supervelocity.

It has been known for some time that the rate of loading, as well as the duration of loading, has an effect on the breaking strength of glass. A statistical consideration by Hirata and Terao[2)] indicates that, when loading or the applied stress increases linearly with time, the mean stress at the moment of fracture, i.e. the breaking strength, may increase rapidly with the increasing rate of loading. With regard to the effect of the duration of loading, Glathart and Preston[3)] proposed the following empirical relation:

$$1/f = a + m \log t \qquad (1)$$

where f is the breaking strength, t is the duration of loading, and a and m are constants. These two results coincide in suggesting that a very large value of stress is required for producing a fracture within a very short time. Therefore, it would not be so extravagant to assume a relation as shown by the curve in Fig. 1 between the breaking strength of glass and the time required for starting the fracture. To draw this curve the values extrapolated from Eq. (1) were used as a measure. According to this equation the strength at the "threshold time" would become infinite, so an 'ideal strength' supposed as $10\,\mathrm{kg^3/mm^2}$ was adopted as a substitute for it.

It is worthy of noticing that in ordinary discharge circuits, where the damping condition is satisfied, the duration of impact by underwater sparks is comparable to the "threshold time" of all those glasses which were tested wet by Preston and his collaborator. It appears, therefore, not so unreasonable to assume a very high rate of loading in the case of underwater spark impact as shown by the line (A) in Fig. 1, so that fracture may be initiated within such a short time after the beginning of application of stress. On the other hand, the stress-time curves of glass under other mechanical impacts are supposed to be in the hatched area on the right side of the line (B). Positive

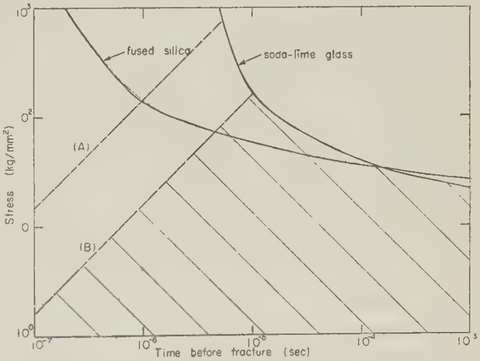

Fig. 1. Schematic representation of variation of the breaking strength of glass with the length of time before fracture, and of the increase of loading.

supports for this assumption, however, are difficult to find except in the difference of impact velocity: while the velocity of rifle bullets is usually not more than 800 m/sec, the propagation velocity of the pressure wave generated by underwater sparks is at least twice as large.*

From these presumptions it may be deduced that the breaking strength of soda-lime glass when subjected to impact by underwater sparks is greater than in the case of impact given by other methods by nearly one order in magnitude. If Young's modulus of soda-lime glass at room temperature is taken as 7.2×10^3 kg/mm^2, the percentage strain for such a high stress must attain 10% or more. On the basis of Anderegg's[4)] experiment, Taylor[5)] assumes that a fracture starts when the strongest bond in the atomic network of glass is suddenly stretched to 14.5%. So long as Hooke's law holds, it may be considered that, in the case of underwater spark impact, nearly all the bonds in the region of glass subjected to impact must have been compressed, or, in the peripheral region elongated, to such a limiting extent safely before fracturing. It seems unlikely that such a rubber-like process can take place in glass. As the stress-strain relation of solids generally tends to deviate from linearity for large strains, it is not so absurd to suppose that the effective Young's modulus of glass under the impact of underwater sparks would have become considerably larger than the one in an ordinary state. Although the stress-strain curve is apt to bend downward for large strain in the elongation test due to plastic deformation, for high-speed compression such as underwater spark impact, the curve is considered to bend upward because of the presence of a high atomic repulsion force. This is partly suggested by the results of the high pressure experiment made by Bridgman, which shows that the compressibility of matter generally decreases from the normal value under a very high hydrostatic pressure.

From the energy condition during the propagation of a Griffith-type crack (whose length is $2c$) Mott[6)] indicated that the fracture velocity $\dot{c}$ is determined by

$$\dot{c}=(2\pi/k)^{\frac{1}{2}}(E/\rho)^{\frac{1}{2}}(1-c_0/c)^{\frac{1}{2}}\ , \qquad (2)$$

where $2c_0$ is Griffith's critical crack size, E is Young's modulus, ρ is the density, and k is a constant. This shows that as c increases $\dot{c}$ tends toward a certain fraction of the sound wave velocity $(E/\rho)^{\frac{1}{2}}$. It is no wonder then that the limiting value may increase if the value of E increases. In addition, the coefficient $(2\pi/k)^{\frac{1}{2}}$ may change, probably increase a little, from the value 0.38 estimated by Robert and Wells,[7)] for, in order to determine k by solving an integral equation, they assumed a Westergaad condition, which would not be satisfied to a sufficient degree when the rate of loading grows to a very high value.

In other words, with the glass-fracture caused by underwater spark impact, the strain energy to be released by fracture would be more concentrated near the origin of the crack than in usual cases, so the higher production of kinetic energy following a higher fracture velocity is required to be balanced with the rapid decrease of the elastic strain energy.

Various objections against the foregoing opinion may be expected. The writer thinks it his duty to give answers beforehand to some conceivable objections. The first objection may be that, "as the water is able to lower the activation energy of glass-fracture, the difference of the breaking strength illustrated in Fig. 1 may be an over-estimation." It may be true to some extent, but except for the glass baked out in vacuum the effect of water on the strength of glass is not so remarkable as to influence the order of magnitude, according to Baker and Preston.[8)] The second one is that, "in the experiment of Kolsky[9)] who used stress waves from a small charge of explosives to study the fracture of soda-glass rods, their breaking strength was only about twice as great when specimens were loaded for a few microseconds as when loaded for a few seconds." This result was brought out from the observation of the circular cracks on the cylindrical surface of glass rods, but he remarked that no cracks were observed inside the rods, and so he predicted that there might be a very high internal strength of soda glass for loading time of the order of a microsecond. It should be this high internal strength that makes the region of glass around the origin of fracture capable of bearing such a high strain energy as fore-mentioned. The third one may be that, "if the rate of loading plays an important part in the supervelocity of fracture as the writer asserts, why has it not been found in the cracking caused by high explosives?" "Really Pugh and his co-workers[10] found by Kerr-cell photography that the glass fracture velocity went as high as 3500 m/sec, but they attributed it to the development of secondary fractures." This may be true, for the shock wave was so fast (6150 m/sec) and so intense that it maintained the ability to develop secondary fractures successively in front of the proceeding cracks all the way of propagation. However, if they had traced each of these secondary cracks individually, which, they said, was actually impossible with their photographs on account of the complete shattering by too violent shock waves, a supervelocity would have been observed.

---

* As there are some photographic evidences showing that cracks have started already just before a bullet reaches the surface of glass, the initial loading rate of a bullet impact may be somewhat lowered by the "cushion" of the Mach wave accompanying it.

It should be borne in mind that, when a comparison is made with the impact by explosives, the impact by underwater spark is characterized not only by high rate of loading but also by short duration of loading. In the longer duration of loading the excess strain energy to drive a crack would be continuously supplied to the specimen for a longer period after the initiation of fracture, so the local stress field around the tip of the proceeding crack would keep a "quasi-equilibrium" during such a short time as covered by the total frames in high-speed photography. This may be, in the writer's opinion, the reason why a gradual decrease of fracture velocity has not been found until quite recently. On the other hand, the duration of underwater spark impact is sufficiently short and the stress wave accompanying a large strain is attenuated much faster than the elastic wave of small amplitude.

In conclusion of this article it is to be remarked that as shown in Fig. 1, the "threshold time" for fused silica lies at about 0.2 μ sec, so the supervelocity of fracture of fused silica would not be observed so distinctly as in soda-lime glass, unless any adequate procedure to increase the rate of loading, such as decreasing the time constant of a discharge circuit, is taken.

The writer is greatly indebted to Prof. Moriso Hirata of the University of Tokyo for his helpful suggestions.

Spontaneous Magnetization of Magnesium Ferrite-Manganite System

By Kiyoshi MURAMORI and Syohei MIYAHARA
Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received September 1, 1960)

In the previous paper[1] it has been shown that magnetic behaviors of $MgMn_2O_4$ are consistent with the theory of triangular arrangements. In order to clarify the magnetic properties of solid solutions of $MgFe_2O_4$, which is confirmed to be typically ferrimagnetic, and $MgMn_2O_4$, we measured saturation magnetizations of those compounds.

Specimens measured are powders with the formula $MgFe_{2-a}Mn_aO_4$, where a are values from 0.0 to 2.0 at intervals of 0.2 and were prepared by the same way as $MgMn_2O_4$ reported previously[1]. X-ray patterns of those specimens at room temperature indicate a cubic spinel for a from 0.0 to 1.2, two phases of a cubic and a tetragonal spinel for $a=1.4$ and 1.6, and a tetragonal spinel for $a=1.8$ and 2.0. The details of the structures of those specimens will be published soon. Magnetizations were measured by Sucksmith's ring balance from Curie temperatures to liquid nitrogen temperature under a magnetic field up to about 13000 oersteds which is enough strong to saturate the magnetizations of all specimens.

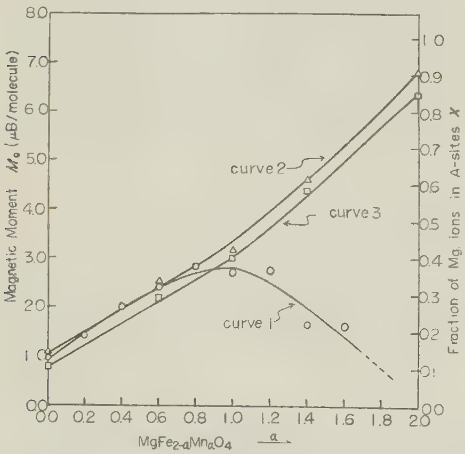

Fig. 1. Curves 1 and 2 show experimental and theoretical values of magnetic moments (M_0) and Curve 3 shows fraction of Mg ions located on A-sites (x).

It has been known that the cation distribution, and consequently, the saturation magnetic moment of $MgFe_2O_4$ depends sensitively on the thermal treatment of the specimen. Therefore the determination of the cation distributions of the series were all made for specimens which were cooled from 900°C to room temperature at the rate of 0.5° C/min. The distributions were determined from the intensity ratios of (220) and (422) X-ray diffraction lines to (400) line, where all manganese ions were assumed to be located on B-sites. The fractions of magnesium ions (x) located on A-sites are plotted in Fig. 1. In the same figure, the magnetic moments calculated by Néel's theory[3] from observed cation distributions are compared with the observed magnetic moments. Observed magnetic moment of $MgFe_2O_4$ agrees with the data by Kriessman et al.[2] for a specimen quenched from 500°C and is equal to the value expected from Néel's theory[3]. For specimens from $a=0.0$ to about 1.0, observed magnetic moments are in good agreement with the values expected from Néel's theory, where experimentally determined cation distributions are assummed. Magnetic moments of specimens $a>1.0$, however, are much smaller than those expecied from Néel's theory and decrease with increasing manganese compositions. This tendency of magnetic moments is the same feature as that of solid solutions of magnetic ferrites and zinc ferrite obtained by Guillaud et al. and Gorter[4]. Susceptibility measurements are now going on. Details will be published shortly.

Anisotropy on Poly-Crystalline Sheets of V-permendur

By Chinji KURODA

Electrical Communication Laboratory Nippon Telegraph and Telephone Public Corporation
1551, Kichijoji, Musashino-shi
Tokyo, Japan

(Received June 20, 1960)

An unusual magnetic anisotrpy of the ferromagnetic poly-crystalline sheet material was found. The specimens containing Fe 49-5 wt. %, Co 48.9 wt. % and V 1.6 wt. % were prepared by rolling at room temperature the sheet of 2 mm thickness and punching out. Their dimensions were 21 mm in diameter and 0.35 mm in thickness. For the measurement of anisotropy, torque magnetometer method was used, the principle of which was alike that of Penoyer's[1], and torque curves were recorded automatically. After verifying that the magnetic qualities for technical magnetization were most favorable by annealing at 850°C in dry hydrogen atomosphere, the measurements of torque curves were performed for the specimens which had undergone the same heat-treatment.

Figs. 1 and 2 show the torque curves obtained at field strengths from 200 oe to 440 oe and from 500 oe to 9,500 oe respectively. Through that torque curves, it is seen that the directions of easy magnetization are at 45° and 135° to the rolling direc-(R.D.) and the types of the curves are mostly represented by 4θ term. It is an unusual behavior that the torque amplitude has a maximum value at about 500 oe as is shown in the Figs.

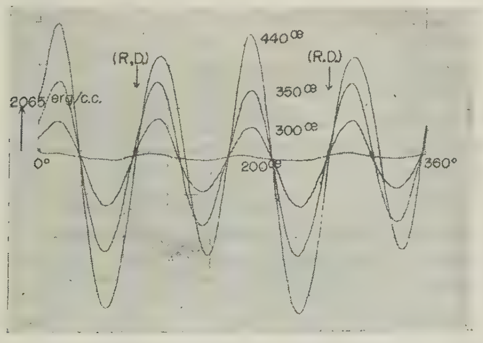

Fig. 1. Torque curves at room temperature obtained at low magnetic fields.

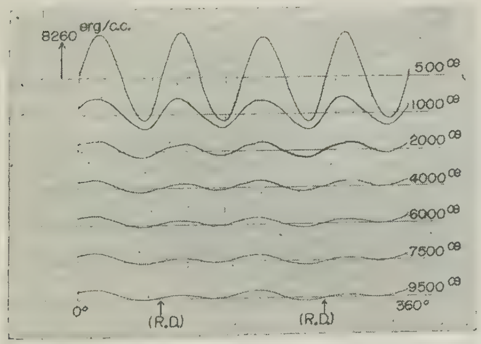

Fig. 2. Torque curves at room temperature obtained at high magnetic fields. They show the decrease of torque amplitude with field strength.

The torque curve measured at 9,500 oe could be thought to represent the recrystallization structure that was obtained by annealing at 850°C. However the decrease of torque amplitude with increase of field strength in rather low field can not be understood by taking in only the recrystallization structure, although the torque curves even in such low fields obviously has a connection with that structure.

Several authors have reported on torque reversal for some single crystals and interpreted it under the consideration of the precipitates or inhomogeneous structures distributed cubically.[2),3)] S. Chikazumi also mentioned[4)] that on the single crystals which exhibit magnetic annealing effect the torque reversal could occur.

Since our specimens were the poly-crystal, these effects should be smeared out at any field strength. Therefore, these interpretations can not be used in a straight manner to understand this torque decrease.

At first sight, it seems to be understood by considering the preferential distribution of grain orientation caused by recrystallization and above mentioned mechanisms. But, the directional order mechanism[4)] gives the too much low field strength for the maximum torque amplitude. Also, because of low V contents and low annealing temperature, no preciptitates are expected. And microscopical observations did not show any precipitates. Then, the precipitation mechanism can not interpret this torque decrease too.

However, if the lattice defects, which were not completely annihilated on the recrystallization at 850°C, formed some ordered structure directionaly arranged to the rolling stress direction and each crystallite orientations, it may be possible that their total shape anisotropy causes this torque decrease. The fact that the re-annealing at 850°C after the annealing at 1,100°C did not give the torque decrease seems to support this mechanism.

More detailed studied studies will be reported later.

Anomalous photovoltaic Effect of CdS Single Crystals

By Sumiaki IBUKI, Hiroyoshi KOMIYA and
Hirosuke YAMASHITA

*Research Laboratory, Mitsubishi Electric Mfg. Co.
(80 Nakano, Minamishimizu, Amagasaki,
Hyogo, Japan)*

(Received September 2, 1960)

Some researches on the hole conduction[1], photovoltaic effect by electron diffusion[2] and efficiency as a solar converter[3] of CdS have recently been reported. We have also investigated the photovoltaic effect of CdS single crystals, then we report some results obtained by another electrode construction.

CdS single crystals were grown by sublimation recrystallization in N_2 atmosphere containing In vapor and their resistivities were about several KΩ cm in dark. As shown in Fig. 2., a half side of crystal is covered with evaporated layer of Cu and after heat-treatment of several minutes at 600°C, both ends of the crystal are soldered with in metal. Using these cells we obtained open circuit voltage of 0.5 V (positive for Cu side) and short circuit current of about 1 mA/cm² under direct sun light. It was found, however, that in a low light level polarity of photo-induced voltage was changed to negative sign for Cu side as shown in Fig. 1. It is supposed that this effect may be induced by the electron diffusion. In order to verify this hypothesis, the photovoltage was measured, scanning a light spot on the crystal surface. The measured results are shown in Fig. 2.

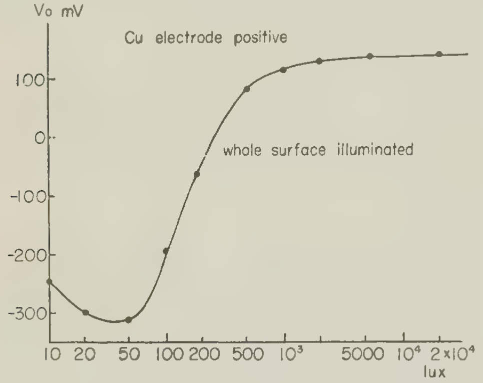

Fig. 1. Open circuit voltage-light intensity.

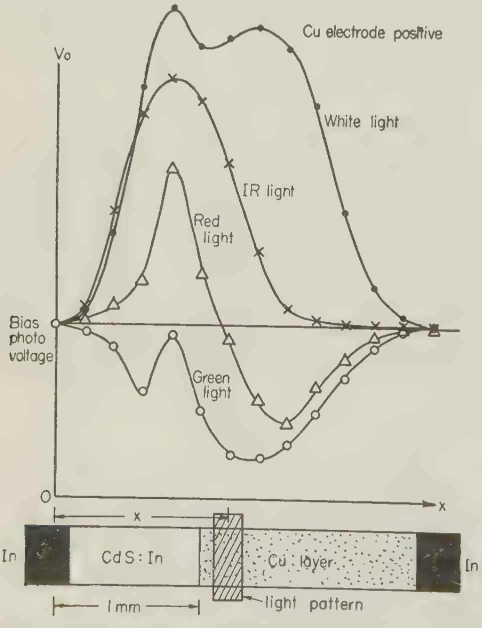

Fig. 2. Photo voltage caused by local illumination.

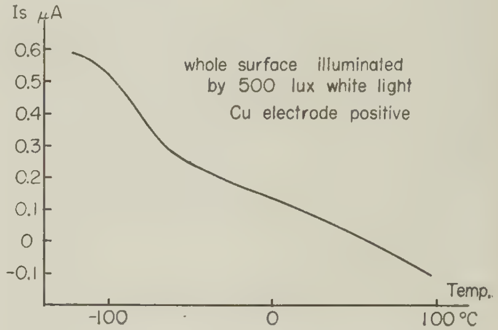

Fig. 3. Temperature dependency of short circuit current.

From above results, it is concluded that the photovoltage is caused by P-N junction grown near the boundary between CdS and Cu layer. But from the results observed by means of weak green and red-light spot, the electron diffusion current caused by large gradient of electron densities seems to produce the negative photovoltage[2]. While, the negative photovoltage was neither seen when the crystal whose electrodes are In only was illuminated partially nor when the other crystal whose half side was covered with evaporated Cu layer which was not heat-treated at all. It is considered, therefore, that heat-treated Cu layer plays also a main role upon the electron diffusion. Hence we might be able to conclude that the facts that temperature dependency of short circuit current is so remarkable and at high temperature its polarity is changed as given in Fig. 3, will be explained by the superposition of the above mentioned two phenomena, i.e. P-N junction and electron diffusion current.

Detailed results will be published in near future.

On the Mechanism of Reversible Appearance of Residual Magnetization at low Temperature Transition in αFe_2O_3

By Kiiti SIRATORI, Akira TASAKI and Shūichi IIDA

Department of Physics, Faculty of Science University of Tokyo, Tokyo

(Received September 17, 1960)

αFe_2O_3 is a parasitic ferromagnet above $T_c = -20°C$ where the axis of spin lies in the (111) plane of the rhombohedral crystal. The weak ferromagnetism disappears below T_c where the spin axis changes from in the (111) plane to along [111] axis¹⁾. It has been found experimentally that the weak residual magnetization of αFe_2O_3, which has once disappeared by passing through the transition point from high temperature, appears again in the same direction when the temperature is raised²⁾. The intensity, however, decreases in the first cycle to about 2/3~1/2, and remains constant for the following repetitions. (Fig. 1)

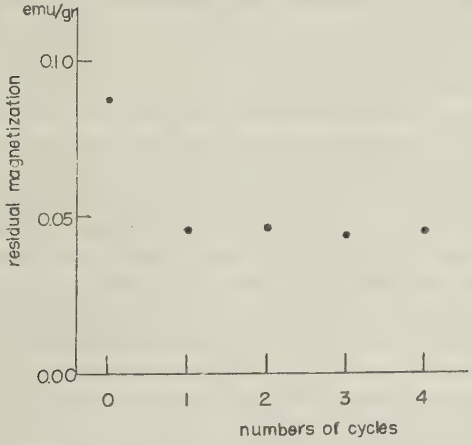

Fig. 1. Residual magnetization of polycrystalline αFe_2O_3 at room temperature after cooling-heating cycles.

Now there are three easy spin axes in a basal plane above T_c. We put an assumption that in each domain, one of the three axes is more preferable than the other two, probably due to the presence of internal irregularies. Then there exist two lowest energy states in each domain, corresponding to the two degenerate spin states of a usual antiferromagnet. This crystal being the canted antiferromagnet³⁾, the two states have weak magnetizations pointing in antiparallel with each other along U_2 axis perpendicular to the preferred axis. It is pointed out, in this paper, that the spin axis should rotate reversibly from within the basal plane to along [111] axis in the transition, which results in one to one correspondence of the two degenerate states before and after the transition or a complete recovery of the residual magnetization.

The assumed expression of the magnetic anisotropy is

$$E = K_u \cos^2\theta + K_1' \cos\theta \sin^3\theta \sin 3\phi - K_u' \sin^2\theta \sin^2\phi \quad (1)$$

where θ and ϕ are the polar angles of the spin axis from [111] and U_2 axis respectively, and $K_u > 0$ when $T > T_c$. The first two terms are those that are considered to be dominant in trigonal crystals and have been presented already by Dzyaloshinsky*. The third term is added to express the presence of the preferred axis. As is known already, Eq. (1) gives a deviation of spin axis from (111) plane even above T_c, where $\theta (\lesssim \pi/2)$ is given by

$$\cos\theta / \sin 3\theta = -|K_1'|/2K_u \quad \text{if} \quad K_u' \ll |K_1'| \quad (2)$$

On lowering the temperature, K_u and θ will be decreased continuously. If the condition that $-K_u > |K_1'|/2$ (or $\theta > \theta_1 = 45°$) is attained, the energy of a spin with $\theta = 0°$ becomes lower than that with θ of Eq. (2). Further, when $-K_u > 1.18|K_1'|/2$ or ($\theta > \theta_2 = 34° 16'$), the latter becoming unstable, the spins may flip to the [111] direction from this region ($\theta_1 > \theta > \theta_2$) through wall displacement or rotation. On reheating the spins are turned back reversibly to the original position, the process of which is accompanied with a small hysteresis as has been observed by Lin⁵⁾.

In actual crystals the direction and the value of K_u' will be distributed statistically. But, so long as the value of K_u' is large enough to restrict the spin axis in one σ_d plane, spins will "remember" their states and magnetization will appear again after a cooling-heating cycle.

It is very interesting to notice that if it is possible, by applying a strong field, to cool down the specimen aligning the spins of the entire crystal to a direction perpendicular to the magnetic field, the present mechanism (if the mutul interaction of the domains through strain, antiferromagnetic wall etc. is neglected) will results in a zero residual magnetization after reheating process. However, the first trial to check this point (with a field of 40 KOe) gives negative results. The details will be published shortly.

Note added in proof: This correspondence of states will be confirmed by the observation of piezomagnetism of αFe_2O_3 below the transition point. This experiment is now in preparation. The authors wish to thank Mr. T. Inoue for this suggestion.

Antiferromagnetism of $FeSn_2$

By Kazuo KANEMATSU, KŌ YASUKŌCHI
Department of Physics, College of Science and Engineering, Nihon University, Tokyo
and Tetuo OHOYAMA
Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received September 21, 1960)

In the course of our study on magnetic properties of intermetallic compounds composed of iron group transition elements and those of IVb group in the periodic table, a variety of magnetic behaviors was found in various compounds[1)2)3)]. As to the iron—tin system, it was reported by Asanuma[4)] that γ-FeSn ($Fe_{1.3}Sn$) was a ferromagnetic with the Curie point of 676°K, and we also found a strong ferromagnetism in Fe_3Sn_2. In this note the antiferromagnetic behavior found in the compound $FeSn_2$ is reported.

As the compound is formed peritectically at 496°C[5)], the specimen was prepared by a sintering method as in the following: Pieces of electrolytic iron (99.9%) and tin (99.999%) were mixed in the stoichiometric proportion, sealed in an evacuated telex tube, and after prefired by an electric furnace at 460°C for 3 days, the product was crushed into powder. The powder thus obtained was heated again at 460°C and the above procedure was repeated for several times, until the finish of the peritectic reaction was ascertained by X-ray diffraction.

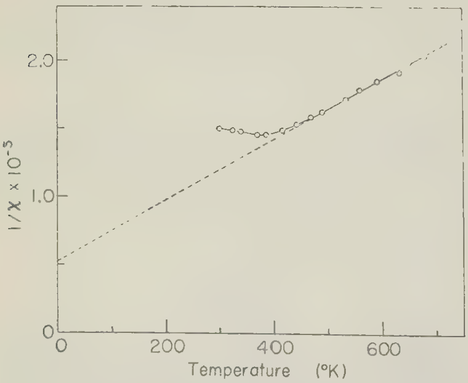

Fig. 1. Inverse susceptibility, $1/\chi_g$, versus temperature curve of $FeSn_2$.

In the X-ray diagram of the specimen used for the magnetic measurements, no diffraction lines were found which come from tin, iron, or any other compounds in the system than $FeSn_2$. The diffraction lines could be indexed as a tetragonal structure with lattice constants $a=6.50_2$Å, $c=5.31_5$Å, and $c/a=0.816$, and the relative intensities of these lines were in good agreement with those reported by Nowotny and Schubert[6)], who determined that the compound $FeSn_2$ has a body centered tetragonal, C16 type of structure.

The temperature dependence of the magnetic susceptibility was measured by a magnetic balance of torsion type from the room temperature up to 460°C with a field of 7.5 kilo-oersteds. The results are shown in Fig. 1. Here the reciprocals of the magnetic susceptibility are plotted against temperature. It is seen that the behavior is antiferromagnetic, and the temperature corresponding to the minimum of the curve, 380°K, may be considered as the antiferromagnetic Néel point. The Curie-Weiss law holds very well at temperatures above 500°K. The effective magnetic moment per iron is calculated from the Curie constant to be 3.36 μ_B and the asymptotic Curie temperature is estimated to be −230°K.

Among the intermetallic compounds between iron group transition elements and those of IVb group, $MnSn_2$, $FeGe_2$, and $CoSn_2$, as well as $FeSn_2$, are known to have the C16 type of structure. In recent magnetic measurements on the compounds of above series, we found that $MnSn_2$[2)], like as the present compound $FeSn_2$, was antiferromagnetic, and $FeGe_2$[3)] was parasitic ferromagnetic, while $CoSn_2$ was weakly paramagnetic. When the temperature was increased from the room temperature to 750°K, the magnetic susceptibility of $CoSn_2$ increased monotonically from 1.5×10^{-7} to 3.5×10^{-7}. Though the origin of this increase is uncertain at present, it would not be ascribed to antiferromagnetism.

Thermoelectric Power of Titanium- and Vanadium-Carbides

By Seiichiro NOGUCHI and Takao SATO
Department of Physics, Tokyo Metropolitan University, Tokyo

(Received September 24, 1960)

A number of investigations have been made for the metallic carbides and nitrides with the sodium chrolide structure and the nature of their bonding has been discussed[1),2)] in conjunction with their properties such as hardness and melting point, etc. The metallic carbides such as TiC and VC are of great interest since they have appreciably higher melting point and hardness than their constituent metals. These properties suggest that the compounds have stronger bonding and the nature of the principal bonding is the homopolar bond. Although the metal atoms and carbon atoms in these substances may be considered to bind each other in homopolar sense, they are present as considerably good electric conductors.

To reveal the nature of the conduction in these compounds, we must obtain further informations on the electrical properties of them. The Hall coefficients of TiC and VC have been measured by Tsuchida and Takagi[3)], who have shown that the numbers of the conduction electrons are 0.18 and 1.21 for TiC and VC, respectively, using the nearly free electron approximation. It is much interested that the difference between these numbers is almost unity. The number of outer electrons of titanium is four while that of vanadium is five. If all the outer electrons of the metal atoms contribute the bonding, the melting point of VC should be higher than that of TiC. In the fact, however, VC has rather lower melting point than TiC. This indicates that the numbers of the electrons contributing to the bonding may be slightly less in VC than in TiC. Assuming that the number of the electrons contributing to the bonding is nearly the same in both substances, we may expect that the number of conduction electrons of VC is more than that of TiC by almost unity per metal atom. The numbers of the conduction electrons supposed by their melting points are in good agreement with those obtained by the Hall measurements. To obtain further informations of the conduction electrons in these compounds, we made the measurement of the thermoelectric power of them at room temperature and at liquid nitrogen temperature. The data shown in Table I were analyzed with the assumption that the conduction electrons are nearly free. Then we may write the absolute thermoelectric power as

$$S=-(\pi^2k^2T/e\zeta)\,, \qquad (1)$$

where ζ is Fermi energy, the other symbols have their usual meanings.

Table I.

	S (μV/deg)		ζ (eV)
	R.T.	Liq. N_2	
TiC	-10.81	-7.2	2.02
VC	-4.12	$+0.34$	5.31

The Fermi energy can be derived from the absolute thermoelectric power at room temperature. Employing the values of these Fermi energies and the condition that VC has one more electron than TiC per metal atom, we can obtain the following relations in the nearly free assumption;

$$\left.\begin{aligned} \frac{2\pi(2m^*)^{3/2}}{h^3}\int_0^{2.02} E^{1/2}dE&=x,\\ \frac{2\pi(2m^*)^{3/2}}{h^3}\int_0^{5.31} E^{1/2}dE&=1+x\,. \end{aligned}\right\} \qquad (2)$$

The numbers of the conduction electrons are easily obtained from above relations and they are 0.31 per titanium atom for TiC and 1.31 per vanadium atom for VC. Although our assumption is very simple, the agreement between the numbers of the electrons reduced by the present experiment and those by the Hall measurements is wonderfully good. The results therefore will be considered that the assumption used here is rather good one for these systems, namely it will be said that the behavior of their conduction electrons is nealy free. The effective mass of the electron is obtained to be 0.78 m from the relation between the provisional state density and the energy, where m is the mass of free electron.

Recently, the band-model approximation of the metallic carbides with NaCl structure has been proposed by Bilz.[4)] In his model, the Fermi energies are shown as about 3 eV for TiC and 5.5 eV for VC. The values of the Fermi energy obtained from our measurements are in good agreement with the values estimated by Bilz.

The authors wish to express their sincere thanks to Prof. Takagi and Mr. Tsuchida for their kind offer of the specimens.

Indirect Transition in Narrow Junction of Ge–Si Alloy

By Kei-ichi ANDO
Semiconductor Department, Research Section,
Sony Corporation, Shinagawa
Tokyo

(Received Sept. 28, 1960)

This concerns only Si rich Ge–Si alloys. The impurity that is doped is phosphorus ($\sim 10^{19}\,\mathrm{cm}^{-3}$). Al-b (B:2 3%) was used as p-type dot of alloying and made abrupt p–n junctions by alloying.

Contents of Ge in Ge–Si were determined by X-ray in measuring of lattice constant.

Voltage-current characteristic of the diode was measured in room temperature, in liquid nitrogen, and in liquid helium. Details of the characteristics in helium are shown in Fig. 1. The cusps were found only in liquid helium. These cusps represent the energies of phonons that help indirect transition in conserving momentum during the tunneling, but in low temperature, electron cannot absorb phonons as the lattice vibrations do not produce such phonons.

Results of the measurement on the various content of Ge–Si are given in Table.

Contents of Ge in Si % (atomic)	Energy of Phonons (Mc/sec)					
	TA	O		(O+TA)		(O+O)
0	3.87	13.35		20.10		28.80
3.35	4.10	13.3		19.3	24.2	27.8
4.13	4.83	13.3	16.6	19.0	24.6	
5.44	4.83	13.0		19.1	23.2	29.0
9.1	4.35	13.3		18.4	24.2	29.5

Mc/sec was used to facilitate a contrast with the spectrum of lattice vibration.¹⁾ The data of Si were measured by Esaki-Miyahara and Holonyak et al.²⁾ Optical researches of Si were also performed by Macfarlane et al and Hayne et al.³⁾

Energy of TA does not gradually decrease but makes maximum in 4–5% Ge. O is almost the same, (TA+O) decreases and (O+O) increases in the region of this measurement. According to the calculation of Braunstein et al,⁴⁾ Hamiltonian of lattice vibration of Ge–Si is

$$\boldsymbol{H} = -\frac{1}{2}\hbar^2\left[\sum_{\mathrm{Ge}} M_{\mathrm{Ge}}{}^{-1}\cdot\frac{\partial^2}{\partial X_{\mathrm{Ge}}{}^2} + \sum_{\mathrm{Si}} M_{\mathrm{Si}}{}^{-1}\cdot\frac{\partial^2}{\partial X_{\mathrm{Si}}{}^2}\right] + \frac{1}{2}\left[\sum_{\mathrm{Ge}}\sum_{\mathrm{Ge}} X_{\mathrm{Ge}}X_{\mathrm{Ge}}\frac{\partial^2\phi}{\partial X_{\mathrm{Ge}}\partial X_{\mathrm{Ge}}} + \sum_{\mathrm{Ge}}\sum_{\mathrm{Si}} X_{\mathrm{Ge}}X_{\mathrm{Si}}\frac{\partial^2\phi}{\partial X_{\mathrm{Ge}}\partial X_{\mathrm{Si}}} + \sum_{\mathrm{Si}}\sum_{\mathrm{Si}} X_{\mathrm{Si}}X_{\mathrm{Si}}\frac{\partial^2\phi}{\partial X_{\mathrm{Si}}\partial X_{\mathrm{Si}}}\right].$$

Energy of phonons decrease as Si goes to Ge. But in this measurement, the energy of phonons are not so.

As this measurement covers only a small region of Ge in Ge–Si, it is impossible to infer the mechanism and the structure of band. But in Si side of Ge–Si, it is necessary to consider that the conduction minimum of Si moves toward the minimum of Ge in the direction of [100], and where the minimum of Ge is.

Besides four cusps, more cusps have been found, which are not possibe to imply now.

The author would like to thank the members of Electrotechnical Lab. and Mr. Hoshi in Sony Corp.

Weak Ferromagnetism of $NaNiF_3$

By Shinji OGAWA

Research Institute of Applied Electricity,
Hokkaido University, Sapporo

(Received Sept. 28, 1960)

Rüdorff and Kändler[1)] have briefly mentioned that $NaNiF_3$ was ferromagnetic at liquid nitrogen temperature. In this note some characteristics of the so-called weak ferromagnetism found in $NaNiF_3$ will be reported.

The crystal structure of $NaNiF_3$ has been determined by X-ray to be orthorhombic. The lattice constants at 295°K are: $a=5.361$Å, $b=5.524$Å, and $c=7.688$Å. The most probable space group is D_{2h}^{16}-Pbnm. The magnetization of polycrystalline $NaNiF_3$ measured from 77°K to 300°K has a field-dependence expressed as $\sigma=\sigma_0+\chi H$ below about 150°K. The magnetic torques, L, of a $NaNiF_3$ single crystal in the planes containing the c-axis have an angular dependence of $L=\pm\sigma_0 H\sin\theta$, below 149°K. Near the direction perpendicular to the c-axis, the torque was extremely unstable and suddenly changed its sign. Typical torque curves in the b–c plane at 77°K are shown in Fig. 1. In the a–c plane torque curves deviated somewhat from the $\sin\theta$ curve. In the plane perpendicular to the c-axis a torque of two-fold symmetry, the amplitude of which is nearly proportional to H^2, was observed and is shown in Fig. 2. It is concluded from the torque measurement that the spontaneous magnetization, σ_0, appears in the c-direction and it is not rotated toward the b-direction but rotated in some degree toward the a-direction by an applied magnetic field of up to 10 kOe.. The σ_0 determined from the torque in the b–c plane is plotted against temperature in Fig. 3. It disappears above a cirtical temperature $T_c=149$°K. At 77°K σ_0 is 0.058 μ_B per molecule of $NaNiF_3$. It is only about 3% of the spin magnetic moment of a Ni^{2+} ion.

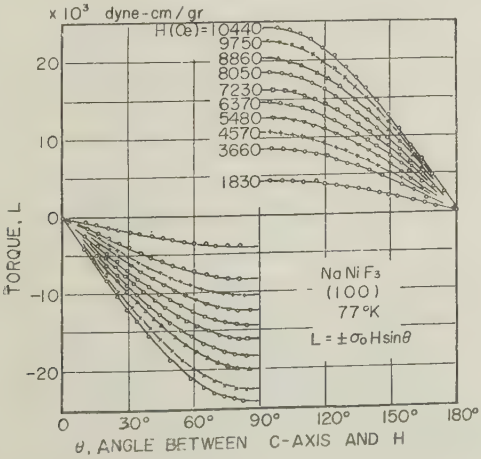

Fig. 1. Torque curves in (100) plane.

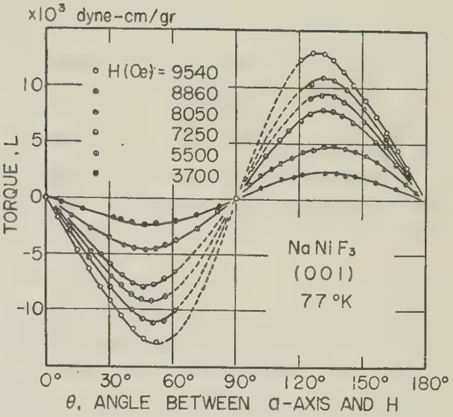

Fig. 2. Torque curves in (001) plane.

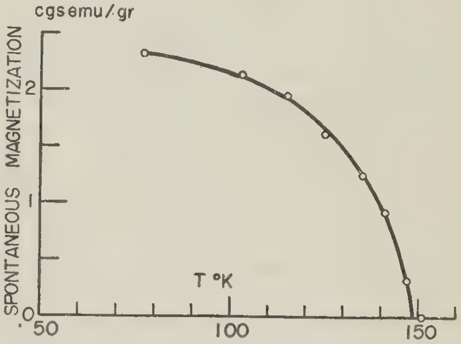

Fig. 3. Temperature dependence of σ_0.

Some rare earth orthoferrites show a similar torque behavior[2)], and Bozorth[3)] has discussed a relation among their spin structure, spin direction, and direction of spontaneous magnetization from the symmetry consideration which was first pointed out by Dzyaloshinsky[4)]. His argument can be applied to $NaNiF_3$ crystal which has the same crystal symmetry. $NaNiF_3$ has probably a G-type spin structure[5)] and is believed to be a canted antiferromagnet in which the spins of Ni^{2+} ions are approximately directed along the a-axis and slightly incline toward the c-axis.

A rapid increase of the anisotropy of paramagnetic susceptibility, which is characteristic of a weak ferromagnet[6)], has also been observed near T_c. Details will be published elsewhere.

Anomalous Temperature Dependence of Lattice Constant of Cr O_2

By Kiiti Siratori and Shūichi Iida

Department of Physics, Faculty of Science University of Tokyo, Tokyo

(Received Oct. 11, 1960)

Previously, we studied the crystallographic and magnetic properties of $Mn_xCr_{1-x}O_2$ system, and reported that the Vegard's law is not satisfied in this system[1]. All the specimens crystallize in rutile type tetragonal structure, but c vs. x curve shows two anomalies. In order to study the reason of these anomalies, temperature dependence of the lattice constants were measured.

The specimens used were the same as had been in the previous study. Variation of the X-ray diffraction angles of (211) and (220) lines was observed at several temperatures with a counter type spectrometer and with Cu $K\alpha$ radiation. Relative accuracy of the measurement is about ± 0.002A for both a and c. The temperature dependence of a, c and $\sqrt[3]{a^2c}$ for CrO_2 and $Mn_{0.05}Cr_{0.95}O_2$ are shown in Fig. 1. As is shown, c has a maximum at about 0°C, which becomes broad when Mn is added, whereas the unit cell volume varies almost linearly with temperature. It seems that this phenomenon is independent of the magnetic transition, since there is no anomaly at the Curie temperature (124°C). It has been confirmed that all the specimens with $x<0.17$ have negative temperature coefficient of c in the temperature range of $0° < T < 200°$C.

It will be very probable that these anomalous variation of c will cease at a certain temperature, T_s, above 200°C, and will show a normal linear increase with temperature above this point. Therefore, it is concluded that there is a certain structural transition in the temperature range $0° < T < T_s$. The authors are now inclined to believe that this transition is a Jahn-Teller distortion of $(3d)^2$ orbitals of Cr^{4+}.

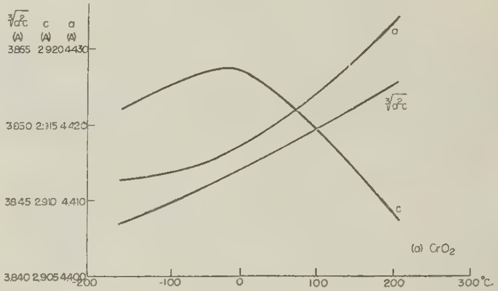

Fig. 1 (a).

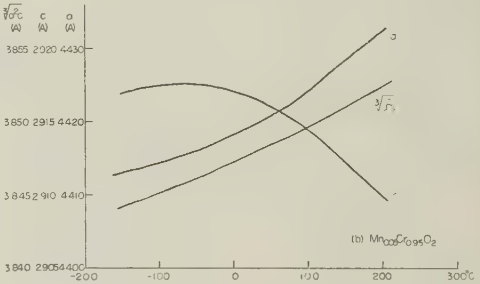

Fig. 1 (b).

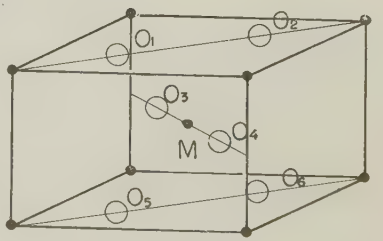
Fig. 1. Temperature dependence of a, c and $\sqrt[3]{a^2c}$.

It is well known that many magnetic oxides have a crystal distortion that cannot be expected merely from the symmetry of the crystal and is accounted for well by the Jahn-Teller effect of the magnetic ions participated[2]. There are also some oxides as CuO, CrF_2 and $CrCl_2$, that have a crystal

Table I.

Parameters of oxygen octahedron around cation in CrO_2 and MnO_2

	CrO_2	MnO_2
O_1 O_2	2.57 A	2.51 A
O_1 O_3	2.68	2.66
O_1 O_5	2.92	2.87
M $O_{1,2}$	1.94	1.91
M O_3	1.84	1.85
$\angle O_1$ M O_2	83°	82.5°



structure with no distortion apparently, but the legand anions construct a distorted octahedron and the distortion of which can be most reasonably explained by the Jahn-Teller effect of the cations at the center³⁾. However, few is known on the effect of the cations with degenerated $d\varepsilon$ orbitals (π orbitals) only. It is considered that the order of magnitude in this case will not be so small compared with those of the typical degenerated $d\gamma$ orbitals (σ orbitals).* But care should be taken in this case (1) to the presence of spin-orbit coupling interaction of the $d\varepsilon$ electrons (this term is not active in the case of $d\gamma$ orbitals) and (2) to the admixture of the state ($d\varepsilon^1\, d\gamma^1$) through interelectronic Coulomb interaction.

In relation to these argument, the shape of the oxygen octahedron around Cr^{4+} ion becomes important. From the intensity measurements of (111) and (210) reflection, parameter u is determined to be 0.294±0.005 for CrO_2 and 0.298±0.005 for MnO_2 at room temperature (temperature factor is neglected). Parameters of the oxygen octahedron calculated from these values are shown in Table I.

However, the study is in an initial stage at present and no decisive answer is given whether this crystal is strictly rutile type or not. Detailed report will be presented in the near future.

Thanks are due to Mr. T. Inoue for his helpful suggestion and discussions.

A Note on Date's Paper "Magneto-plasma Resonance in Semiconductors (I)"

By Kazuo YAMAGATA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received October 5, 1960)

A theory of magneto-plasma resonance in semiconductors was developed by Date in his paper entitled "Magneto-plasma Resonance in Semiconductors (I)" which appeared in this journal¹⁾. It may be said that the treatment can be justified under the assumptions that the specimen is spherical and that the energy surfaces of the semiconductors are spherical. In his paper the author stated that the theory can be applicable to the usual semiconductors such as silicon and germanium. It must, however, be noticed that the energy surfaces of the usual semiconductors are not spherical but highly anisotropic except a few ones such as indium antimonide.

From the physical point of view, there are three difference effective masses, conductivity or plasma, magneto-plasma and cyclotron mass. It seems apart from reality to assume that the three masses can be represented by one mass parameter even in the case that the parameter may depend on the directions of the static magnetic field and the oscillating electric field. For the purpose of clarifying these ambiguities, we performed calculations on the case of spherical specimen of semiconductors with one type of carriers with anisotropic effective mass.

All the reports preceding the above mentioned one are developed for the case of spherical energy surfaces²⁾. We must, therefore, start from the fundamental equation of the electron transport theory. The starting equation is

$$\frac{d}{dt}\{M\cdot\boldsymbol{v}(t)\}=q\{\boldsymbol{E}(t)-L\cdot\boldsymbol{P}(t)\}+\frac{q}{c}\{\boldsymbol{v}(t)\times\boldsymbol{H}\}-\nu\{M\cdot\boldsymbol{v}(t)\},$$

where M is the mass tensor with principal values m_1, m_2 and m_3, $\nu=1/\tau$ is the relaxation frequency. In the case that the oscillating electric field is parallel to the x-direction and the static external magnetic field to the z-direction, one of the diagonal elements of couductivity tensor is

$$\sigma_{xx}=\frac{Nq^2}{m_1}\cdot\frac{1}{(i\omega_1'+\nu)+\dfrac{\omega_c{}^2}{(i\omega_2'+\nu)}},$$

where $\omega_1'=\omega-(\omega_{1p}^2/\omega)$ with $\omega_{1p}=(L_lNq^2/m_1)^{1/2}$, $\omega_2'=\omega-(\omega_{2p}^2/\omega)$ with $\omega_{2p}=(L_lNq^2/m_2)^{1/2}$ and $\omega_c=(qH/c)(m_1 m_2)^{-1/2}$.

The above result shows that three types of effective mass must be introduced. That is to say m_1, $(m_1 m_2)^{1/2}$ and m_2. It is not much accidental to meet with the anisotropy with the factor of 20, and in such a case we have three effective masses with the ratio of 1 and 4.5 to 20. This is the consequence of the fact that the motion of carriers in the magneto-plasma resonance consists of longitudinal plasma motion, transeverse plasma motion and cyclotron motion. In the cases that the energy surfaces are many valley type, that the sample is not a sphere and that the magnetic field are not parallel to the principal axes, the calculation may be somewhat laborious. The principal features of the above result may not, however, be altered.

Optical Bleaching of Gamma-Irradiated KCl at Room Temperature

By Noriaki ITOH and Tokuo SUITA

Department of Nuclear Engineering, College of Engineering, Osaka University

(Received September 8, 1960)

It has been already shown[1] that a part of F centers formed by ionizing particles bleaches quickly by F light illumination, whereas the remaining part bleaches at a considerably slower rate. In order to clarify such two step bleaching, we investigated the effects of bleaching temperature and initial concentration of F centers on the bleaching phenomena in gamma-irradiated KCl.

The specimens were obtained from the ingot purchased from Harshaw Chemical Co. In order to obtain uniform coloration, the specimens were gamma-irradiated in the Co^{60} cave of JAERI (Japan Atomic Energy Research Institute). The optical absorption was measured with Cary Spectrophotometer, and F light illumination was done by the spectrometer with 3 mm slit width.

From the bleaching curves at 18°C and at −25’C for gamma-irradiated specimens at various dosage the concentration N_q of quickly bleaching F center was obtained. Fig. 1 shows the dependence of N_q on the gamma ray dose for the two bleaching temperatures. When the gamma-ray dose is lower than 3×10^6 r, there is no difference in N_q for the two bleaching temperatures. This difference, however, increases with increasing gamma ray dose, accompanied with the increasing rate of formation of complex centers such as M, R_1, and R_2 centers. The dependence of the ratio of N_q at −25°C to the initial concentration N_F of F centers on the gamma ray dose is also shown in Fig. 1.

Qualitatively, the difference between N_q at two bleaching temperatures may correspond to the formation of complex centers. This seems to be supported by the fact that this difference is nearly proportional to the initial rate of M center formation, which will be a measure of complex center formation by F light bleaching. (In the early stage of bleaching, the growth rate of R centers is much smaller than that of M centers). It is also interesting that the difference is proportional to the initial concentration of F centers.

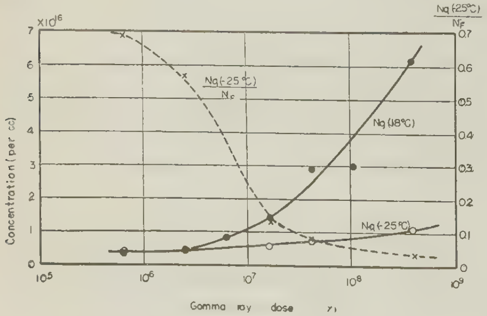

Fig. 1.

The above results seem to show that the quickly bleaching component of F centers at room temperature is composed of two parts; one which is related to the complex center formation, increases with the bleaching temperature;[3] the other is independent of the bleaching temperature. The latter may be due to recombination of electrons with positive holes at some hole trapping centers which have larger cross section for electron trapping than those which correspond to more stable F centers. It should be noted that the relation between the latter part and the gamma ray dose shows a saturation curve on a linear scale and its saturation value is nearly 10^{16}/cc.

The bleaching curve at −25°C which does not include the effect of complex center formation shows that F centers formed by gamma-irradiation have two different kinds of bleaching characteristic. As clearly seen from the (N_q/N_F)-dose curve in Fig. 1, in the early stage of irradiation only quickly bleaching F centers are formed, while with increasing irradiation dose the concentration of this type of F centers saturates and stable F centers increase.

It has been reported by several authors that F centers formed by ionizing radiation have two parts, by studying the formation curve of F centers[4] and that the first part which is dependent on impurities and increases with higher rate saturates nearly at the value of 10^{16}/cc, in Harshaw KCl. Combining with the present results it seems possible to conclude that F centers formed in the first stage bleach at much higher rate by F light illumination. The formation mechanism of F centers in the early stage seems to be different from that in the later stage, which may cause the differences in the trapping states of positive holes recombining with electrons from F centers. In order to clarify the formation mechanism in each stage further experiments should be done.

Most parts of the present work were done while the one of the authors was in the course of Nuclear Engineering School of JAERI. The authors would like to express their gratitude to Prof. Y. Takagi and Dr. K. Kubo for their valuable discussions.

The Energy Spectra of Secondary Electrons in Various Materials Irradiated by Gamma Rays from ^{60}Co and ^{137}Cs

By Nobuo ODA

Department of Physics, Rikkyo (St. Paul's) University, Tokyo

and Hirosi SUZUKI

Institute for Physics, College of General Education, Tokyo University, Tokyo

(Received September 16, 1960)

A knowledge of the energy distribution of the electrons traveling past a point in the medium under irradiation of X- or γ-rays is necessary for a complete understanding of the physical, chemical, and biological processes which occur during irradiation. It can be shown that the electron flux spectrum, $n(E)$, within a medium having a stopping power $S(E)$ is, under the equilibrium conditions and with the effect of δ-ray neglected,

$$n(E)=\frac{1}{S(E)}\int_{E}^{E_{\max}} N(E_i)dE_i \tag{1}$$

where $N(E_i)$ is the number of electrons set in motion with the initial energy E_i per energy interval per cubic centimeter of medium absorbing the quantum radiation and called the initial distribution.

Hayward[1] measured the initial distribution in water for non-collimated ^{60}Co γ-rays with a scintillation spectrometer. The same quantity was also measured for collimated ^{60}Co γ-rays with a similar apparatus by Bruce and Johns[2] and the electron flux spectrum was derived with use of the equation (1). Using a magnetic beta spectrometer, Aglintsev et al[3] measured directly the energy spectra of secondary electrons knocked out from plexiglas, copper, and lead irradiated by ^{60}Co and ^{137}Cs γ-rays.

We have tried to measure the secondary electron flux spectra for ^{60}Co and ^{137}Cs γ-rays with a scintillation spectrometer. The target materials used are plastic (polyethylene), aluminum, copper, and lead.

The experimental arrangements are as follows: an about 8 mc ^{60}Co or 10 mc ^{137}Cs source was held on a plastic support behind a 10 cm long, 3 mm diameter lead collimator. The gamma-ray beam leaving the collimator passed through three 2 mm thick aluminum diaphragms of adequate diameters which were provided to prevent the secondary electrons ejected from the inner surface of the collimator from reaching the detector, and then was incident normally on the target disk. The thicknesses of the target materials were 400 mg/cm^2 for ^{60}Co source and 200 mg/cm^2 for ^{137}Cs source respectively. These thicknesses are large enough to give the secondary electron equilibrium condition in these targets. The plastic scintillator of 5 mm thickness mounted on a lucite light pipe which was optically coupled to the face of a EMI 6097 photomultiplier tube was placed in contact with the back surface of the target disk. The scintillator was covered with an aluminum foil light reflector of about 1 mg/cm^2 thickness. The pulse-height distribution from the detector was measured with a linear amplifier and a single channel differential analyzer. The linearity and zero of the discrimination level of the analyzer were checked with a mercury-relay pulse generator. The resolution and the factor relating pulse-height to energy of the instrument were determined from the internal conversion line of ^{137m}Ba (625 Kev). The peak resulting from the internal conversion line was appeared as a Gaussian distribution with a half-width of about 100 Kev.

In this arrangement, however, it is inevitable that the detector system is exposed to primary γ-rays. Consequently, in order to obtain the spectrum of secondary electrons which enter into the scintillator from the target, it is necessary to subtract from the pulse-height spectrum directly obtained the part due to the Compton recoil electrons produced in the scintillator-light pipe system by the primary γ-rays.

The energy spectra of secondary electrons released from the various target materials were thus obtained by subtraction of the pulse-height spectra measured without target disks from those measured with target disks. In order to prevent the gain drifts to introduce a noticeable error in the subtractions, the pulse-height distribution measurements with and without target and the pulse-height calibration with the coversion line of ^{137m}Ba were performed in a cyclic fashion. Three to five times of these cycles were performed per each target.

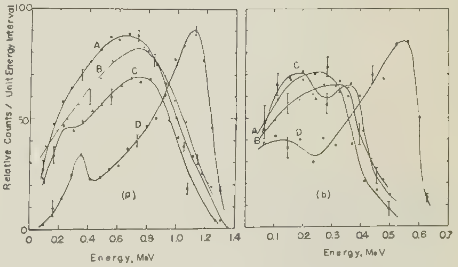

Fig. 1. Energy spectra of secondary electron flux for gamma rays of ^{60}Co (a) and ^{137}Cs (b) sources: (A) polyethylene; (B) aluminum; (C) copper; (D) lead.

The results for ^{60}Co and ^{137}Cs γ-rays are shown in Figs. 1 (a) and (b), respectively. These spectra are the ones for electrons traveling into the forward hemisphere past a point in the medium and do not contain the ones for the backward direction. The backward part may be appreciable for the medium with a higher atomic number such as lead.

Electroluminescence of CdS Single Crystal

By Hirosuke YAMASHITA, Sumiaki IBUKI, Michio YOSHIZAWA and Hiroyoshi KOMIYA

Research Laboratory, Mitsubishi Electric Mfg. Co, Ltd. Amagasaki, Japan

(Received August 15, 1960)

The electroluminescence of CdS Single Crystals, containing carrier injection type, have been reported by G. Diemer[1] and R. W. Smith[2]. Here we describe our new experimental results and some interpretations about the above phenomena.

Samples of crystals have flaky forms of about 7 mm in length, 2 mm in width and 0.4 mm in thickness. These crystals are thought to be very pure and show high resistances above $10^{10}\Omega$ under illumination of 1000 lx from a tungsten lamp. Electrodes are In which are soldered on both ends in length of the crystal and d.c. voltage is applied between these electrodes through a suitable series resistance at room temperature.

As increasing applied voltage on the sample and increasing current through the sample, yellow, green and orange spots appear on and near the anode electrode as the same manner of luminescence observed by Diemer[1] and Smith[2].

When the current intensity exceeds a few hundreds of μA, clear green curtains begin to appear (Fig. 1). They stretch towards the cathode from preceding green or yellow spots and their lengths are about 1 mm. Throughout the observation green curtain sways to right and left, spreading or contracting in parallel to the field. By more detailed inspections it becomes clear that the green curtain consists of many stripes perpendicular to the field and the stripes flow into the end of the curtain. Rates of the fluctuations of these green curtains are seemed to be as slow as about several cycles per sec., and consequently it is supposed that the fluctuation is caused by the change of internal space charge related to the hole injection.

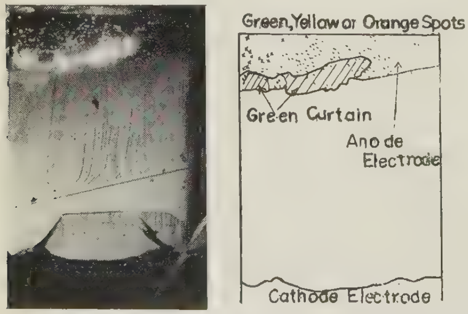

Fig. 1. Microscopic photograph of electroluminescence of CdS Single Crystal. Due to the long exposure time green curtains are overlapped together.

Increasing current up to about 1 mA, red luminescence appears and breakdown occurs in the crystal. After that the resistance of crystal is seen to be about a few hundreds of kilo-ohms. In this state wherefore it may be considered that the interior construction of the crystal has been changed by oxidation or thermal dissociation.

As the results of studying the spectral distribution of emitted light, it has become clear that the green emission has a very narrow band at about 5300 Å and the orange emission has a broad band whose maximum lying at about 6000 Å. It is considered that the yellow emission is composed of mixing green and orange emission. Measuring the brightness of luminescences through optical filters of 5300 Å or 6000 Å, we find out that they have not linear but rather sublinear characteristics against the value of current, therefore it is concluded that the recombination producing green and orange emission is not monomolecular such as exciton decay but rather bimolecular mechanism. The orange emission is caused perhaps by the recombination of electron with hole through an impurity center or a Cd vacancy but further detail can not be yet explained.

We are considering that the green luminescence is due to the recombination of shallow trapped electron with free hole, both of them are injected from electrodes of opposite signs respectively and that the depth of the electron trap related to the radiative recombination producing the green luminescence is about one tenth of eV from the bottom of conduction band.

X-ray Study of Lattice Defects in Si Single Crystals by Transmission Berg-Barrett Technique*

By Mitsuru Yoshimatsu
Rigaku Denki Co. Ltd., Haijima, Akijima, Tokyo
and Kazutaka Kohra
Institute of Physics, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo

(Received Sept. 27, 1960)

The Berg-Barrett technique, which has been used for taking X-ray diffraction micrographs in reflection, is possible to be extended to take micrographs in transmission. With this technique, which might be called the transmission Berg-Barrett technique, lattice defects in thin specimens of Si single crystals were studied.** In comparison with the Lang technique,[3] no special apparatus is necessary, the exposure time is much shorter and, although resolution is poorer, individual dislocations can be resolved in favourable cases.

Experimental arrangement (Fig. 1) is the same in principle as those used by some other investigators,[4],[5],[6] but extinction effect instead of abnormal transmission is utilized to obtain the image contrast. Accordingly the specimen must be sufficiently thin. A Mo tube of ordinary focal size (Philips) was used. Instrumental resolution[7] due to apparent focal width and dispersion between $K\alpha_1$ and $K\alpha_2$ is roughly estimated to be of order of 10 microns in both directions perpendicular and parallel to the incident plane for low index reflection of the symmetrical Laue case.

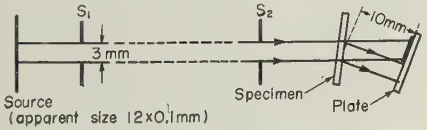

Fig. 1. Schematic diagram of the transmission Berg-Barrett technique.

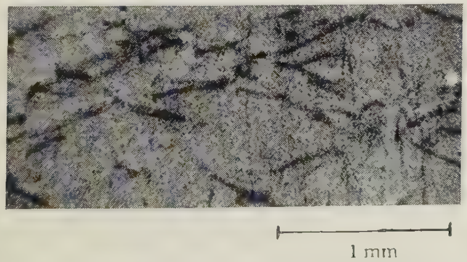

Fig. 2. Individual dislocations in a Si single crystal. (220) reflection.

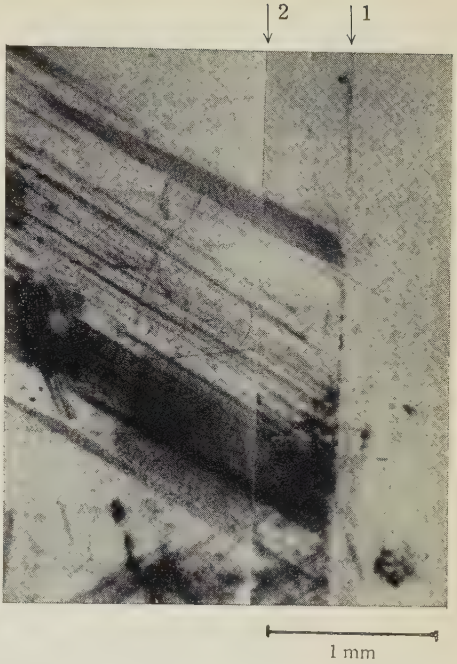

Fig. 3. Lattice defects in the neighbourhood of a twin boundary of a Si single crystal. (111) reflection. The twin boundary lies at the line 1. Two photographs are connected at the line 2.

Fig. 2 shows a (220) reflection photograph from a slice (0.28 mm thick) of Si single crystal, the surface of which is normal to the growth axis [111]. Individual dislocation lines are resolved. The width of each dislocation line image is about 20 microns, being about twice as large as the estimated value.

Fig. 3 shows a (111) reflection photograph from the neighbourhood of a twin boundary (111), which is normal to the growth axis. The specimen (0.5mm thick) was cut normal to the twin plane. To obtain a good contrast of the image, it is desirable to take the photograph from small area of the specimen, in order to suppress the background due to continuous X-rays. For this reason, two photographs were successively taken and connected to each other. It is to be noted that there are many streaks and a few bands besides dislocation lines at only one side of the twin boundary. These streaks and bands seem to be attributed to lattice defects such as stacking faults. A further study will be soon reported.

"Energy Analysis of Electron Diffraction Patterns"

By Hiroshi WATANABE
Hitachi Central Research Lab. Kokubunji, Tokyo, Japan

(Received Oct. 8, 1960)

The energy analysis of electron diffraction patterns was carried out by Leonhard[1] and the present author[2] using Möllenstedt type velocity analysers[3]. However, the diffraction patterns analysed by them were *selected area* diffraction patterns which are not so suitable for the intensity measurement as *ordinary* diffraction patterns. A selected area diffraction pattern does not exactly correspond to the area defined by the selector aperture, as pointed out by Agar[4]. Therefore, in order to study the exact intensity distribution of energy spectrum the analysis of ordinary diffraction pattern is required. The present note describes a new experimental arrangement which meets the above requirement and some preliminary results obtained by it.

The electron optical system is shown in Fig. 1. Both transmission and reflection patterns can be analysed. A focusing lens and a reducing lens (Fig. 1) project the reduced diffraction pattern on a plane with a fine slit, and then the part of the projected pattern passing through the fine slit is analysed by the analyser lens. The pattern on the plane of the fine slit and energy loss spectrum obtained in the analysis are shown schematically in (b) and (c) of Fig. 1. In this analyser the angular deviation due to the energy loss of 1 ev is about 10^{-4} radians, and the scattering angle in which we are interested is between 10^{-3} and 10^{-1} radians. By the reducing lens the scattering angle is reduced to the order of angular deviation due to energy loss.

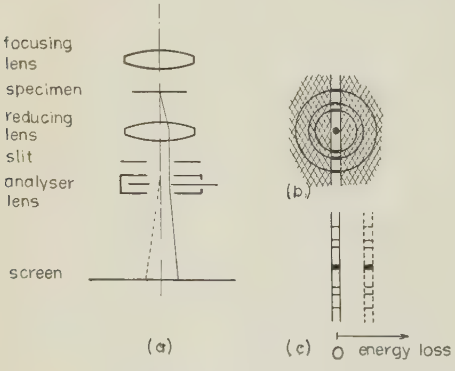

Fig. 1. (a) Schematic diagram of the electron optical system. (b) Diffraction pattern on the fine slit plane. (c) Energy loss spectrum on the final screen.

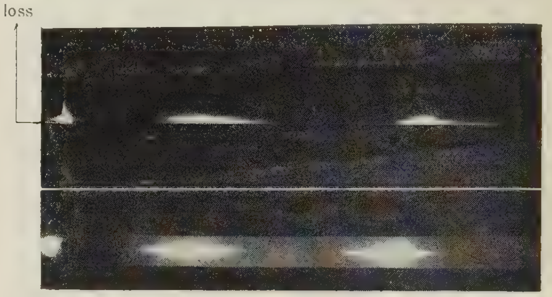
The energy analysis was carried out with the following specimens: (a) single crystals of molybdenite (tr), Ge, CdS and Si (re), (b) smoke particles of ZnO and MgO (tr), (c) evaporated metals of Al and Au (tr). Here (tr) and (re) mean transmission and reflection observation, respectively.



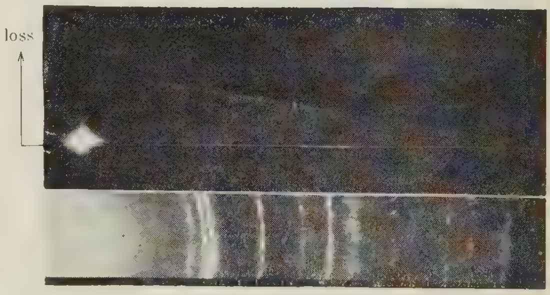


Fig. 2. Energy loss spectrum of reflection diffraction pattern from CdS single crystal.

Fig. 3. Energy loss spectrum of transmission diffraction pattern from ZnO smoke particles.

Some examples are shown in Figs. 2 and 3. The accerelating voltage is 30 kv, and the diameter of the electron beam on the specimen is about $0.1\,\mathrm{mm}\phi$. Summerizing the experimental result the following conclusions are drawn regarding electron scattering phenomena in crystals:

(a) In single crystals the inelastic scattering occurs mainly in the directions of diffracted beam as will as in the direction of the incident. The elastic diffuse scattering, i.e. the scattering with no detectable energy loss and in the directions satisfying no Bragg condition, does not occur strongly. These results are independent of transmission or reflection.

(b) In smoke particles, on the contrary, the most portion of the inelastic scattering occurs only in the direction of the incident. The elastic diffuse scattering occurs remarkably.*

(c) In evaporated metals, the inelastic scattering occurs in the same way as in case (a). The elastic diffuse scattering occurs remarkably, too.*

The author wishes to thank Professors R. Uyeda, S. Takagi, K. Kohra and Mr. F. Fujimoto for their helpful discussions on the experimental results.

Errata

Volume Magnetostriction of Cobalt-Nickel Alloys .... Takejiro KANEKO 738
Maxwell's Formula for Three-Dimensional and Large Deformation.... Wataru SEGAWA 738

No. 5

The Reaction Li$^7(p, n)$Be^7, B$^{11}(p, n)$C^{11} and Al$^{27}(p, n)$Si^{27} at 8 to 14 MeV .... Kazuo HISATAKE, Yoshihide ISHIZAKI, Akira ISOYA, Teruo NAKAMURA, Yoshihiro NAKANO, Bunsaburo SAHEKI, Yoshio SAJI and Kazunori YUASA 741
Protons from the $p+d$ Breakup Reaction at Proton Energies of 14 MeV and 10 MeV .... Seishi KIKUCHI, Junpei SANADA, Shigeki SUWA, Izuo HAYASHI, Keigo NISIMURA and Kiyoji FUKUNAGA 749
Measurements of the Polarization in Proton-Helium Elastic Scattering .... Keigo NISIMURA Shigeki SUWA, Izuo HAYASHI, Kiyoji FUKUNAGA, Norio RYU and Masao SEKI 754
Elastic and Inelastic Scattering of Protons from N, Ne, Mg, Si, S and A in the Energy Range from 7.6 MeV to 14.2 MeV .... Yukiyasu ODA, Minoru TAKEDA, Takashi YAMAZAKI, Chuin HU, Naoyuki TAKANO, Ken KIKUCHI, Shinsaku KOBAYASHI, Kazuhisa MATSUDA and Yukio NAGAHARA 760
Radial Distribution Function of Fluids, III .... Kazuo HIROIKE 771
Expansion Theorem of Density Matrix, Virial Expansion and New Formula of Multiple Scattering .... Toshio YOKOTA 779
Theoretical Study on the Properties of Coercive Field of BaTiO$_3$ Single Crystal .... Ryuji ABE 795
Heitler-London Approach to Electrical Conductivity and Application to d-Electron Conductions .... Jiro YAMASHITA and Tatumi KUROSAWA 802
Anomalous Growth of MoO$_3$ Crystals .... Eiji YODA 821
The Change in Electron Mobility in Indium Antimonide at Low Electric Field .... Yasuo KANAI 830
Visible Light Emission and Microplasma Phenomena in Silicon $p-n$ Junction, I. .... Makoto KIKUCHI and Kenkichi TACHIKAWA 835
A Possible Mode of Twin in the ε-phase of Cu-Sb Alloy .... Michiyasu DOI 849
Shape of Nucleus Domain Anchored to a Screw Dislocation in Ferroelectric Crystal .... Hidetosi TAKAHASI, Terutaro NAKAMURA and Yoshihiro ISHIBASHI 853
Dynamical Theory of Electron Diffraction in Laue-case, II. Numerical Calculation of Intensities .... Fuminori FUJIMOTO 859

The effects of Deuteron Irradiation on the Nuclear Magnetic Resonance in Teflon .... Hazime KUSUMOTO 867
On the Intramolecular Light Scattering of the Non-Gaussian Chain .... Akira MIYAKE 875
Influence of the Molecular Weight Distribution on the Polymer Properties .... Akira MIYAKE 883
Theory of the Nuclear Magnetic Resonance of Co^{59} in CoO .... Kazuo MOTIZUKI 888
Interaction between Rold-like Polyelectrolytes .... Tsuyoshi OHNISHI, Nobuhisa IMAI and Fumio OOSAWA 896
Formation of Plasma by Low Energy Ion Injection and Cyclotron Heating .... Tarô DODO 906
The Study of the Opitical Properties of Conducting Tin Oxide Films and their Interpretation in Terms of a Tentative Band Scheme .... Toshihiro ARAI 916

SHORT NOTES

Screened Impurity Potentials in Metals .... E. C. MCIRVINE 928
Magnetic Anisotropy Induced by Cold Rolling of Cu–Co Alloy .... Tadayasu MITUI 929
On the Alpha-particles from the N^{14}(d, α)C^{12} Ground State Reaction .. Nawoyuki KAWAI 930
Ferromagnetism of Mn–Zn Alloy .... Seiji TEZUKA, Sukeyoshi SAKAI and Yasuaki NAKAGAWA 931
Ferrimagnetism of Mn$_5$Ge$_2$ ... Kō YASUKŌCHI, Kazuo KANEMATSU and Tetuo OHOYAMA 932
Spin Order in the Doublet at the Second Excited Level in Even-even Medium Nuclei .... Mitsuo SAKAI 933
On the $F \to F'$ Conversion in the Presence of A-, M-, R-, and Z_1-Centers .... Hiroshi OHKURA, Katsunobu AWANE and Shigeko MIYAMOTO 934
Observation of Microplasma Pulses and Electroluminescence in Gallium Phosphide Single Crystal .... Makoto KIKUCHI and Takashi IIZUKA 935
Magnetic Annealing of Co and Co–Ni Alloys .... Minoru TAKAHASHI and Tatsuo KŌNO 936
Electrical Properties of Stannic Oxide Films .... Isamu IMAI 937
Post-Irradiation Effect in Visible Absorption Spectra of Polyvinyl Chloride Sheets .... Yoichi OKADA, Takao ITO and Ayao AMEMIYA 938
Interaction Effects in K$_3$Fe(CN)$_6$ .... Taiichiro OHTSUKA 939
Temperature Dependence of Infrared Absorption Bands of n-Higher Alcohols .... Mitugi HASIKUNI 941
Stress in Very Thin Vacuum-Evaporated Films of Silver .... Koreo KINOSITA, Hideki KONDO and Ichiro SAWAMURA 942
Electron Spin Resonance in Irradiated Polytetrafluoroethylene: Decomposition of the Complex Spectrum .... Maoyuki TAMURA 943

Errata

Theory of Viscoelasticity of Amorphous Polymers, II. A Note on the Time-Temperature Reducibility of the Relaxation and Retardation Spectra .... Osamu NAKADA 945
Measures of Finite Strain and Stress-Strain Relations .... Wataru SEGAWA 945

No. 6

Further Study of the Reaction ^{7}Li(γ, t)^{4}He ...... Mitsuo MIWA and Mikio YAMANOUCHI 947
Reactions of Argon-40 with Alpha-Particles .... Shigeo TANAKA, Michiaki FURUKAWA, Takashi MIKUMO, Shiro IWATA, Masuo YAGI ahd Hiroshi AMANO 952
On the First and the Second Excited States in Ge^{74} .... Toshimitsu YAMAZAKI, Hidetsugu IKEGAMI and Mitsuo SAKAI 957
Theory of Formation Energy of the External and the Internal Surface for Free Electron Metals .... Akira SUGIYAMA 965
Interaction of Conduction Electrons with Acoustic Waves in Simple Semiconductors .... Nobuo MIKOSHIBA 982
Electrical Properties of Germanium Selenide GeSe .... Sizuo ASANABE and Atuyosi OKAZAKI 989
Low Field Magnetoresistance Effect of Plastically Deformed n-type Silicon .... Koji KAMADA 998

Growth and Evaporation of Tungsten Oxide Crystals .... Hatsujiro HASHIMOTO, Kenzo TANAKa and Eiji YODA 1006
Dislocations in Pure Iron Foils Deformed by Bending .... Tadayoshi YAMASHITA and Youji TANEDA 1015
Dynamical Theory of Electron Diffraction in Laue-case, III. Forbidden Reflection .... Fuminori FUJIMOTO 1022
Study on the Ordered Alloys of Gold-Manganese System by Electron Diffraction, I. Au_3Mn .... Denjiro WATANABE 1030
Re-appreciation of the Second Order Transition Phenomena in Polyethylene .... Ryuichi NAKANE 1040
The Binding Energy of the σ Bond, I. General Theory .... Kiyosi O-OHATA 1048
Intramolecular NMR Second Moment of the Polymer Chain .... Akira MIYAKE 1057
Zeeman Quadrupole Spectra in p-dichlorobenzene and p-chlorobenzoic Acid .... Shizuko OGAWA and Kikuo OHI 1064
Statistical Mechanics of Antiferromagnetic Layer Crystal, $FeCl_2$ .... Sigeo YOMOSA 1068
Ionization in Argon Mixtures by Electrons in an Electric Field ...... Mikiya YAMANE 1076
Non-linear Effects on Electron-Plasma Oscillations .... Masao SUMI 1086
Oscillations in a Plasma in a Weak Magnetic Field .... Kiyoe KATO 1093
Transport Properties of Plasmas in a Strong Magnetic Field .... Taro KIHARA, Yukio MIZUNO and Shobu KANEKO 1101
Flow of a Condensing Vapour with Heat Exchange .... Keishiro NIU 1108
Selbstzündung des n-Hexan-Luft-Gemisches in Stoßwellen .... Kunio TERAO 1113

SHORT NOTES

Magnetic Anisotropy of Chalcopyrite .... Teruo TERANISHI 1123
Electron Emission Current from Oxide Coated Cathode Subject to High Electric Field .... Chokichiro SHIBATA 1124
Magnetic Hyperfine Structure of the 3,2 Line of Ammonia .... Koichi SHIMODA and Kunitaka KONDO 1125
Some Observations on the Domain Walls in Thin Films .... Yasuo GONDO and Zenya FUNATOGAWA 1126
On the Possibility of Ferromagnetism for an Electron Gas .... Masao SHIMIZU 1127
Structure of Giant Resonance in $Al^{27}(p,\gamma)$ Reaction .... Motoharu KIMURA, Katsufusa SHODA, Naoshi MUTSURO, Tsutomu TOHEI, Kazuo SATO, Kunishige KURODA, Katumi KURIYAMA and Tosimitu AKIBA 1128
The Behaviours of Free Radicals Trapped in γ-Irradiated Polyethylene .... Hisatsugu KASHIWABARA and Kenichi SHINOHARA 1129
Temperature Dependence of Tunnel Diode Characteristics ...... Yoshitaka FURUKAWA 1130
Paramagnetic Resonance of Mn^{++}–F^- Pair in Sodium Chloride .. Yasaburo YOKOZAWA 1131
Inverse Solution of the Thomas-Fermi Equation .... Louis GOLD 1132
A Simple Model of Aqueous Solution of Strong Electrolyte .... Takeshi SATOH 1134
Correction to the Paper "Two-dimensional Flow of an Ideal Gas with Small Electric Conductivity past a Thin Profile" .... Takeo SAKURAI 1135
The Magnetic Properties of Mn-Sn-C Alloys .... Mitsuru ASANUMA 1136
Conductivity Induced by Injected Electrons in Liquid Dielectrics .... Pyong-un CHONG, Tomihiko SUGIMOTO and Yoshio INUISHI 1137

Errata

Magnetic Hyperfine Spectrum of H_2CO by a Maser .... Hiroshi TAKUMA, Tadao SHIMIZU and Koichi SHIMODA 1139
Angular Dependencies of Efficiencies for Sodium-Iodide Crystals .. Tadayoshi DOKE, Atsushi NAKAMOTO, Yasukiyo TAKAMI, Manabu HATTORI and Shinji OKANO 1139
Theory of the Nuclear Magnetic Resonance of Co^{59} in CoO .... Kazuko MOTIZUKI 1140

No. 7

Gamma Rays from Several Elements Bombarded by 10 and 14 MeV Protons .... Tetsuo WAKATSUKI, Yasuo HIRAO, Eiji OKADA, Iwao MIURA, Kenzo SUGIMOTO and Akira MIZOBUCHI 1141

Elastic and Inelastic Scattering of Protons from Nickel Isotopes; Ni^{58} and Ni^{60}, in the Energy Range from 7.0 MeV to 15.3 MeV .... Shinsaku KOBAYASHI, Kazuhisa MATSUDA, Yukio NAGAHARA, Yukiyasu ODA and Nobuhiro YAMAMURO 1151
Elastic and Inelastic Scattering of Alpha Particles by Carbon .... Takashi MIKUMO, Hisashi YAMAGUCHI, Itaru NONAKA, Masatoshi ODERA, Yoshio HASHIMOTO, Motoo KONDO and Takashi MAKI 1158
Elastic and Inelastic Scattering of Protons by Oxygen in the Energy Region of 6.9 MeV and 15.6 MeV .... Shinsaku KOBAYASHI 1164
On the High Energy Soft Component Near Sea Level .... Tadashi KAMEDA 1175
Ferroelectricity in Potassium Ferrocyanide Trihydrate and its Isomorphous Substances .... Shigeru WAKU, Kunio MASUNO, Toshisuke TANAKA and Hiroshi IWASAKI 1185
Interaction of Conduction Electrons with Acoustic Waves in Many-Valley Semiconductors .... Nobuo NIKOSHIBA 1189
Filamentary Crystals grown from the Solid Metal .... George SINES 1199
Heitler-London Approach to Electrical Conductivity, II. A Proof of the Hopping Motion .... Tatsumi KUROSAWA 1211
Exchange Interaction and Cubic Crystal Field Splitting Parameter of Fe^{3+} in Spinel Structure .... Yoshikazu SUGIURA 1217
Characteristics of Germanium p-n Junction with Irregular Structure.. Masami TOMONO 1223
Note on the Field Dependence of the Mobility in Semiconductors .... Masumi HATTORI and Hisanao SATO 1237
Dynamic Behaviour of Twinning in Tin Crystals at Various Temperatures and Strain Rates .... Saiyu MARUYAMA 1243
Study on the Ordered Alloys of Gold-Manganese System by Electron Diffraction, II. Au$_4$Mn .... Denjiro WATANABE 1251
The Binding Energy of the σ Bond, II. Application to the Diamond Crystal .... Kiyosi O-OHATA 1258
Magnetic Properties of the Pd and Pt Group Transition Metal Complexes .... Hiroshi KAMIMURA, Shoichiro KOIDE, Hisao SEKIYAMA and Satoru SUGANO 1264
Microwave Spectrum of Ethyl Iodide, II. .... Takahiro KASUYA 1273
Proton Magnetic Resonance in Hydrogen Bonded Dimers in Solids .... Kiyoshi KUME and Yoshinobu KAKIUCHI 1277
Microwave Spectrum of Methyl Mercaptan .... Takeshi KOJIMA 1284
Heating of a Plasma by Acoustic Waves................................. Tarô DODO 1292
Exciton-Induced Luminescence in KI/Tl.............. Masao TOMURA and Yozo KAIFU 1295
Dichroism of Z Bands .... Masakazu ISHIGURO, Etsu SUGIOKA and Nozomu TAKEUCHI 1302
Thermal Bleaching of Color Centers in KCl Crystals Containing U Centers........ .... Masamitsu HIRAI 1308
Effect of Transverse Magnetic Field on the Flow due to an Oscillating Flat Plate, II. .... Tsunehiko KAKUTANI 1316
Steady Temperature Field in a Composite Doubly Infinite Strip ...... Václav VODIČKA 1332
Circulation Preserving Motions .... A. C. SRIVASTAVA 1337

SHORT NOTES

Thickness-Dependence of Stress in Vacuum Deposited Silver Films............... .... Koreo KINOSITA and Hideki KONDO 1339
Electron Spin Resonance of Mn^{++} in SrCl$_2$, CdCl$_2$ and CdBr$_2$ .... Hiroshi KOGA, Kazumi HORAI and On MATUMURA 1340
Ultrasonic Measurement of Magnetization in Mn-ferrite Single Crystal........... .... Kazuo HUSIMI, Katsumi NISHIGUCHI and Toshimasa SUZUKI 1341
The Temperature and Pressure Dependence of the Nuclear Resonance of Co^{59} in Face-Centered-Cubic Cobalt Metal .... Yoshitaka KŌI, Akira TSUJIMURA and Yoshinori YUKIMOTO 1342
The Ferromagnetism of the Compound γ-FeSn .... Mitsuru ASANUMA 1343
Optical Absorption of Localized Exciton in KCl:I and NaCl:I Single Crystals...... .... Kuniya FUKUDA, Riso KATO, Kaizo NAKAMURA and Yoichi UCHIDA 1344
Avalanche Breakdown in CdS Single Crystal ...... Sigeru IIZIMA and Makoto KIKUCHI 1345
Pulse Photoconduction and Carrier Lifetime in CdS Single Crystals .... Junji SHIRAFUJI and Yoshio INUISHI 1346

Some Observations on Plastic Deformation and Slip Lines of Sodium Chloride Whisker........................Kan-Ichi KAMIYOSHI and Tsutomu YAMAKAMI 1347
Dislocation Etch Pits on a- and b-Faces of GASH Crystal ....Terutaro NAKAMURA and Kikuo OHI 1348
On A-centers in Colored KCl Crystals........Hiroshi OHKURA and Katsunobu AWANE 1349
Absorption Band due to a Presence of Impurity Bromine in KCl Crystal ....Koichi KOBAYASHI and Tetsuhiko TOMIKI 1350
Induced Magnetic Anisotropy of Evaporated Ni-Fe Films.............................Minoru TAKAHASHI, Denjiro WATANABE, Tatsuo KŌNO and Shiro OGAWA 1351
Fixing of Magnetic Moment of Ferromagnetic Fine Precipitates in Cu-Co Alloy during Aging..Kazuo KOBAYASHI 1352
Ferrimagnetic Resonance in a Single Crystal of Europium-Iron Garnet ....Tomonao MIYADAI, Hisao TAKATA and Yūzō SHICHIJŌ 1354
Electrical Properties of Chromium Sulfides .... Takahiko KAMIGAICHI, Kan-ichi MASUMOTO and Tadamiki HIHARA 1355
Exciton-Induced Photoconductivity of U Centers in KCl Crystal ....Masayasu UETA and Masamitsu HIRAI 1356

Errata

Excitation Functions for Alpha-Induced Reactions on Manganese-55.. Shigeo TANAKA, Michiaki FURUKAWA, Takashi MIKUMO, Shiro IWATA, Masuo YAGI and Hiroshi AMANO 1357

No. 8

Angular Distribution of n-p Scattering at 14.1 MeV ....Teruo NAKAMURA 1359
On the High Energy Soft Components at 2770m Altitude..Tadashi KAMEDA and Toshio MAEDA 1367
Graphitization Stress in Polycrystalline Carbon as An Origin of Dislocations ....Takuro TSUZUKU 1373
Kinematic Theory of Ferroelectric Domain Growth ....Terutaro NAKAMURA 1379
Change in Modulus of Rigidity of Brass Wires by Cold-Working and Subsequent Annealing... Jun KUROYANAGI 1386
Study on Some Tl Base Alloys, with Reference to their Electronic Structure...Ryōji SUGANUMA 1395
Observations of Dislocation Networks in an Alloy of Body-Centered Cubic Lattice by Electron Microscopy .... Soji NENNO, Toshio SABURI, Masayoshi TAGAYA and Zenji NISHIYAMA 1409
An X-ray Study on the Structure of Cobalt Dichloride Hexahydrate ......Joji MIZUNO 1412
Study on the Twin Formation in Evaporated Silver Films .... Akira NAGASAWA and Shiro OGAWA 1421
X-ray Line Broadening from the Polished Surfaces of Silver and Gold..Masao KURIYAMA 1426
X-Ray Measurement of the Scattering Factor of Iron in Ordered Fe_3Al............................... Yukitomo KOMURA, Yujiro TOMIIE and Robert NATHANS 1434
The Photoionization of H_2 and the Spatial Correlation between Electrons.. Mikio SHIMIZU 1440
The Binding Energy of the σ Bond, III. Discussion on the Ionic Structures ....Kiyoshi O-OHATA 1449
On the Effect of Heat Treatment in a Magnetic Field on Magnetic Properties of Iron-Aluminium Alloys ....Makoto SUGIHARA 1456
Magnetic Anisotropy of Iron-Cobalt Ferrite Measured by Ferromagnetic Resonance .... Yoshikazu SUGIURA 1461
The Recovery of Initial Magnetic Susceptibility in Pure Nickel ....Mitsuru ASANUMA 1469
The Electron Paramagnetic Resonance of Mn^{2+} Ions Surrounded by an Octahedron of Fluorine Ions ....Shinji OGAWA 1475
The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, I. Mutual Dependence between Dipole Moment and End-to-end Length ....Tsugio MORI 1482
Magneto-plasma Resonance in Semiconductors ....Muneyuki DATE 1488

Proton Magnetic Resonance in Pure and Doped Ice ....Kiyoshi KUME 1493
Radiation Effects on Dimethyl-diphenyl Siloxane Copolymer. I. Protective Effect of Phenyl Radical on the Cross-linking......Mitsuru KOIKE and Akibumi DANNO 1501
Interpretation of Exciton Induced Luminescence in KI/Tl ....Masao TOMURA 1508
Jets of a Perfectly Conducting Inviscid Gas in the Presence of a Magnetic Field parallel to the Stream ....Shigeki MORIOKA 1516
Some Remarks on the Magnetogasdynamic Linearized Theory ....Shigenori ANDO 1523

SHORT NOTES

On the Ferromagnetism in Manganese-Aluminium-Iron System ....Ichiro TSUBOYA and Makoto SUGIHARA 1534
The Influence of Oxidation and Reduction on the Parasitic Ferromagnetism of αFe_2O_3 ....Akira TASAKI, Kiiti SIRATORI and Shūichi IIDA 1535
Emission Spectra from Glow Discharge through Vapors of Aromatic Hydrocarbons and n-Hexane...........Masato NISHI, Shiro HAMAMURA and Hiroshi ARAKI 1536
Observation of an Anomaly in Transistor Characteristics.........Osamu NAKAHARA 1537
Resonance Transfer of Ionization Energy in Semiconductors ....Shigeharu KOSHINO and Toshihiko ANDO 1538
Dislocations in Ferroelectric Glycine Sulfate Single Crystals ....Hiroo TOYODA 1539
A Diffuse Reflexion from a Silicon Carbide Crystal ....Takanori TOMITA 1540
On the Determination of Diffusion Coefficient of Boron in Silicon .... Jiro YAMAGUCHI, Shiro HORIUCHI, Koji MATSUMURA and Yasumasa OGINO 1541
On the Weak Interaction of Baryons............................Seitaro NAKAMURA 1543

Errata

Dynamical Theory of Electron Diffraction in Laue-case ....Fuminori FUJIMOTO 1545

No. 9

Reactions of Iron-54 with Alpha-Particles...............Shigeo TANAKA, Michiaki FURUKAWA, Shiro IWATA, Masuo YAGI, Hiroshi AMANO and Takashi MIKUMO 1547
Gamma-rays from the 7.56 MeV Level in O^{15} ...Tatsuo TABATA and Kotoyuki OKANO 1552
Lower Excited States in P^{29} from the $Si^{28}(p,\gamma)P^{29}$ Reaction ....Kotoyuki OKANO, Tatsuo TABATA, Kyue FUKUDA and Jiro MUTO 1556
On the Electronic Component of Extensive Air Showers near the Axis................................. Tadashi KAMEDA, Yoshio TOYODA and Toshio MAEDA 1565
Lattice Frequency of Ionic Crystals ....S. S. MITRA and S. K. JOSHI 1575
The Resonance Type Absorption of Very Thin Silver and Gold Films ....Shigeo YAMAGUCHI 1577
Electrical Properties of Pseudo-binary Systems of Ag_2VI's; $Ag_2Te_xSe_{1-x}$, $Ag_2Te_xS_{1-x}$, and $Ag_2Se_xS_{1-x}$..Shin-ya MIYATANI 1586
Temperature Dependence of the Optical Absorption Edge of Tungsten Trioxide Single Crystal...Tsuruji IWAI 1596
Association of Vacancies with Calcium Impurities in Potassium Chloride Crystals .... Tosiyuki NINOMIYA 1601
Measurement of the Intensity in Electron Diffraction by a CdS Single Crystal .... Satio TAKAGI and Fuminori FUJIMOTO 1607
Elektronische Wechselwirkung zwischen Wasserstoff und aufgedampften Nickelfilmen ....Yoshihiko MIZUSHIMA 1614
The Binding Energy of the σ Bond. IV. Discussion on the Higher Order Terms ....Kiyosi O-OHATA 1632
The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, II. A Special Simplified Model and Numerical Calculations ....Tsugio MORI 1638
The Superexchange Interaction between Cr^{+3} pair in Chromium Bi-nuclear Complex Ions..Hanako KOBAYASHI, Taiichiro HASEDA, Eizo KANDA and Masayasu MORI 1646
A Study of Sorbed Water on Cellulose by Pulsed NMR Technique......Masahumi SASAKI, Takao KAWAI, Akira HIRAI, Tsuneo HASHI and Akira ODAJIMA 1652
Study of Aqueous Solution of Strong Electrolyte—Reexamination of Molecular Refraction ....Takeshi SATOH and Koreaki HAYASHI 1658

On the Magnetic Properties of a $CrBr_3$ Single Crystal .... Ichiro TSUBOKAWA 1664
The Three-Level Gas Maser as a Microwave Spectrometer .... Tatsuo YAJIMA and Koichi SHIMODA 1668
Monte Carlo Calculations of Motion of Electrons in Helium .... Tomizo ITOH and Toshimitsu MUSHA 1675
Ion Optics in Long, Multistage Accelerator Tubes .... Masateru SONODA, Akira KATASE, Masao SEKI and Yoshihisa WAKUTA 1680
Transport Coefficients of Plasmas in a Magnetic Field .... Shobu KANEKO 1685

SHORT NOTES

Effect of Heat-Treatment upon Sintered Cadmium Sulphide Photoconductive Films .... Saburo KITAMURA 1697
Ferroelectricity in the Potassium Ferrocyanide Group Ferroelectrics Substituted by Deuterium for Hydrogen .... Shigeru WAKU, Kunio MASUNO and Toshisuke TANAKA 1698
Impurity Shift of Pure Quadrupole Resonance Frequency .... Yoshiro IMAEDA 1699
Measurement of Temperature Dependence of T_1 of Proton in Some High Polymers by Pulsed NMR Technique .... Takao KAWAI, Masahumi SASAKI, Akira HIRAI, Tsuneo HASHI and Akira ODAJIMA 1700
On the Mechanism of the Electrical Conduction in CdSe .... Hirosi TUBOTA, Hiromichi SUZUKI and Kazuyoshi HIRAKAWA 1701
Characteristics of Krypton Counters .... Tatsusaburo SUZUKI and Jiro YUHARA 1702
Magnetoresistance Effect in the Magnetization Reversal of Permalloy Films .... Eiji TATSUMOTO, Kaizo KUWAHARA and Mitita GOTO 1703
Magnetostriction of Yttrium Iron Garnet... Akira NAKAMURA and Yoshikazu SUGIURA 1704
The Influence of Aging Treatment on the Temperature Dependence of the Electric Resistance in Alnico 5 Magnet .... Tatsuo FUJIWARA and Tetsuo KATO 1705
Preparation of Ferromagnetic Chromium Dioxide .... Buichi KUBOTA 1706
A New Method to Determine Hydration Energy of Ion .... Yoshio ISHIDA 1707
On the Stripe Pattern during Rolling of Viscous Materials .... Toshimaro SONO, Masayoshi FUKUSHIMA and Eiichi FUKADA 1708
α-Trapping Centers in n-Type Silicon .... Jun'ichi OKADA and Tetsuro SUZUKI 1709
Die Schwankung der Zündstelle eines brennbaren Gemisches bei der Selbst-Zündung in Stosswellen .... Kunio TERAO 1710
Electron Spin Resonance of Manganese in Ammonium Chloride .... Hidetaro ABE and Hiroko SHIRAI 1711
A Note on the Magnetic Resonance in Metals .... Ko SUGIHARA 1712
$1/f$ Noise and Channel in Ge PN Junction .... Kiichi KOMATSUBARA, Yoshio INUISHI, Hiroshi EDAGAWA and Tsutomu SHIBAIKE 1713
Spin Wave Resonance in Ni Films .... Hiroshi NOSE 1714
Magnetic Property of Cr_2O_5 .... Eiichi HIROTA and Buichi KUBOTA 1715
Thermal Bleaching of F-Counters of Gamma-Irradiated KCl at Temperatures .... Noriaki ITOH and Tokuo SUITA 1716
Oscillatory Magnetoresistance in N-Type PbTe .... Yasuo KANAI, Riro NII and Naozo WATANABE 1717
Sign Reversal of Hall Coefficients at Low Temperatures in Heavily Compensated p-type Germanium... Hiroo YONEMITSU, Hajime MAEDA and Hisao MIYAZAWA 1717

Errata

Study on Some Tl Base Alloys, with Reference to their Electronic Structure .... Ryōji SUGANUMA 1696

No. 10

Energy Dependence of Angular Distribution of the Reaction $Al^{27}(p, \alpha)Mg^{24}$ in the Energy Region between 10.5 and 14.5 MeV .... Hiroshi OGATA, Hidehiko ITOH, Yoshiko MASUDA, Kunio TAKAMATSU, Maumi KAWASHIMA, Akira MASAIKE and Isao KUMABE 1719

Angular Distribution of the Reactions $Co^{59}(p, \alpha)Fe^{56}$ at 7.7∼14.1 MeV and $Mn^{55}(p, \alpha)Cr^{52}$ at 7.6∼12.9 MeV ....Hiroshi OGATA, Hidehiko ITOH, Yoshiko MASUDA, Kunio TAKAMATSU, Maumi KAWASHIMA, Akira MASAIKE and Isao KUMABE 1726

A Study of Pulse Height Distribution of Boron—Trifluoride Proportional Counters .... Mikiya YAMANE 1732

Mixing Ratio of the 440-keV Gamma Radiation in ^{23}Na ....Akira MIZOBUCHI, Toshio KATOH and Jian-zhi RUAN 1737

(d, α) Reactions on Some Light Nuclei ....Chuin HU 1741

Emission of ^{8}Li, ^{9}Li and ^{8}B Fragments from Stars Produced by 4.3 GeV π^--Mesons in Nuclear Emulsion..........Kuni IMAEDA, Mitsuko KAZUNO and Nobuo ITO 1753

X-ray Observations on Cleavage Faces of LiF Single Crystals .... Mitsuru YOSHIMATSU and Kazutake KOHRA 1760

Study on the Ordered Phases with Long Period in the Gold-Zinc Alloy System. I. Survey of Crystal Structures and Calorimetric Measurement ....Hiroshi IWASAKI, Makoto HIRABAYASHI, Kunio FUJIWARA, Denjiro WATANABE and Shiro OGAWA 1771

On the Superconducting Ground State ....Ziro MIKURA 1783

Impurity Trapped Interstitials and the Low Temperature Annealing Stages of Irradiated Copper ....Ryukiti R. HASIGUTI 1807

The Structure Analysis of $AuCu_3$ by Means of a Fourier Transformation of X-ray Diffuse Scatterings........Kenji DOI 1815

Visible Light Emission and Microplasma Phenomena in Silicon *p-n* Junction II. Classification of weak spots in diffused *p-n* junctions....Makoto KIKUCHI 1822

Optical and Structural Anomalies in Potassium Ferrocyanide Trihydrate Crystals .... Hiroo TOYODA, Nobukazu NIIZEKI and Shigeru WAKU 1831

Thomas-Fermi-Dirac Model of Compressed Ions ....Shigehiro KOBAYASHI 1842

On the Magnetic Properties of the Compound Mn_2As ....Motoyoshi YUZURI and Motohiko YAMADA 1845

Plasma Oscillations in a Magnetic Field ....Ikuo KAJI and Masafumi KITO 1851

Pulse Photoconductivity of Additively Colored KBr ....Masami ONUKI and Hiroshi OHKURA 1862

Dichroism of Z_4 and F Bands ....Masakazu ISHIGURO and Nozomu TAKEUCHI 1871

Wall-effect upon Two-dimensional Stokes Flow of an Electrically Conducting Liquid in a Uniform Magnetic Field ....Yorisaburo TAKAISI 1876

Glass Transition Phenomena and Rheological Properties of Petroleum Asphalt ....Yasaku WADA and Hidenori HIROSE 1885

On the Flow of an Electrically Conducting Fluid Near an Accelerated Plate in the Presence of a Magnetic Field ....A. S. GUPTA 1894

SHORT NOTES

Time Decrease of Permeability of Substitutional Ferromagnetic Alloys ....Chinji KURODA 1898

The Effect of Cation Vacancies on the Magnetic Annealing of $Co_xFe_{3-x}O_4$ .... Tohru INOUE, Hiroshi MIZUTA and Shūichi IIDA 1899

Colour Center and Gaseous Ions Produced in High Frequency Spark between the Electrodes of Semi-metals, Metal Elements, and Ionic-crystals ....Toshiyoshi YUASA 1900

Magnetic Transition in $TiCl_3$ ....Shinji OGAWA 1901

On "Screened Impurity Potentials in Metals"..Ralph J. HARRISON and Arthur PASKIN 1902

Electrical Properties of Heavily Doped N-type Germanium......Yoshitaka FURUKAWA 1903

Radiation of Plasma Oscillation ....Shoji KOJIMA and Shigeo HAGIWARA 1904

The Effect of θ′ Phase on the Plastic Deformation of an Age-Hardenable Al–Cu 4% Alloy ....Keisuke MATSUURA and Shigeyasu KODA 1905

Magnetic Properties of $MgMn_2O_4$ ....Kiyoshi MURAMORI and Syohei MIYAHARA 1906

Errata

Sign Reversal of Hall Coefficients at Low Temperatures in Heavily Compensated *p*-type Germanium...Hiroo YONEMITSU, Hajime MAEDA and Hisao MIYAZAWA 1907

No. 11

Decay of Potassium 44 .... Kazusuke SUGIYAMA, Tsutomu TŌHEI, Masumi SUGAWARA, Tsunekichi DAZAI and Yukinori KANDA 1909
Absolute Cross Section of the Reaction $Cu^{63}(\gamma, n)Cu^{62}$ for Lithium Gamma Rays.... .... Shinjiro YASUMI, Minoru YATA, Kunio TAKAMATSU, Akira MASAIKE and Yoshiko MASUDA 1913
Multipole Interaction Stabilizing Cubic Molecular Crystals.............Taro KIHARA 1920
Anisotropic Hall Coefficients in n-Type Germanium ....Hisao MIYAZAWA and Hajime MAEDA 1924
On the Electrical and Optical Properties of p-type Cadmium Telluride Crystals.... .... Shôji YAMADA 1940
Concentration Dependence of the Hall Coefficient in the Magnesium-Cadmium Alloys .... Sei-ichiro NOGUCHI and Takao SATO 1945
Theory of Thermoelectric Power of Ionic Crystals, IV..................Eijiro HAGA 1949
Measurement of Microwave Dielectric Constants of Ferroelectrics Part I. Dielectric Constants of $BaTiO_3$ Single Crystal at 3.3 KM c/s........................ .... Eiji NAKAMURA and Jiro FURUICHI 1955
Theory of Resistance Minimum in Dilute Paramagnetic Alloys ....Kensuke TANI 1960
Direct Observation of Lattice Defects in Cold-worked High Manganese Steels by Means of Electron Microscopy..........Zenji NISHIYAMA and Ken-ichi SIMIZU 1963
Antiferromagnetic Resonance in NiO in Far-infrared Region........Hisamoto KONDOH 1970
Magnetostriction and Crystal Anisotropy of Nickel-Chromium and Nickel-Vanadium Alloys............................Tokuo WAKIYAMA and Sōshin CHIKAZUMI 1975
Studies on the Preparation of Pure Alkali Chlorides........................... ....Koichi KOBAYASHI and Tetsuhiko TOMIKI 1982
On the Magnetic Anisotropy of Single Crystal of Chromium Telluride .... Tokutaro HIRONE and Shôko CHIBA 1991
Total Cross Sections of Carbon, Oxygen, Fluorin and Thorium for Fast Neutrons ....Kineo TSUKADA and Takayoshi FUSE 1994
Temperature Dependence of Surface Potential in Silver Chloride Single Crystals.. ....Hisawo WAKABAYASI 2000
On the Magnetic Properties of Cr_2As and Cu_2Sb ....Motoyoshi YUZURI 2007
X-ray Studies on the Ferrite-Haematite Solid Solutions ....Chisato OKAZAKI 2013
X-Ray Study on the Binding Properties of Cu_2O and Ag_2O Crystals....Tadasu SUZUKI 2018
Dislocation Networks and Moiré Patterns of Molybdenite .... Yoshihiro KAMIYA, Keiichi ANDO, Minoru NONOYAMA and Ryozi UYEDA 2025
Beam-Type Masers for Radiofrequency Spectroscopy......................... .... Koichi SHIMODA, Hiroshi TAKUMA and Tadao SHIMIZU 2036
On the Paramagnetic Susceptibility of Sm^{3+} ion ....Norikiyo URYU 2041
Electroluminescence of Insulated Particles, II ....Keiji MAEDA 2051
Pseudokinematical Approximation in Electron Diffraction by Crystal ....Mitsuhiko HAYASHI 2054
Magnetic Properties of Potassium Iron Group Fluorides KMF_3.................. ....Kinshiro HIRAKAWA, Kazuyoshi HIRAKAWA and Takasu HASHIMOTO 2063
The Perturbation Method due to the Small Change in the Shape of the Boundary .... Tomoyuki SAITO 2069
Transonic Flow past a Wavy Wall ....Iwao HOSOKAWA 2080
Selbstzündung von Kohlenwasserstoff Luftgemischen in Stosswellen......Kunio TERAO 2086
Glass Cracking Caused by Underwater Spark....Shin-ichi HYODO and Fumiko OKUDA 2093

SHORT NOTES

Fatigue Properties of Zinc Single Crystals and Polycrystals .... Mikio YAMAMOTO and Jirô WATANABE 2099
NMR of Co^{59} in Ferromagnetic Hexagonal Cobalt Metal .... Yoshitaka KÔI, Akira TSUJIMURA and Toshimoto KUSHIDA 2100
Dielectric Constants and Loss Tangents of $(Glycine)_3H_2SO_4$(TGS) at 3.3 KM c/s .... Eiji NAKAMURA and Jiro FURUICHI 2101
Some Properties of Titanium Sesquioxides Containing Vanadium Ions .... Tatsuyuki KAWAKUBO, Taketoshi YANAGI and Shoichiro NOMURA 2102

Photoconductivity of Cu-activated Cadmium Sulphide-Selenide........Sumitada ASANO 2103
On the Ferrimagnetic Resonance of Europium Iron Garnet ....W. P. WOLF 2104
Reflection and Absorption Spectra of LiF in the Extreme Ultraviolet Region..................Riso KATO, Kaizo NAKAMURA, Atsuo MATSUI and Yoichi UCHIDA 2105
The Effect of Plastic Deformation on the Cluster Formation in an Al-Cu 4 % Alloy .... Keisuke MATSUURA and Shigeyasu KODA 2106
Distribution Coefficient of Zinc in Gallium Arsenide ....Akikazu SHIBATA 2107
Interaction Types and Selection Rules in Baryon Processes........Seitaro NAKAMURA 2108
The Magnetic Properties of $NiBr_2$ ....Ichiro TSUBOKAWA 2109
Infrared Absorption of Electrons Through Piezoelectric Scattering....Toshio TANAKA 2110
Optical Properties of Irradiated LiF Crystals in the Extreme Ultraviolet Region ....Riso KATO, Shin-ichi NAKASHIMA, Kaizo NAKAMURA and Yoichi UCHIDA 2111
Study of Solid-Solution Single Crystals Containing $BaTiO_3$..........Tunetaro SAKUDO 2112
On the Reversible Optical Conversion Between A- and B-centers in Colored KCl Crystals..............................Hiroshi OHKURA and Takeshi UCHIDA 2114
Anomalous Paramagnetic Resonance in $Ni(NH_3)_6Cl_2$ ....Muneyuki DATE 2115
Absorption Spectra of Potassium Bromide-Thallium Phosphors......Tokumichi TAMAI 2116
N Bands in Alkali Halide Crystals..................................Sadao HATTORI 2117
A Correction to my Paper "The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, I." ....Tsugio MORI 2118
Analysis of the NMR Spectra of Acrylic Acid and Ethyl Acrylate...Yoji ARATA, Hiroshi SHIMIZU and Shizuo FUJIWARA 2119
On the Resistance Anomaly of Dilute Zinc Alloys at Low Temperatures....Yoshio MUTO 2119
Infrared Absorption of Free Carriers in Ionic Crystals ....Toshio TANAKA 2121
Strong Interaction of Baryons ....Seitaro NAKAMURA 2122

Errata

Emission of ^{8}Li, ^{9}Li and ^{8}B Fragments from Stars Produced by 4.3 GeV π^--Mesons in Nuclear Emulsion..........Kuni IMAEDA, Mitsuko KAZUNO and Nobuo ITO 2123

No. 12

Excitation Functions for Alpha-Particle Reactions on Fe^{56} and Fe^{57}..Shigeo TANAKA, Michiaki FURUKAWA, Shiro IWATA, Masuo YAGI, Hiroshi AMANO and Takashi MIKUMO 2125
Multipolarity of γ-ray Absorption in $U^{238}(\gamma, f)$ Reaction produced by $F(p, \alpha\gamma)\gamma$ rays ....Eiko TAKEKOSHI 2129
Search for Weak Gamma-Rays in the Positron Decay of Mn^{51} ....Masao NOZAWA, Hisashi YAMAMOTO, Yasukazu YOSHIZAWA and Yujiro KOH 2137
Beta- and Gamma-Ray Spectroscopy of Mn^{52} and $Mn^{53\,m}$ .... Toshio KATOH, Masao NOZAWA, Yasukazu YOSHIZAWA and Yujiro KOH 2140
Polarization of Protons Scattered from Complex Nuclei...................Shotaro YAMABE Michiya KONDO, Shohei KATO, Takashi YAMAZAKI and Jian-zhi RUAN 2154
Reactions of Nickel with Alpha-Particles ....Shigeo TANAKA 2159
Excitation Function for the Reaction $B^{21}(p, n)C^{11}$ up to $E_p=15$ MeV and energy Levels of C_{12}............................Michiaki FURUKAWA, Yoshihide ISHIZAKI, Yoshihiro NAKANO, Tadashi NOZAKI, Yoshio SAJI and Shigeo TANAKA 2167
The $N^{14}(d, n)O^{15}$ Reaction in the Energy Range from 1.5- to 2.9 MeV......Susumu MORITA, Nawoyuki KAWAI, Yorio GOTO, Takashi KAMI and Masahiro MUKAE 2170
Gamma Radiations Following the Decay of Dy^{165}...................................Akira HASHIZUME, Tan TAKAHASHI, Yoshihiko TENDO and Yohko ENOMOTO 2175
Decays of Photoreaction Products of Selenium.................Tokihiro KUROYANAGI 2179
^{8}Li Emission from Nuclear Disintegrations Produced by 4.3 GeV Negative π-Mesons .... Masaomi (Takahata) OHTA 2187
A Model Theory of Liquid ....Akiya OOKAWA 2191
Surface Free Energy of a Dilute Gas ....Takuji TSUZUKI 2197
Ferrimagnetic Resonance in Europium-Iron Garnet ....Tomonao MIYADAI 2205
Thermal Conduction in Ferroelectric Ceramics.......................Ikushi YOSHIDA 2211
Paramagnetic Susceptibility of an Electron Gas in Alkali Metals ......Masao SHIMIZU 2220
Magnetic Susceptibilities of Non-Ferromagnetic Transition Metals .... Masao SHIMIZU and Takeshi TAKAHASHI 2236

The Magnetic Properties of Single Crystals of Chromium Selenide .... Ichiro TSUBOKAWA 2243
The Change of the Curie Temperature of Iron-Nickel Alloys due to Hydrostantic Pressure .... Takejiro KANEKO 2247
Magnetic Resonance in $MnCO_3$ .... Muneyuki DATE 2251
Direct Viewing of Imperfections In Germanium *p-n* Junction .... Masami TOMONO 2254
Microwave Spectrum of Formaldehyde I. K-type Doubling Spectra .... Takeshi OKA, Hiromasa HIRAKAWA and Koichi HHIMODA 2265
Microwave Spectrum of Formaldehyde II. Molecular Structure in the Ground State .... Takeshi OKA 2274
Theory of Non-Linear Responses .... Osame NAKADA 2280
Theory of Electrochemical Diode .... Isao OSHIDA 2288
Dielectric β-Relaxations in some Linear High Polymers .... Kaoru YAMAFUJI 2295
Hyperfine Structure of the Spectra of Pr I and Pr II .... Kiyoshi MURAKAWA 2306
On the Viscosity of Irradiated Polymers. III. Effect of Branching.. Kanji KATSUURA 2310
Ultrasonic Studies in Chemically Active Liquid Media (1) Aqueous Solution of N_2O_4 .... M. KRISHNAMURTHI and M. SURYANARAYANA 2318
Volume Viscoelasticity of Polymers and Other Highly Dissipative Metals .... Yasaku WADA, Hidenori HIROSE, Hiromichi UMEBAYASHI and Motoharu OTOMO 2324
Optical Properties of KCl:Tl in the Extreme Ultraviolet Region .... Kiyoshi AOYAGI and Goro KUWABARA 2334
Effect of Oxygen upon Sintered Cadmium Sulphide Photoconducting Films .... Saburo KITAMURA 2343
Possibility of Supervelocity of Glass Fracture .... Shin-ichi HYODO 2351

SHORT NOTES

Spontaneous Magnetization of Magnesium Ferrite-Manganite System .... Kiyoshi MURAMORI and Shohei MIYAHARA 2354
Anisotropy on Poly-Crystalline Sheets of V-permendur .... Chinji KURODA 2355
Anomalous Photovoltaic Effect of CdS Single Crystals .... Sumiaki IBUKI, Hiroyoshi KOMIYA and Hirosuke YAMASHITA 2356
On the Mechanism of Reversible Appearance of Residual Magnetization at low Temperature Transition in αFe_2O_3 .... Kiiti SIRATORI, Akira TASAKI and Shūichi IIDA 2357
Antiferromagnetism of $FeSn_2$ .... Kazuo KANEMATSU, Kō YASUKŌCHI and Tetuo OHOYAMA 2358
Thermoelectric Power of Titanium- and Vanadium-Carbides .... Seiichiro NOGUCHI and Takao SATO 2359
Indirect Transition in Narrow Junction of Ge-Si Alloy .... Kei-ichi ANDO 2360
Weak Ferromagnetism of $NaNiF_3$ .... Shinji OGAWA 2361
Anomalous Temperature Dependence of Lattice Constant of $Cr\ O_2$ .... Kiiti SIRATORI and Shūichi IIDA 2362
A Note on Date's Paper "Magneto-plasma Resonance in Semiconductors..(I)" .... Kazuo YAMAGATA 2363
Optical Bleaching so of Gamma-Irradiatec KCl at room Temperature .... Noriaki ITOH and Tokuo SUITA 2364
The Energy Spectra of Secondary Electrons in Various Materials Irradiated by Gamma Rays from ^{60}Co and ^{137}Cs .... Nobuo ODA and Hirosi SUZUKI 2365
Electroluminescence of CdS Single Crystal .... Hirosuke YAMASHITA, Sumiaki IBUKI, Michio YOSHIZAWA and Hiroshi KOMIYA 2366
X-ray Study of Lattice Defects in Si Single Crystals by Transmission Berg-Barrett Technique .... Mitsuru YOSHIMATSU and Kazutaka HOHRA 2367
"Energy Analysis of Electron Diffraction Patterns" .... Hiroshi WATANABE 2368
